DICTIONARY

OF

MACHINES, MECHANICS, ENGINE-WORK,

AND

ENGINEERING.

ILLUSTRATED WITH FOUR THOUSAND ENGRAVINGS ON WOOD.

IN TWO VOLUMES.

VOL. I.

NEW EDITION, WITH APPENDIX.

NEW YORK:
D. APPLETON & CO., 90, 92 & 94 GRAND STREET.
1869.

PUBLISHERS' PREFACE.

TO THE SECOND EDITION.

In presenting to the public a new edition of the "Dictionary of Mechanics, Machines, Engine Work, and Engineering," the publishers have thought it necessary that the whole work should be revised; that those novelties which were presented in the original work, and have not stood the test of use, should be struck out; those processes which have been superseded, should give place to those at present employed; and that those new machines which have not as yet been fully tested by time, but bid fair to be of practical value, as well as older machines previously omitted, should be added.

They are aware that in the first work many errors both in commission and in omission crept in—errors in judgment, and errors in arrangement—that though in general standard authors were drawn from, yet credit was often not given to the authority in the article itself. Time, experience, and consultation with persons of practical minds, have helped to correct errors in judgment. As to the arrangement, many articles were introduced into the original edition under their least characteristic heads; references were not full, often wrong. This has been remedied: the captions of articles have been changed, references have been made fuller and more accurate, and we trust that the knowledge contained in this work may be much more available.

With reference to the citation of authorities, the publishers are aware that in such a work as this, being but a compilation of abstracts, without in every case the full carrying out of the reasoning *ab initio,* the value of the results depends on the author; in the

same way, when the results of experiments are given, it is of the utmost importance that the name of the experimenter should be given. Readers prefer to exercise their own judgment in this matter to the *ipse dixit* of any editor or editors that could be brought to the compilation of this work. In this view, authorities have been supplied to the older articles as far as possible, and invariably to the new.

With the above prunings, the supplying of omissions, and the introduction of much new matter, to a work containing as much really valuable material as any of its class, the publishers offer the present edition with confidence, as worthy of the appreciation of the public.

PREFACE.

Encyclopædias and Dictionaries of Art have now become so popular, and their advantages so thoroughly tested, that it is entirely unnecessary to usher in the present work by dwelling on the peculiar merits of such publications. Every such work marks the era, or defines the position of the sciences treated, at its time of publication; and, in the lapse of years, is record of a step by which such sciences have advanced, affording material for history rather than practical working examples. On this account the older encyclopædias have become almost useless to the practical man of the present day; but the later the works, the greater their value—provided they are, as they should be, latest records of the progress of science.

No work like the one now offered to the public has ever originated here; and of the foreign works republished, none occupy the same ground, or exhibit, in the slightest degree, the state of mechanical arts in this country. The Dictionary is intended to be a Dictionary of Machines, Mechanics, Engine-work and Engineering; to present concisely and compendiously the details of valuable machines in actual use, the laws of matter and their application, the construction and proportion of parts of engines and mill-work, together with the most successful and useful examples in engineering.

In the progress of nations, it has always been remarked that the more liberal the government, the more rapid are the strides and the greater the advance in mechanical and industrial pursuits, and nowhere in history can a more brilliant illustration of this be found than in the progress of our own country; rich in natural resources, under a free and beneficent government, industry is encouraged and protected, yet comparatively sparsely populated, the country cannot, to the fullest extent, develop its resources or compete with the overstocked and poorly paid population of the older countries, unless machines are brought to supply the place of manual labor. Without encroaching on the grounds of Free Trade or Protection, it is evident that, to stand on fair ground with our competitors, we must understand the machines and processes employed by them, that these machines must be adapted or improved by us if possible, or new ones invented better to suit our resources and develop them.

To show, therefore, the advance of the mechanical arts both here and abroad, to define their exact position at the present time as far as possible, but more particularly in regard to machinery, to make, as it were, a "World Industrial Exhibition" of useful machines, and a record of their application, is the object of the present work. For this purpose the editors have drawn from the publications of all countries distinguished in mechanical pursuits. Care has been taken, in selection, to admit only such as are considered standard and practical. In many cases, credit has been given for these selections at the end of the articles; annexed also, a list of the books is given, from which selections were made. But credit is to be given especially to the Glasgow Engineer's and Machinist's Assistant, Bourne on the Steam-Engine, Holtzapffel's Turning and Mechanical Manipulation, Allgemeine Maschinen Encyclopädie, from which very able articles have been drawn.

But whilst we have drawn largely from foreign works, we have not been unmindful of our own progress in mechanism and engineering. Many patentees of valuable machines have kindly afforded us drawings and descriptions, among whom we would name

E. B. Bigelow, Esq., Henry Burden, Wm. Mason, G. H. Corliss, John J. Howe, and many others. Very many drawings and specifications have been taken from the Patent Office, and descriptions will be found in this work of machines which cannot be seen in operation; as, from a mistaken consideration of the patentees, they are not open to inspection of visitors. We are also under obligations to Wm. A. Burke, of the Lowell Machine Shop, Caleb M. Marvel, of the Essex Machine Shop, and Wm. Ellis, of the Washington Navy Yard, for drawings and descriptions of machines.

In the Engine department, we are under obligations to Mr. Copeland for the drawings and descriptions of the steamer Pacific. In Engineering, we owe much to the liberality of William J. McAlpine, in furnishing us with the description of the Dry Dock at Brooklyn, and the machinery used in its construction, together with the experiments made on the strength of the gates. The article Gold has been furnished by a distinguished metallurgist. The article on Metallurgy is by F. Overman, whose work on Iron stands deservedly high. The original communications have been numerous and valuable, and the publishers have spared neither labor nor expense to make the work what it should be.

The illustrations have all been engraved expressly for the work, as large as the page would admit, and sufficiently distinct and in detail to answer for working drawings.

The work is intended more directly for the practical and working man, and for those interested in industrial pursuits; but to all classes it will be found important and instructive. It will show how far the world has progressed in mechanical science—the science of automatic labor, the science which is destined to raise our country to the most elevated position in the world, to ennoble the mechanic and artisan, and to extend and diffuse knowledge.

Among the works from which materials have been selected may be mentioned the following:

Annales des Ponts et Chaussées. Bibliothèque des Arts Industriels: (Masson, Paris.) Civil Engineer and Architect's Journal: (London.) Engineer and Machinist's Assistant: (Blackie, Glasgow.) Publication Industrielle: (Armengaud Ainé, Paris.) Jamieson's Mechanics of Fluids. Treatise on Mechanics: (Poisson.) Allgemeine Bauzeitung mit Abbildungen: (Förster, Wien.) Organ für die Fortschritte des Eisenbahnwesens in technischer Beziehung: (Von Waldegg, Wiesbaden.) Glasgow Practical Mechanic. Silliman's Journal. Allgemeine Maschinen-Encyclopädie—Hülsse: (Leipzig.) Cotton Manufacture of Great Britain and America contrasted. Holtzapffel's Turning and Mechanical Manipulation. The Steam-Engine: (J. Bourne.) Eisenbahn-Zeitung: (Stuttgart.) Tredgold on the Steam-Engine. Dictionnaire des Arts et Manufactures: (Laboulaye, Paris.) Origin and Progress of Steam Navigation: (Woodcroft.) Essai sur l'Industrie des Matières Textiles: (Michel Alcan, Paris.) Griers' Mechanic's Pocket Dictionary. Templeton's Millwrights and Engineer's Pocket Companion. Marine Steam-Engine: (Brown.) Weisbach's Mechanics and Engineering. Barlow on Strength of Materials. Hann's Mechanics. Mechanical Principles of Engineering and Architecture: (Mosely.) Journal of the Franklin Institute. The Transactions of the Institute of Civil Engineers: (London.) The Artisan. Quarterly Papers on Engineering: (Published by Weale, London.) Imperial Dictionary —Blackie: (Glasgow.) Professional Papers of the Corps of Royal Engineers. Student's Guide to the Locomotive-Engine. Railway Engine and Carriage-Wheels: (Barlow, London.) Recueil des Machines Instrumens et Appareils: (Le Blanc, Paris.) Buchanan on Mill-Work. Practical Examples of Modern Tools and Machines: (G. Rennie.) Repertoire de l'Industrie Française et Etrangère: (L. Mathias, Paris.) Treatise on the Manufacture of Gas: (Cleg, London.) Hodge on the Steam-Engine. Scientific American. Railroad Journal: (New York.) American Artisan. Mechanics' Magazine: (London.) Nicholson's (Peter) Dictionary of Architecture. Dictionnaire de Marine à Voiles et à Vapeur: (De Bonnefoux, Paris.) Conway and Menai Tubular Bridges: (Fairbairn.) Brees' Railway Practice. Barlow's Mathematical Dictionary. Bowditch's Navigation. Gregory's Mathematics for Practical Men. Engineers' and Mechanics' Encyclopædia: (Luke Herbert.) Patent Journal: (London.) Brees' Glossary of Engineering. Encyclopædia of Civil Engineering: (Cresy.) Craddock's Lectures on the Steam-Engine. Assistant Engineer's Railway Guide: (Haskoll.) Mechanical Principia: (Leonard.) Weale's Mathematical Tables.

A DICTIONARY

OF

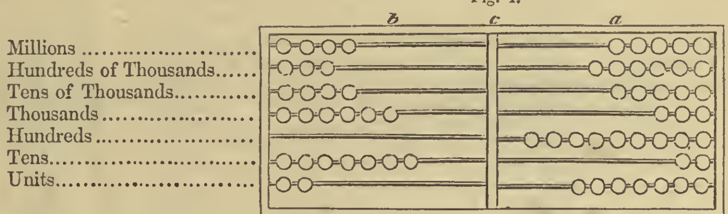
MACHINES, MECHANICS, ENGINE-WORK, AND ENGINEERING.

AAM. A measure of liquids among the Dutch, equal 288 pints.

ABACUS. An instrument employed by the ancients for facilitating calculations; similar to that now frequently employed for teaching children the rudiments of arithmetic, and which is commonly sold in our stationers' shops. It usually consists of twelve parallel wires, fixed in a light rectangular frame; each wire carrying 12 beads or balls. There are thus 12 times 12, answering to the common multiplication table, all the results of which it demonstrates to the dullest capacity. All the operations of addition or subtraction are likewise performed by it, by merely moving the beads from one side to the other of the frame. By thus smoothing the difficulties of acquiring arithmetical knowledge at the very outset, and rendering it quite obvious and amusing at the same time, the apparatus becomes one of considerable importance in education.

Another kind of Abacus consists of a series of parallel wires fixed in a frame like the former. On each wire there are nine little balls; the lowest stand for *units*, the next above for *tens*, the next *hun-*

Fig. 1.



dreds, and so on up to any number. The frame is divided into two compartments, *a* and *b*, by a cross wire at *c*, which is sufficiently raised above the wires to allow the little balls to slide under it. Suppose the whole 63 balls to be placed in the compartment *a*, and it be proposed to note the sum of 4,346,072 it is effected by sliding the balls shown in *b* from their previous situation in *a*.

ABACUS. The *plate* or shallow block forming the uppermost member of a capital, so called for the sake of distinction, for when a similar one is placed beneath the base of a column, it is called a *plinth*.

ABELE. See Woods, *varieties of*.

ABUTMENT is a term commonly applied by engineers to those fixed parts of mechanism used to resist a thrust. In the case of Bridges the term is applied to the land pier, whether subject to thrust or not.

ACACIA. See Woods, *varieties of*.

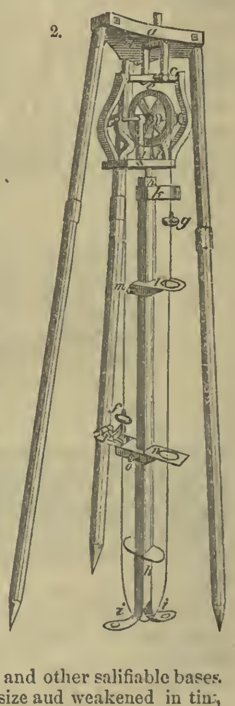
ACCELERATION is the increase of velocity in a moving body, caused by the continued action of the motive force. When bodies in motion pass through equal spaces in equal times, or, in other words, when the velocity of the body is the same during the period that the body is in motion, it is termed uniform motion, of which we have a familiar instance in the motion of the hands of a clock over the face of it; but a more correct illustration is the revolution of the earth on its axis. In the case of a body moving through unequal spaces in equal times, or with a varying velocity, if the velocity increase with the duration of the motion, it is termed accelerated motion; but if it decrease with the duration of the motion, it is termed retarded motion. A stone thrown up in the air, affords an illustration of both these cases, the motion during the ascent being retarded by the force of gravity, and accelerated by the same during the descent of the stone. All bodies have a tendency to preserve their state, either of rest or of motion; so that if a body were set in motion, and the moving force were withdrawn, the body, if unopposed by any force, would continue to move with the same velocity it had acquired at the instant the moving force was withdrawn. And if a body in motion be acted upon by a constant force, (as the

force of gravity,) the motion becomes accelerated, the velocity increasing as the times, and the whole spaces passed through increasing as the square of the times; whilst the proportional spaces passed through during equal portions of time, will be as the odd numbers, 1, 3, 5, 7, &c.; and the space passed over in any portion of time will be equal to half the velocity acquired at the end of such time: which results will be better brought to view in the following Table:

Times.	Velocities.	Spaces for each Time.	Total Space
1	1	1	$1 = 1^2$
2	2	3	$3 + 1 = 4 = 2^2$
3	3	5	$5 + 3 + 1 = 9 = 3^2$
4	4	7	$7 + 5 + 3 + 1 = 16 = 4^2$

It has been ascertained by experiment, that a body falling freely by its own weight from a state of rest, will descend through 16 feet 1 inch in the first second of time, and will have acquired a velocity of 32⅙ feet; but from the rapidity with which the velocity increases, we cannot extend the experiment, for in only four seconds a body falling freely would pass through a space of 256 feet. But by an ingenious contrivance of Mr. Atwood, the laws of motion above laid down may be verified experimentally. The machine is called "Atwood's machine," after the name of the inventor; and the principle of its action consists in counteracting a portion of the gravitating power of a body, by the gravitating power of a smaller body; so that the absolute velocity, and the spaces passed through, shall be less than in the case of bodies descending freely, whilst, as the force is constant, the same ratio of progression will hold in both cases. The annexed figure represents one of these machines: *a a a* is a triangular frame upon three moveable legs; *b*, a small platform suspended from it by a universal joint *c c*, and supporting two upright standards *d d*, in which the axis of a light brass wheel *e* revolves with very little friction. Over a groove in the periphery of the wheel passes a very light and pliable silk thread, from the ends of which hang two equal weights *f*, *g*. Into the under side of *b* is screwed a square rod *h*, descending to the floor, to which it is secured in a perpendicular position by small pins passing through holes in the claws at *i i*. On the face of the rod is a scale of inches; *k* is a brass guide, fixed at the upper part of the rod *h*, so that when the top of the weight *g* touches the lower side of *k*, the under side of *g* is on a level with the top, or commencement of the scale; *l* is a small stage, moveable along the rod *h*, and having a hole in it sufficiently large for the weight *g* to pass: on one side is a tightening screw *m*: *n* is another moveable stage, fitted with a tightening screw *o*, as also a fork *p*, turning upon a hinge. The experiments are conducted as follows:—A small circular weight is placed upon *g*, which is pulled up to the top of the scale, and the stage *n* is screwed to the rod *h*, on a level with the lower part of the weight *f*, which is held down upon it by the fork *p*. Upon releasing *f* from the fork, the weight *g* descends with a slow, but gradually accelerated motion, and the number of inches the weight has descended, at each successive beat of a pendulum, (suspended from another triangle,) is observed upon the scale; and if the additional weight be such as to cause *g* to descend through three inches in the first second, then it will cause it to descend through one foot in two seconds, and through 6¼ feet in five seconds. If the additional weight be removed, and a small bar of equal weight, but of a length exceeding the diameter of the hole in *l*, be placed upon *g*, and the stage *l* be set at any division of the scale, at which the weight would arrive at the end of any number of seconds, the stage will intercept the bar in its descent, and the weight will continue to descend with the velocity it had acquired upon reaching *l*. Thus, if the velocity at the end of the second second be two feet, in which case the weight would have descended one foot in that time, if the stage be set at one foot upon the scale, it will intercept the bar at the end of the second second, and the weight *g* will move with a uniform velocity of two feet per second, through the remaining portion of its descent. If it is required to illustrate the case of retarded motion, the small circular weight is placed upon the weight *g*, and a similar small weight upon the weight *f*, so that *g*, still outweighing *f*, will descend; but as soon as the stage *l* intercepts the bar with the small weight upon it, *f* becomes the heaviest, and *g* will descend with a velocity decreasing as the squares of the times, counted from the time of *g* passing the stage *l*.

2.



ACIDS. Sour substances, or in chemistry such as neutralize the alkalis and other salifiable bases.

AERIAL PERSPECTIVE, is that which presents objects diminished in size and weakened in tint, in proportion to their distance from the eye: but the term relates principally to the color.

AFFINITY, a term used in chemistry to denote that kind of attraction by which the particles of different bodies unite, and form a compound possessing properties distinct from any of the substances which compose it. Thus, when an acid and alkali combine, a new substance is formed, called a salt, perfectly different in its chemical properties from either an acid or an alkali; and the tendency which these have to unite, is said to be in consequence of affinity.

AFRICAN BLACKWOOD. See Woods, *varieties of.*

AIR. Pure air consists almost entirely of nitrogen and oxygen gases, with a very small portion of carbonic acid gas. Of 100 parts of air, reckoning by weight, 75.55 parts are nitrogen, 23.32 oxygen, and 1.13 carbonic acid and watery vapor. Both as respects weight and bulk, nitrogen forms the chief ingredient of the atmosphere.

The weight or pressure of the atmosphere is equal to the weight of a column of water 34 feet in

height, or to a column of mercury 30 inches in height, or 14.7 lbs. per square inch at a mean temperature. But air and all kinds of gases are rendered lighter by the application of heat, for then the particles of the mass are repelled from each other or rarefied, and occupy a greater space. Rarefied air, being specifically lightest, mounts above that of common density; hence, change of temperature is the principal cause of winds. If air be very suddenly compressed into a small compass, the heat given out is so considerable as to be sufficient to ignite inflammable substances. This property has been turned to advantage in an apparatus denominated, "An Instantaneous Light Machine," which consists of a piston accurately fitted and worked in a cylinder, by the sudden stroke of which the volume of air contained in the cylinder becomes so much compressed as to give out sufficient heat to set fire to a piece of the substance termed German tinder.

For the necessity of air in respiration and combustion, see WARMING and VENTILATION.

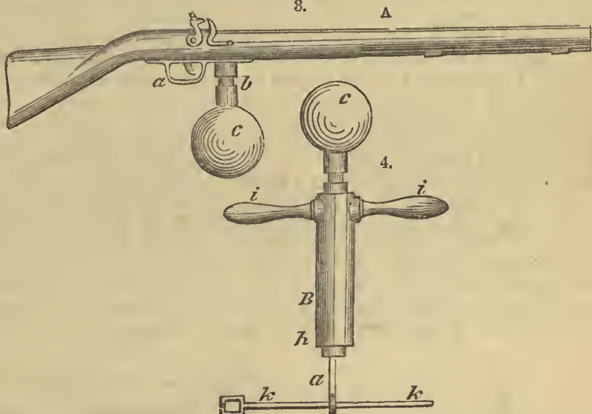
AIR CHAMBER, See PUMPING ENGINES.

AIR ESCAPE, a simple and ingenious contrivance for letting off the air from water-pipes. If a range of water-pipes be led over a rising ground, it will be found that air will collect in the higher parts and obstruct the progress of the water; to remedy which inconvenience the Air Escape is employed. A hollow vessel is attached to the upper part of the pipe, in the top of which vessel there is fixed a ball cock, adjusted in such a way, that when any air collects in the pipe, it will ascend into the vessel, and by displacing the water, cause the ball to descend, and thus open the cock, when the air is allowed to escape. No water, however, can escape, for when that fluid rises in the vessel above a certain height, the ball rises and shuts the cock; new air then collects, displaces the water, lowers the ball, the cock is opened, and it again escapes.

AIR-GUN. A machine in which highly-compressed air is substituted for gunpowder to expel the ball, which will be projected forward with greater or less velocity, according to the state of condensation, and the weight of the body projected.

It consists of a lock, stock, barrel, ramrod, &c., of about the size and weight of a common fowling-piece. Under the lock at *b* is screwed a hollow copper ball *c*, perfectly air-tight. This ball is fully charged with condensed air, by means of the syringe B, previous to its being applied to the tube at *b*. Being charged and screwed on as above stated, if a bullet be rammed down in the barrel, and the trigger *a* be pulled, the pin in *b* will, by the spring-work in the lock, forcibly strike out into the ball, and thence by pushing it suddenly, a valve within it will let out a portion of the condensed air, which, rushing through the aperture in the lock, will act forcibly against the ball, impelling it to the distance of 60 or 70 yards, or farther if the air be strongly compressed. At every discharge only a portion of the air escapes from the ball; therefore, by re-cocking the piece another discharge may be made, which may be repeated for a number of times proportioned to the size of the ball. The air in the copper ball is condensed by the syringe B in the following manner. The ball is screwed quite close on the top of the syringe; at the end of the steel-pointed rod *a* is a stout ring, through which passes the rod *k*; upon this rod the feet should be firmly set; then the hands are to be applied to the two handles *i i* fixed on the side of the barrel of the syringe, when, by moving the barrel B steadily up and down on the rod *a*, the ball *c* will become charged with condensed air, and the progress of condensation may be estimated by the increasing difficulty in forcing down the syringe. At the end of the rod *k* is usually a square hole, that the rod may serve as a key for attaching the ball to either the gun or syringe. In the inside of the ball is fixed a valve and spring, which gives way to the admission of the air, but upon its emission, comes close up to the orifice, shutting out the external air. The piston-rod works air-tight by a collar of leather on it, in the barrel B; it is therefore obvious, that when the barrel is drawn up, the air will rush in at the hole *h*; when it is pushed down, it will have no other way to pass from the pressure of the piston but into the ball *c* at the top. The barrel being drawn up, the operation is repeated, until the condensation is so great as to resist the action of the piston.

3.



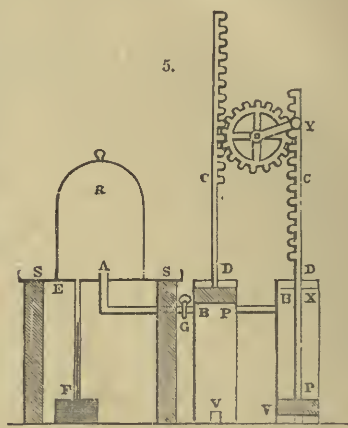
AIR-VALVE, a valve commonly applied to steam-boilers for the purpose of preventing the formation of a vacuum when the steam happens to be condensed within the boiler. The mode of action of these valves is very simple. A valve in the top of the boiler opening inwards, is kept shut by a counterweight at the end of a lever; but whenever the steam in the boiler happens to be condensed, a vacuum is formed, and the air-valve is opened by the pressure of the atmosphere, consequently the air enters and destroys the vacuum. The interior of the boiler being allowed to remain in the state of vacuum, the atmospheric pressure from without might cause its sides to collapse, and thus effect the destruction of the boiler.

AIR-PUMP. An apparatus to extract or exhaust the air from a vessel, to produce a vacuum.

Fig. 5 is a sectional view of the common form of the Air-pump. R is a bell-shaped glass vessel, open only at the bottom, and whose rim is ground perfectly flat, so that it may rest on every point, on a brass plate S S. which is likewise ground to a flat surface, so that when a little hog's-lard is

rubbed upon the edge of the glass vessel, commonly called the receiver, and then the rim placed, by a kind of circular sliding motion, upon the brass plate, no air can pass in or out of the receiver, between its edge and the plate. Through the centre of the brass plate there is drilled an orifice A, from which orifice there is led a pipe AB, forming a communication between the receiver R and the interior of the cylinder BPV, which communication may be opened or closed by means of a stop-cock at G. The cylinder or barrel BPV is furnished with a piston BP accurately fitted to the cylinder, but capable of free motion up and down, which motion is effected by means of a piston-rod DC, which moves through a stuffed or air-tight collar at D. The bottom of the cylinder or barrel is furnished with a valve V opening outwards. This cylinder communicates with another BXPV, constructed and furnished in similar manner; and the two piston-rods are provided with racks C C at the top, the teeth of which are acted upon by those of a wheel placed between them, as may be seen in the figure. Let us now attend to the mode of action. Suppose the stop-cock at G open, and the pistons as they are in the figure. The piston BP being at the top, a free communication is formed between the receiver R and the first cylinder, and the piston being pushed down past the orifice at B, the air contained in the cylinder or barrel will be forced into less space or compressed, and of course its elastic force increased. In consequence of this increased elasticity, the valve at V will be opened, and the air expelled. When the piston is lifted, this valve will be shut by the pressure of the atmospheric air without thus a portion of the air which was contained in the receiver, communication pipe, and barrel, has been expelled, and that which remains will consequently be less dense; another stroke of the piston will diminish the density still more; and this process may be continued until the density be so diminished, that when compressed by the descent of the piston to the bottom of the barrel, its elastic force is only sufficient to open the valve V. It will be easily seen, that the exhaustion of the air in the receiver depends on the elasticity of the air; for when the piston descends and expels the air contained within the barrel, which it will do completely, if it go to the bottom, and then in returning, the valve V being shut, a vacuum will be formed in the barrel until the piston in its ascent passes the orifice B, when the air within the receiver will expand and fill the whole cavity. The operation of the second barrel and piston is precisely similar to that of the first, so that when the one is understood, the other requires no explanation.

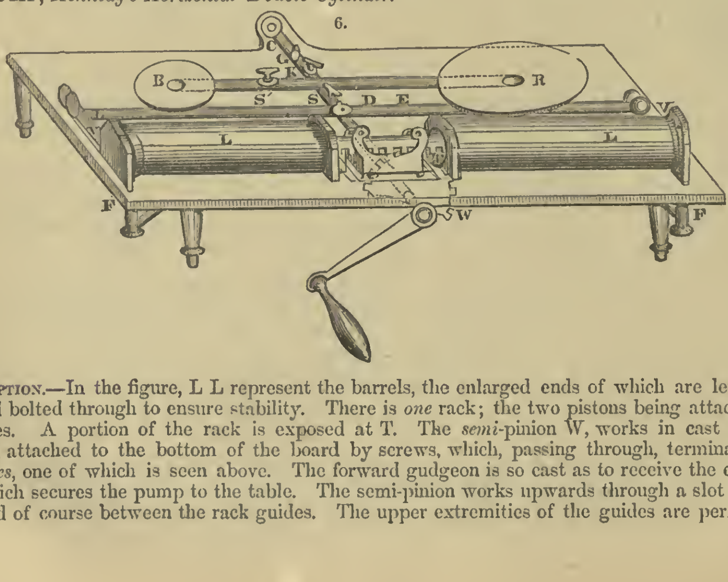
5.



The degree of exhaustion will depend upon the workmanship of the pump, the number of strokes of the piston, and the relative capacities of the receiver and barrels; but perhaps in no case can the vacuum in the receiver be made perfect. For the purpose of determining the degree of exhaustion, a mercurial gauge is employed, which acts on a similar principle with the common barometer. A glass tube EF, rests in a basin of mercury F, and its upper orifice opens into the brass plate SS. When the exhaustion of the receiver has commenced, the pressure of the air in the receiver must be less than that of the atmosphere without. Wherefore, since the air in the receiver presses the mercury down the tube, and the atmosphere pressing on the mercury in the basin forces it up the tube, with the greater force the mercury will rise in the tube, and it will rise the higher according to the difference of the density, and consequently elastic force of the air in the receiver, and that of the atmosphere.

AIR-PUMP, *Kennedy's Horizontal Double Cylinder.*

6.



Description.—In the figure, L L represent the barrels, the enlarged ends of which are let into the board and bolted through to ensure stability. There is *one* rack; the two pistons being attached to its extremities. A portion of the rack is exposed at T. The *semi*-pinion W, works in cast straps, or gudgeons, attached to the bottom of the board by screws, which, passing through, terminate in the *rack guides*, one of which is seen above. The forward gudgeon is so cast as to receive the end of the *clamp* which secures the pump to the table. The semi-pinion works upwards through a slot cut in the board, and of course between the rack guides. The upper extremities of the guides are perforated to

receive rollers, against which the back of the rack may work when necessary. None have yet been required. To the axis of the semi-pinion the handle is attached in the usual manner. The piston may be either solid or valved, and the cylinders may communicate with the plates R and B, in the way most approved by the maker. In the pump from which the sketch is taken, the pistons are solid. The farther extremities of the cylinders bear female screws, which connect with corresponding male screws on the block. On the posterior portion of each block is cut a female screw; the male of which bears the valve V V, of course opening inwards. On those portions of the blocks which project into the board are cut male screws bearing valves opening outwards. Perforated nuts over these secure the blocks to the board, and the valves against injury. At V V is attached the tube leading from the plates. D is the screw for restoring atmospheric pressure. The general stop-cock S, connects this with the parallel tube which, bearing the gauge-cock S′, forms at pleasure a communication between the plates.

The original of the figure both exhausts and condenses. The remaining letters refer to the parts used in condensing. This is effected by simply connecting, by means of tubes under the board, the valves F′, F, with a third tube passing upward to the stop-cock K. Then the air drawn in at R, will be condensed in a receiver screwed on C. The condensing gauge is borne by the screw G. This instrument is furnished thus with all the facilities for exhaustion, transfer, and condensation, without any shifting of parts.

AIR-PUMP. See ENGINES.

AIR-PIPES, an invention for clearing the holds of ships and other close places of their foul air. The contrivance is simply this: a long tube, open at both ends, is placed with one end opening into apartment to be ventilated, and the other out of it. The air in the outer end of the tube is rarefied by heat, and the dense air from the hold comes in to supply the partial vacuum, the escape of the foul air in the hold being supplied by fresh air introduced through an opening above; and this process is carried on until the air becomes everywhere equally elastic.

AJUTAGE, a tube fitted to the mouth of a vessel for the purpose of modifying the discharge of water.

ALARMS. Machines intended to give notice of danger, as from fire, from fire-damp, from lowness of water or excess of pressure in steam boilers, &c. Automatic fire alarms depend in general on some arrangements of strings traversing behind the wainscot and ceiling, which if burned off detach some mechanism connected with a bell, by which an alarm is given; the expansion of metal wire or rods is also applied for the same purpose. Burglar alarms are sometimes employed by drawing strings across passages, connected with alarm bells, or the bells are attached to doors and windows in such a manner that a slight opening of the same may cause them to strike.

For an alarm showing the presence of fire-damp, M. Chuart has made use of a ball or globe, contained in a chemical solution highly sensitive to any deterioration of the atmosphere, and acting upon a lever, which sets an index in motion, and thus shows the vitiated state of the atmosphere, whether in a mine or elsewhere, long before the common air can be so saturated with gas as to explode on the application of light. M. Chuart has added to his invention an alarum bell, which is struck by the lever when the ball is thrown off its equilibrium by the vitiated state of the atmosphere.

7.

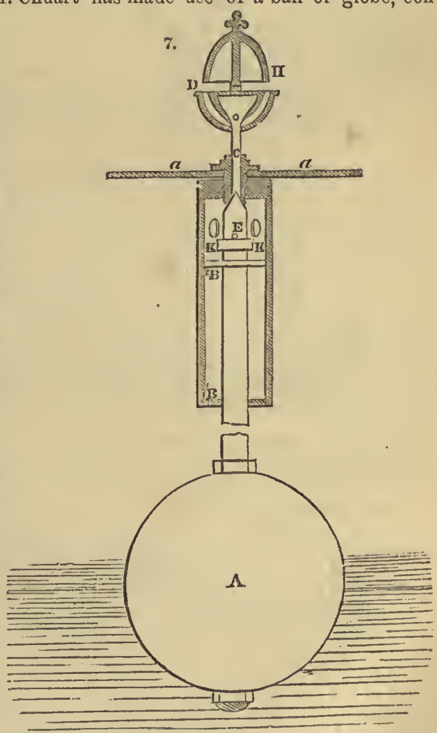


Fig. 7 is an illustration of a method proposed to give notice of the lowness of water in boilers. A is a float attached to a stem or rod which passes upwards through a tube B^1, and a diaphragm, B^2, fixed within that tube, and terminates in a conical top, which fits into the hollow pipe C, of the steam whistle D. The lower end of the whistle D is passed through an orifice in the top of the boiler, (indicated by the letters *a a*,) and screwed into the top of the tube, which is thus kept steady, if in a vertical position. E is a collar attached to the stem of the float, near the top, which, catching against the plate B^2, on the fall of the stem or rod A, prevents it from descending further. When the water falls below the safety-line, and the float along with it, the descent of the stem of the float opens the pipe C of the whistle, and allows the steam to escape, which, impinging against the bell H at top, produces the alarm required. In Dunn's alarm for boilers, the falling of the water below the proper level establishes by means of a battery a galvanic current, and rings a bell or bells in any part of the establishment in which it is desirable that notice should be given.

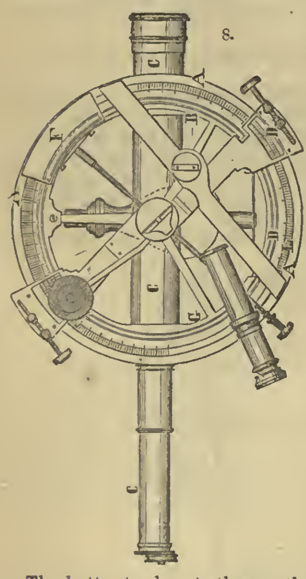
For the transmission of intelligence of fire in cities see "FIRE ALARMS."

ALDER. See WOODS, *varieties of.*

ALLOYS. Baser metals mixed with more valuable ones. See ASSAY.

ALMOND-TREE. See WOODS, *varieties of.*
ALOES-WOOD. See WOODS, *varieties of.*
ALTIMETER. Beatson's patent, for taking, measuring, and computing angles. Fig. 8 is a side elevation of this instrument. A is a broad ring of brass, to one side or the back of which a telescope, C, is affixed in a horizontal line exactly coinciding with the centre of the ring. B is a glass tube of about the sixteenth of an inch in the bore, which is let into a groove made in the front of the ring, and extends all around with the exception of about an inch or two, where a segmental air-tight junction piece F, of metal, is inserted between the two ends of the tube, which are left open, and communicate freely with the piece F. The tube is about half filled with mercury, (or other suitable fluid) which forms itself into a continuous thread of a crescent shape, with a fixed quantity of air between the two cusps. As long as the two fluids are left at liberty, they may of course be shifted round to any parts of the circle; but in the middle of the junction piece F, there is a valve, V (not seen in the figure), inserted, which is worked by a spindle and thumb-piece, from the opposite side of the instrument; and when this valve is closed, the motion of the fluid to either side of that valve is from that moment necessarily stopped. The eye-piece of the telescope is provided with darkened glasses to save the eye from the glare of the sun, and the field of view is divided in the centre by a wire, to show the line of collimation. On the front of the brass ring A, immediately outside of the groove containing the glass tube, and on opposite sides of the telescope, there are two quarter circle scales, R, and L, engraved. Both of these scales have their zero points on the same line with the axial line of the telescope, but the numbers in R run upwards from 0 to 90, while those in L run downwards from 0 to 90; the 90° in the one case (R) representing the zenith, and in the other the nadir. These scales are subdivided by two verniers, D D. The mode of using the instrument is as follows: The observer first releases the alcoholic or other fluid in the tube B from the pressure of the columns of air at each end, by turning the thumb-piece from left to right; he then directs the telescope towards the sun or other object whose altitude it is desired to ascertain, and brings the cross-wire into contact (so to speak) therewith; which having done, he turns the thumb-piece the reverse way, which fixes the mercury at the exact level it had attained at the moment of contact, the column of air in B pressing on the mercury at each end, and thus necessarily preventing the slightest displacement.

8.



The observer next proceeds to read off the indications furnished by the two scales of the instrument; he sets first down the numbers on the left-hand scale R, which come opposite to the top line of the fluid on the left-hand side, and then the numbers opposite the top line of the fluid on the right-hand side; which done, he adds the two sets of numbers together, and divides by 2, which gives the required altitude.

For example; if the

Left altitude be	46 20
Right altitude	47° 40′
The sum divided	2)94°
Would give for the desired altitude . .	47°

The necessity for taking a mean of the two readings arises from the liability of the fluids to expansion, for were no change to take place in their thermometric condition after the contact, the numbers would remain necessarily alike on both sides.

The better to show to the eye the movements of the fluids in the tube, the bottom of the groove G may be stained of a red or some other bright color.

The "Universal Altimeter" may be contained in one framework with any of the ordinary sea and land surveying instruments; as is exemplified in the fig., where it is shown combined with a common sextant.

AMBOYNA-WOOD. See WOODS, *varieties of.*
ANALYSIS. See ASSAY.
ANASTATIC PRINTING. (The term "Anastatic" means rising up, or a reproducing as it were, and very significantly does the name express the result; for by it any number—thousands upon thousands—of reproductions of any printed document may be obtained, each of which is a perfect *facsimile* of the original, no matter how elaborate the engraving may be, or how intricate the design.)

The print of which an Anastatic copy is required is first moistened with very dilute nitric acid, (one part of acid to seven of water,) and then being placed between bibulous paper, all superabundance of moisture is removed. The acid being an aqueous solution, will not attach itself to the ink on the paper, printers' ink being of an oily nature; and if the paper thus prepared be placed on a polished sheet of zinc and subjected to pressure, two results follow:—in the first place, the printed portion will leave a set-off or impression on the zinc; and secondly, the nitric acid attached to the non-printed parts of the paper will eat away and corrode the zinc, converting the whole, in fact, into a very shallow stereotype. The original being removed (perfectly uninjured), the whole zinc plate should next be smeared with gum-water, which will not stick to the printed or oily part, but will attach itself to every other portion of the plate. A charge of printers' ink being now applied, this in its turn only attaches itself to the set-off obtained from the print. The final process consists in pouring over the

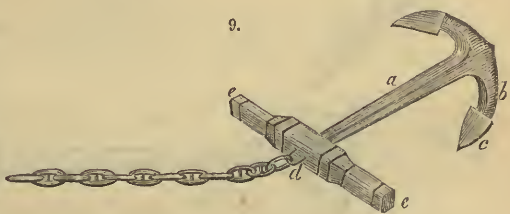
plate a solution of phosphorous acid, which etches or corrodes more deeply the non-printed portion of the zinc, and produces a surface to which printers' ink will not attach. The process is now complete, and from such a prepared zinc plate any number of impressions may be struck off.

The Anastatic process is not only applicable to the copying of the impressions made with printers' ink, but any other inks however, even the most fugitive, may be adapted to this operation; and hence, without some safeguard, the dishonest practices to which the Anastatic process might be applied would be numerous. The paper invented by Messrs Glynn & Appel afford this safeguard. It consists merely in impregnating or dying the pulp of which the paper is made with an insoluble salt of copper. After a series of experiments, the patentees preferred phosphate of copper to any other salt; and for this purpose sulphate of copper and phosphate of soda are successively mixed with the pulp, which, of course, produce an insoluble salt, the phosphate of copper. Besides this, a very small portion of a peculiar oily and non-drying soap is introduced, which affords a double protection. Should the forger attempt to submit a note or check printed on the patent paper to the Anastatic process, a film of metallic copper separates between the paper and the zinc, not only preventing a set-off, but cements the paper so strongly that the paper must be destroyed—it can only be removed in small pieces.

ANACLASTICS. That part of Optics which considers the refraction of light, and is commonly called Dioptrics.

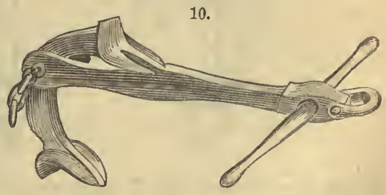
ANCHOR. A heavy curved instrument, used for retaining ships in a required position. The forms of anchors, and the materials of which they are made, are various. In many parts of the East Indies the lower part of the anchor is formed of a cross of a very strong and heavy kind of wood, the extremities of which are made pointed. About the middle of each arm of the cross is inserted a long bar of the same wood, the upper ends of which converge to a point, and are secured either by ropes or an iron hoop, and the space between the bars is filled up with stones to make the anchors sink more deeply and readily. In Spain, and in the South Seas, anchors are sometimes formed of copper, but generally in Europe they are made of forged iron. Anchors may be divided into two classes—mooring anchors, and ships' anchors. Mooring anchors are those which are laid down for a permanency in docks and harbors, and are considerably heavier than ships' anchors, from which they differ in form, having sometimes but one arm, and sometimes, instead of arms, having at the extremity a heavy circular mass of iron and no stock: these latter are called mushroom anchors. The general form of ships' anchors is shown in the annexed figure. There is a long bar of iron, *a* called the shank, from the lower extremity of which branch two curved arms *b b* in opposite directions, and forming an angle of 60° each with the shank. Upon each arm towards the end, is laid a thick triangular piece of iron *c c*, termed the *fluke*. In the upper end of the shank is an eye, through which passes a ring *d*, to which the cable is attached. The stock *e* is composed of two strong beams of wood, embracing the shank, or an iron rod passing through the shank. The stock stands at right angles to the plane of the arms, and serves to guide the anchor in its descent, so as to cause one of the flukes to enter the ground. Ships are generally provided with three large anchors, named the best bower, the small, and the sheet anchor; a smaller anchor, termed the stream anchor; and another, still smaller, named the kedge, which latter has generally an iron stock passing through an eye in the shank, secured thereto by a key, or forelock, which admits of its being readily displaced: its principal use is in changing the position of a ship in harbor, and in an operation termed kedging. From the great mass of iron in large anchors, (some weighing from 3 to 4 tons,) the perfect forging of them becomes a matter of much difficulty; as from the great heat necessary to weld such masses, the iron is liable to become "burnt" as it is termed. Workmen also cannot always observe what is going on in the forge, where the iron is exposed to ignition from the blasts of the bellows, or to the presence of sulphur in quantity among the coals. When the welding of a large mass, like the shank of an anchor, is to be completed by the sledge-hammer, the workmen are subjected to a scorching heat radiating therefrom, which renders it impossible to make a very close inspection, and the consequence frequently is, the beating up of cinders within the body of the iron. To this cause, and to burning, may be often attributed the breaking of anchors, followed too frequently by a distressing loss of lives and property. Many attempts have been made of late years to construct anchors not liable to these defects, by dividing the mass into separate parts, and by a more judicious arrangement.

9.

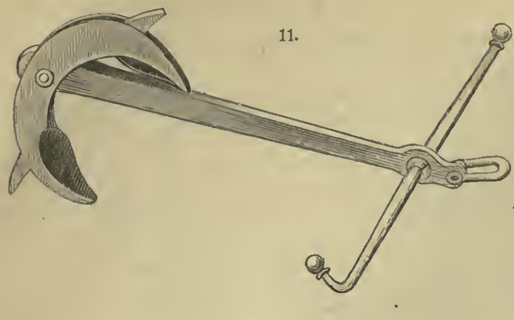


Figs. 10 and 11 represent the two most popular forms of anchors, Porter's and Bloomer & Co.'s. In both, the difficulties of the welding the shank to the arms is obviated. The construction of Bloomer & Co.'s is as follows:

10.



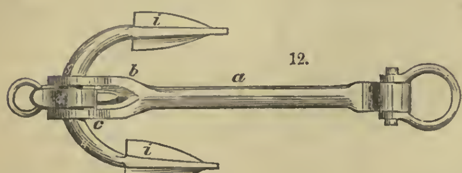
The arms or flukes of the anchor are made in *two separate pieces*, or *plates* of iron of the entire size required, which are bent to the required sweep, or angle, and secured to the shank by a bolt at the crown. The palm and toggle are constructed in one solid piece; the toggle (or horn) being bent into the required form, is passed through, between the two plates, and secured in its position by them; the point of the palm and the two pointed ends of the plates are then welded together at one heat, which completes the work. The shank is made of one solid piece, and is inserted *between* the plates of the flukes, (instead of the flukes being inserted between the two *welded jaws*, as fig. 10,) and is secured by a crown bolt.



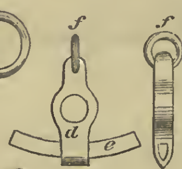
11.

It will thus be seen that this anchor is formed with only *two welding heats*, (viz., at each point of the fluke,) and those at the places least liable to accident, and of less vital importance in case of fracture than any other part of the anchor.

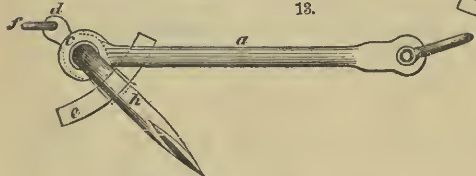
One differing materially in form and construction from the ordinary anchor was invented by Mr. R. F. Hawkins, and is represented in the subjoined engravings. The shank of the anchor *a* is forked at the lower part or crown, into two parts or loops *b* and *c*, in each of which is formed a hole or eye; between the loops is a block of iron *d*, termed a crown-piece, having a circular aperture to receive the arms and a square aperture at right angles to the former, into which is screwed a stout bar of iron *e*, termed a toggle, projecting equally on each side of the crown-piece; on the end of the crown-piece, opposite to that in which is inserted the toggle, is a ring, *f* for the buoy rope. The arms *g h* are formed in one piece, and before the palms *i i* are attached, one end of the arms must be passed through the eyes in the loops of the shanks and through the eye of the crown-piece; the palms are then to be put on, and must both lie in the same plane; after which the arms are to be curved in the same plane with the palms. The crown-piece is firmly keyed to the arms, and the toggle must be of such a length and form as to make it bear firmly against the fore part of the fork in the shank, so as to prevent the crown-piece and arms from turning round upon it, and to retain them at an angle of 50° with the shank. When the anchor is let go, one end of the toggle will come in contact with the ground, which puts the flukes in a position to enter; and when the strain is upon the cable, that end of the toggle which is upwards comes in contact with the throat of the shank, and sets the anchor in the holding position, as shown in perspective at fig 14. The advantage of this mode of constructing anchors is, that both arms take the ground, and therefore the weight of metal may be diminished, and yet an equal, if not a greater effect be obtained; also, as there is no stock, and no projecting upper fluke, there is little risk of *fouling*, as it is termed; that is, of the cable entwining round the arms.



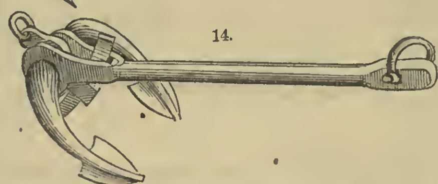
12.



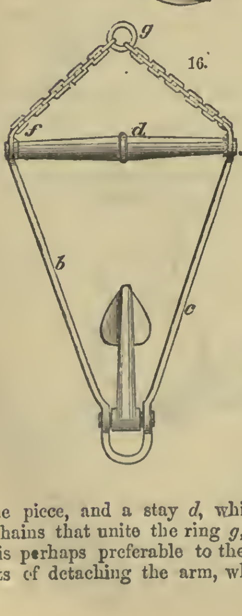
15.



13.



14.



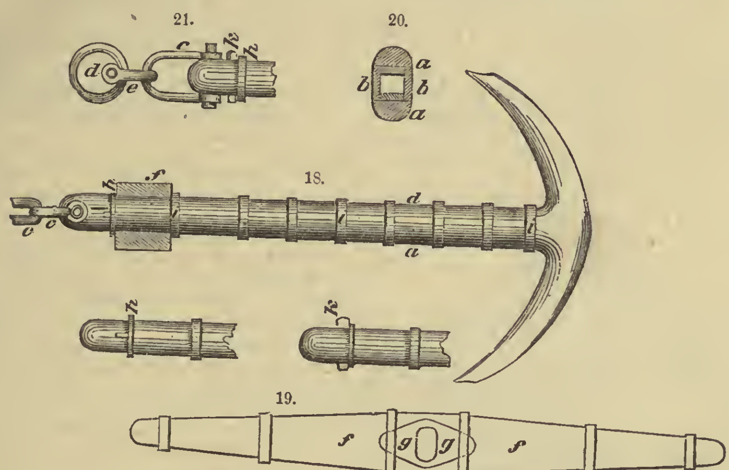
16.

17.

An anchor upon a similar principle, but of a somewhat different construction, was invented by Mr. Soames, a front and side elevation of which is exhibited in the subjoined cuts. In this anchor there is but one fluke *a*, which is T shaped, and works on a pivot in a triangular frame, composed of the two sides *b* and *c*, forged in one piece, and a stay *d*, which serves as a stock; *f f* are loops, or eyes, for the reception of the chains that unite the ring *g*, to which the cable is to be fastened. For general purposes, this anchor is perhaps preferable to the former, it being free from the objection we made to that one, as it admits of detaching the arm, which renders it more convenient to stow away; also, as the shank is

formed in two parts, instead of one of equal area, they are more easily forged soundly, and consequently less liable to breakage.

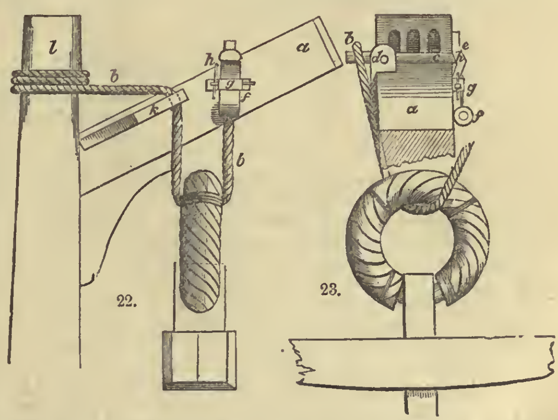
The peculiarity of the anchor proposed by W. Rogers, consists in its having a hollow shank, formed out of six bars of iron, of such a thickness as to insure the forging of them perfectly sound for anchors of the largest dimensions. Fig. 18 represents a side view of the anchor, and fig. 19 a plan of the stock. The two principal pieces *a a* are bent so as to form a part of the arms or flukes; the other four are formed into a hollow tube *b b* (as shown in section at Fig. 20) for a centre-piece, and the whole are firmly welded together at both ends of the shank. The intermediate parts are secured by strong hoops *i i*, so that every piece must bear its proportion of the entire strain. In place of the usual ring, there is a bolt and shackle *c*, Figs. 18 and 21, when the anchor is to be used with chain cables; but when hempen cables are to be used, a ring *d* is connected to the shackle *c* by an additional shackle and bolt *e*. The anchor-



stock *f* may be formed either of a single piece, or of two pieces hooped together, and is secured in its place as follows: The bolt and shackle *c* being withdrawn, the small end of the shank is passed through the eye of the stock *f*, (which is defended by an iron plate *g* on each side;) the collar *h* is then put over, and the stock is keyed up against the hoop *i* by the forelock key *k* passing through a hole in the shank;

Two improved methods of letting go anchors are described in the *Transactions of the Society of Arts.* The principle is the same in each, and consists in supporting the end of what is termed the standing part of the cat-head stopper and shank-painter, by bolts turning upon pivots, and retained in a proper position by a catch, which being withdrawn, the bolt turns upon its pivot, and the stopper slips off, by which means all risk of jamming the turns of the stopper (as in the common method of letting go the running end) is avoided; the danger to the men on the forecastle is done away, and the anchor can be let go at a moment's warning.

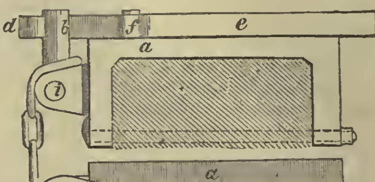
The arrangements in each of these inventions being the same, whether applied to cat-head stoppers or shank-painters, we shall therefore show one invention as applied to cat-head stoppers, and the other to shank-painters. The subjoined cuts show Capt. Burton's method of letting go a cat-head stopper. *a* is the cat-head; *b c* a bolt, turning upon a pivot *d;* the end *c* forms an oblique plane, and is held down by the clamp *e* turning upon a pivot *f*, the clamp being secured by a hasp *g* and pin *h*. The standing end of the stopper, having an eye formed in it, passes over the end *b* of the bolt *b c;* the other end of the stopper passes through the ring of the anchor, and over the thumb-cleat *k*, and is made fast round the timber-head *l*. When it is required to let go the anchor, a handspike is inserted between the thumb-cleat *k*, so as to nip the clamp *e*, and the hasp *g* is cast off; then, upon withdrawing the handspike, the bolt being no longer held by the clamp *e*, turns upon its pivot *d*, by the weight of the anchor on the stopper, and the eye of the stopper slips off the end of the bolt.



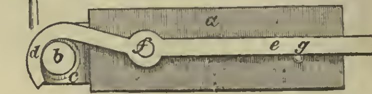
The following cut represents Mr. Spence's invention for letting go a shank-painter. Fig. 24 is an

elevation, and Fig. 25 the plan. *a* is a cast-iron carriage, bolted through the ship's side, and supporting the hook *d* by a pin or pivot at *b*; *d e* a lever turning upon a centre *f*, the end *d* being formed into a hook, which clasps the upper end of the bolt *b*, the lever being retained in the position shown in the plan, by a pin *g*; *h* is part of a chain forming the standing part of the shank-painter, and supported by the bolt *b*. To the other end of the chain is spliced the *running* part of the shank-painter, which passes round the shank of the anchor, and is made fast to a timber-head. When it is required to let go the shank-painter, an iron bar is inserted into the end *e* of the lever *d e*, which is made hollow for the purpose, and the pin *g* being withdrawn, the lever is turned round its centre until the bolt is released from the hook *d*, when it falls, and the chain end of the shank-painter slips off.

24.



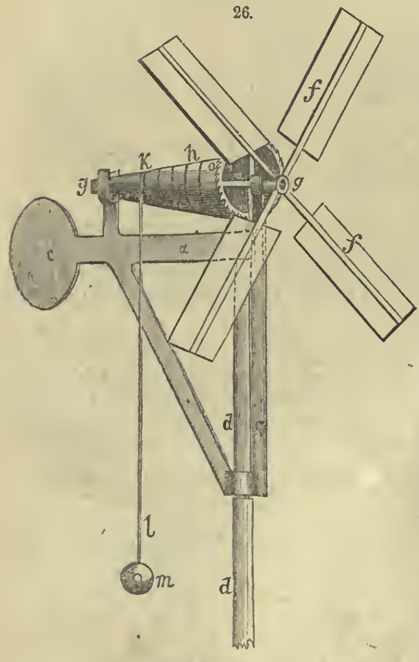
25.



ANGICA-WOOD. See Woods, *Varieties of.*

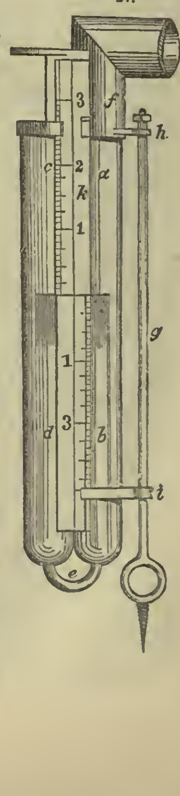
ANEMOMETER. An instrument for measuring the strength or velocity of the wind. Among various machines which have been constructed for this purpose, the following one has been found to answer very well. It consists of an open frame *a c*, supported by a shaft *d*, upon which it turns by the action of the wind upon the vane *e*. *f f* are sails, fixed to one end of the axis *g*, and disposed to be influenced by the wind in the usual manner. Upon this axis is also fixed a conical barrel of wood *h k*, on the smaller end of which *k* is attached a line *l*, with a weight appended to it. The wind acting upon the sails, causes the barrel to revolve, and the line to be wound up on its superficies. To prevent any retrograde motion, a ratchet wheel *o* is fixed to the base or larger end of the cone, having a clicker falling into the notches as it revolves. It is evident that the power of the weight will continually increase as the line advances towards the base of the cone, as the weight acts at a greater distance from the axis or fulcrum; consequently, the variable force of the wind may be readily ascertained by fixing the line at the smallest end, and marking the barrel with spiral lines, as taken up by the coiling of the rope round its superficies, placing also between the lines numerals to denote the force of the wind, which may be calculated with tolerable precision upon the principles of the lever. The diameter of the cone should be such in comparison with its smallest end, that the force of the strongest wind should have scarcely sufficient force to bring the line on to the base of the cone.

26.



Although the instrument described above gives an accurate idea of the comparative force of the wind at different times, it does not point out the actual force exerted on a given surface, nor can observations made with one instrument in a particular place, be compared with observations made by another instrument elsewhere. It is also cumbersome, and not portable. In the *Philosophical Transactions* for 1775, Dr. Lind gives a description of a very ingenious portable wind gauge, which indicates the actual force of the wind by the column of water which it will support. This instrument consists of two glass tubes *a b*, *c d*, which should not be less than 8 or 9 inches long, the bore of each being about four-tenths of an inch in diameter, and connected together by a small bent glass tube *e*, of about only one-ninth of an inch bore, to check the undulations of the water caused by a sudden gust of wind. On the upper end of the tube *a b* is fitted a thin metal tube *f*, which is bent at right angles, and has its mouth open to receive the wind blowing into it horizontally. The two branches of the tube are at liberty to turn round a steel spindle *g*, which passes through two slips of brass *h i* near the top and bottom of the instrument. The spindle is fixed into a block of wood by a screw in its bottom. When the instrument is used, a quantity of water is poured in until the tubes are about half full, and the instrument being then held perpendicularly, with its mouth exposed to the wind, the water will be depressed in the tube *a b*, and proportionably elevated in the tube *c d*; and the distance between the surfaces in the two tubes measured by a sliding scale of inches, and parts *k* attached to the instrument, will be the height of a column of water which the wind is capable of sustaining at that time; and as a cubic foot of water

27.

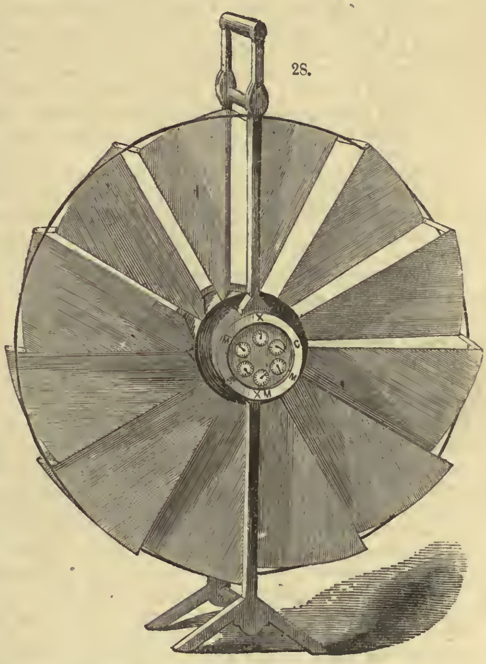


weighs 1000 ounces, or 62½ pounds nearly, the twelfth part of which is 5 5-24 pounds; therefore every inch the surface of the water is raised, the force of the wind will be equal to so many times 5 5-24 pounds on the square foot. This instrument shows the *force*, but not the *velocity*, of the wind; but as the force is as the square of the velocity, if the velocity due to a given force be ascertained, a table of the velocities corresponding to each inch the water is elevated, may be calculated and engraved upon the scale of equal parts. The table at the right, showing the corresponding height of water, velocity of the wind, and the force exerted upon a square foot of surface, has been calculated from some experiments made by Dr. Hutton.

Height of Water. Inches.	Force of Wind. lbs.	Velocity per Hour. Miles.
¼	1.3	18
½	2.6	25.6
1	5.2	36
2	10.4	50
3	15.6	62
4	20.8	76
5	26.	80.4
6	31.25	88
7	36.5	95.2
8	41.7	101.6
9	46.9	108
10	52.1	113.6
11	57.3	119.2
12	62.5	124.

BIRAM'S ANEMOMETER, (Fig. 28,) is designed to register the current of air in mines. In the recent report of the Committee appointed by the British House of Commons, for inquiring into the causes of accidents in coal mines, the adoption of some mode of measurement and registry, is strongly recommended. In this country the same degree of necessity for such precautions has not yet been reached, because our mines of bituminous coal are mostly shallow, and yield comparatively little of the combustible gases. In order to displace by fresh air these poisonous gases, as also the smoke of gunpowder, of lamps, and the products of respiration, it is necessary to build a fire in one of the shafts of the mine, and to keep it up at all times; so that the draught of the furnace shall cause a movement of the stagnant air in the galleries.

28.



Biram's Anemometer registers these movements of the air by a combination of wheels with indices, similar to a gas meter. It is only 12 inches in diameter, and weighs about 2½ lbs. Any slackening of the furnace, or inattention in the furnace man, will be at once detected by the registry of this simple apparatus. The observer has only to record the position of the several indices at the first observation, and deduct the amount from their position at the second observation, to ascertain the velocity of the air which has passed during the interval; this multiplied into the area in feet of the passage where the instrument is placed, will show the number of cubic feet which have passed during the same period.

ANEMOSCOPE, a machine that shows the course or direction of the wind.

Of late years instruments have been introduced into observatories for tracing continuously the force and direction of winds; the most common are those by Dr. Whewell and Mr. Osler. In the machine as arranged by Dr. W., a windmill fly is constantly presented to the wind in whatever direction it may blow, and the fly of course revolves with greater or less rapidity according to the velocity of the current. An intermediate train of wheels set in motion by the fly, causes a pencil to descend over a fixed cylinder, leaving thereon a trace of variable length, according as the wind is more or less strong. 10,000 revolutions of the fly causes the pencil to descend only one-twentieth of an inch. The surface of the fixed cylinder is japanned white, and is divided into 16 or 32 equal parts by means of vertical lines, the intervening spaces corresponding to 16 or 32 points of the compass, and a mark left by the pencil upon one or more of these spaces, shows the direction of the wind. The pencil has two motions, the first from above downwards, and this increases in rapidity as the wind blows more strongly, and by the extent of its depression registers the whole amount of wind that has been blowing. The second motion depends on the changes in the direction of the wind; and the pencil and its frame being carried round by the vane, the direction is registered by this cross movement. In this arrangement therefore, the vane, the windmill fly, the intermediate train of wheels and the pencil, all obey the direction of the wind; while the cylinder which marks the points of the compass remains fixed, so that the pencil in descending and moving about with the wind, thus traces an irregular line on the cylinder. If the fly revolves in the simple proportion of the velocity of the wind, the length of line marked by the pencil is proportional to the space which would be described by a particle of air in a given direction in a given time, such as one day, taking into account the strength of the wind and the time for which it blows.

In Osler's Anemometer, the force and direction of the wind, and also the amount of rain are regis-

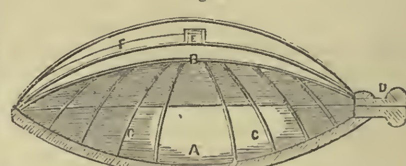
tered on a paper placed on a board moved by means of clock mechanism. The pressure is measured by a plate always directed so as to face the wind. Three pencils are used, of which one registers the pressure of the wind in pounds per square foot, another the direction of the wind, and the third the quantity of rain falling in a given time. Each paper registers during the 24 hours of the day, although it may be arranged for longer periods. The whole length of the paper is divided by vertical lines into 24 equal parts; at the top is a series of parallel lines, corresponding to the pressure in pounds per square foot; in the centre are lines corresponding to the cardinal points of the compass, and the lowe portion of the paper registers the quantity of rain.

The method by which the pressure plate is always made to face the wind is as follows: a set of vanes or sails revolve vertically in a plane at right angles to that of the pressure plate, and drive a cog wheel, which by rolling on a fixed cog circle, turns all the rest of the apparatus round until the vane are presented edgewise to the current, then the pressure plate being at right angles to the vanes is acted on with full effect. As the vanes turn in the direction of the wind, a spiral worm on the shaft raises or lowers a nut, from which hangs the arm carrying the middle pencil, which thus traces the direction of the wind on one of the long lines of the register paper if the wind be from one of the cardinal points, or a mark between these lines if it be blowing from intermediate points, such as N.N.W., N.W. &c. The rain after falling into a vessel on the roof flows into one of the two divisions of a gauge balanced on an axis and supported by a second balance. As the water accumulates this second balance begins to descend, and so raises the upright rod to which a lever is attached which causes the pencil to rise. When this quantity becomes equal to a certain depth of rain, or to a certain number of cubic inches on a foot square, the small gauge oversets, the water is discharged, and the other compartment of the gauge is brought under the pipe. The pencil then returns to its first position at the bottom of the paper, and begins to rise on the scale as the rain is collected. In a trace of this kind it will be seen that the more rapidly the rain falls, the sharper will be the angles formed by the trace of the pencil; but if the rain be slow and gradual, the elevating or diagonal lines will be drawn out to a considerable length.

ANEROID BAROMETER. The principle of the instrument is dependent upon the action of the atmospheric weight upon the exterior of an exhausted or partially exhausted case of thin metal, the top of which, being slightly flexible, is so contrived as to convey indications of the minutest changes in the atmospheric column to a graduated dial, upon which the readings are exhibited as in the ordinary wheel barometer.

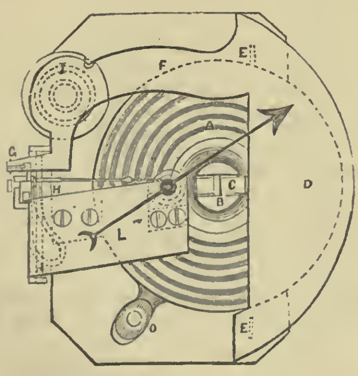
The original instrument of M. Conté bears a resemblance to a watch; it consists of a strong iron or brass box *a*, in the vertical section Fig. 29. To the edges of this box, a very thin and flexible steel cap *b* is fitted with great accuracy. *c c* are a series of springs acting between the bottom of the box and its flexible top, so as to press the latter up. A small cylinder is fitted at *d*, by which the case, when exhausted, may be hermetically closed. The dial is placed immediately over the top of the case, and is pierced in the centre for the passage of a central tube *e*, carring an index-needle *f*, the whole being surmounted by a concave glass. It is obvious that if the space enclosed by the case is exhausted, the flexible top or cap *b* being acted upon by the unbalanced pressure of the atmosphere, will fall, and compress the supporting springs *c*; and the converse takes place when any diminution in the atmospheric pressure occurs. By simple mechanism placed in the tube *e*, this movement of the cap may be communicated to the index-needle, which will thus register the variations in the columnar pressure. It is stated that the thermal changes of the atmosphere disturbed the action of the instrument, and eventually caused M. Conté to discard it as useless.

Fig. 29.

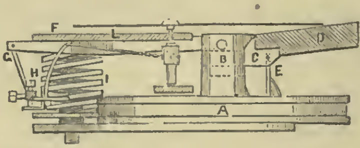


The objection of the want of any temperature compensation, M. Vidi has sought to remove in the Aneroid of the present day. One of the great features which were introduced at this time, was the cir

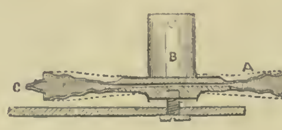
80.



81.



82.



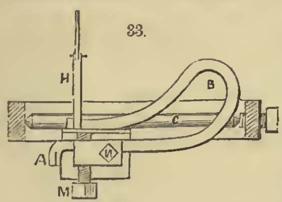
cular corrugation of the flexible diaphragm; and thus a larger and more available range of movement was obtained without danger of rupture. Fig. 30 is a half-size plan of the instrument as now made, under the superintendence of Mr. Dent; Fig 31 is a corresponding side elevation. The vacuum chamber

is represented at a; its top and bottom are formed of disks of thin circularly corrugated copper, held together by a circumferential strip of plain metal, as shown in the detail fig. 32, which is a vertical section of the chamber detached A strong brass stud b, is attached to the upper diaphragm of the chamber, having a slot on its end, through which a small projecting pin c, formed on the lever-plate a projects, the attachment being effected by a pin passed transversely through the slotted portion of the stud, immediately over the pin c. The plate d, which acts as a lever in communicating the movements of the diaphragm, rests upon two pillars e, carried by the supporting base-plate of the vacuum chamber, as fulcra. The projecting lever portion f conveys the movement by a joint at g, which is linked to a rocking spindle carrying the lever h, connected to the arbor of the index-needle by a fine chain which winds upon it, like the main-spring chain of a watch upon the spring box. In the interior of the vacuum chamber, a single helix is fixed upon the base-plate, so as to abut against the lower surface of the lever at i, and thus preserve the two diaphragms of the chamber from actual contact.

To set the instrument to indicate the same scale as the mercurial barometer, the arrangement given full size in Fig. 33 is adopted, to form the connection between the main lever and the index arbor. The link from the end of the main lever is joined to an eye at a, on a stud formed upon the end of a metal bow piece b, the contrary end of which is attached to the lever h, before described. The whole of these parts are carried by a nicely adjusted rocking spindle c, working on centres in the frame l. The office of this contrivance is to afford a means of adjustment for the index movement by the two screws $m\ n$, one of which elevates or depresses the eye a, whilst the other sets it in or out from the centre of the rocking spindle, to give more or less leverage, as may be required to suit the barometrical scale. The connection between the index arbor and the lever apparatus being by a flexible chain, its movement can act only in one direction in bringing round the index, and a fine hair spring is attached to give the return movement.

The tube by which the exhaustion is effected is at o. The process of exhausting, as specified by the inventor in connection with the original plan, is as follows. A little solder is placed round the aperture for the exhaust, in which a flat-headed pin is set, so open as to admit the air to pass. The diaphragm is compressed to its proper position by means of a board, and is then soldered to its box. The whole is afterwards placed under an air-pump receiver, having an air-tight stuffing-box, through which a rod, carrying the heated soldering-iron is passed. When the vacuum is obtained, the soldering-iron is pressed down to melt the solder round the peg, and close the opening.

33.



A simple mode of adjusting the instrument by a standard barometer is obtained by a screw-stud projecting through the back of the instrument, in connection with the reacting spring at i, the tension of which may thus be varied to the extent required. By a simple arrangement, the vacuum case is itself made to afford its own temperature correction, without the addition of a particle of mechanism. Previous to the exhaustion of the vacuum chamber, the top and bottom diaphragms are both perfectly horizontal; but when exhausted, they each take the curve shown in the section fig. 32, and the dotted lines represented as running nearly even with the corrugated surfaces indicate the position they will assume when a portion of gas is introduced to play the important part of a compensator for the disturbance to which the index would be liable from changes of temperature. The expansion of the contained gas, arising from the disturbing cause itself, counteracts the loss of elastic force produced by the same cause in the diaphragms and other parts of the machinery. The external atmosphere is continually endeavoring to press down the diaphragm, whilst the helix beneath the lever is as continually acting to keep it up. An increase in temperature expands the contained gas, which thus diminishes the effect of the external atmospheric pressure, and corrects the disturbance arising from the expansion of the various levers and connections, which would otherwise indicate upon the dial a greater amount of movement than is actually due to the atmospheric change.

ANGLE, in Geometry. If two lines drawn on a plane surface are so situated that they meet in a point, or would do so, if long enough, they form an opening which is called an angle. When one line meeting another makes the angles on both sides equal to each other, then these angles are each called a right angle, and in this case the one line is said to be perpendicular to the other. In the common language of workmen, the one line is said to be square with the other; and if the one line be horizontal, the perpendicular is said to be plumb to it. The arc which measures a right angle, is the quarter of the whole circumference, or is a quadrant, and contains 90 degrees; any angle measured by an arc less than this, is acute, (sharp,) and if by an arc greater than a quadrant, obtuse, (blunt.)

ANIMAL KINGDOM, materials from—used in the mechanical and ornamental arts.

Porcelanous and nacreous shells, bones, etc.—The hard solid substances derived from the Animal Kingdom, are parts of the external or internal skeletons, as shells and bones; or of the instruments of sustenance and defence, as horns, hoofs, nails, claws, and teeth: these, together with the various coverings of animals, whether hair, feathers, or scales, are alike composed of animal and earthy matters, almost exclusively albumen, gelatine, and lime, combined in various proportions, and with a structure more or less interspersed with animal fibre. Many of these are either formed by the deposition of successive annual layers, or they are altogether yearly renewed.

A brief consideration of the chemical difference between their component parts, and of their respective proportions, in such as are used in the arts, will show the reasons for their various characters, and different treatment with tools.

Albumen, the principal ingredient of these animal substances, and which exists in the purest form in the white of eggs, is hardened by a degree of heat less than the boiling temperature of water, and is insoluble in the same. Gelatine, of which jelly and glue are different examples, is softened by heat, and rendered fluid by the addition of water: both are easily cut and scraped, in all their various stages from

soft to hard, and during this change they contract very materially, but without entirely losing their elasticity.

The earthy matters of the animal solids, principally the phosphate and carbonate of lime, are widely different from the foregoing, and also from the substances of the woods and metals. They are inelastic, and often crystalline, and therefore incapable of being cut into shreds or shavings; as when they are divided, they become smaller fragments or particles which are always angular: they are comparatively uninfluenced by water or small changes of temperature, and are incapable of contraction.

When the earthy and crystalline structures prevail, the animal substances are harsh, incapable of absorbing moisture, or of alteration of size or form; when the animal and fibrous characters prevail, they are easily cut, and they absorb moisture, soften, and swell. Enamel of teeth, the hardest of the class, contains from 2 to 3½ per cent of animal matter, (Berzelius.) Porcelanous shells are nearly similar. Nacreous shells, 24 per cent, (Hatchett.) Ivory, 24 per cent, (Ure;) 25 per cent, (Merat Guillot.) Bone, 33 per cent, (Berzelius.) Horn, is coagulated albumen and lime, with ½ per cent of phosphate of lime, (Ure.) Tortoiseshell is nearly the same as horn. The horn of the buck and hart are intermediate between bone and ordinary horn, (Ure.)

In some of the shells, the quantity of animal matter is so small, and the lime is in so hard and compact a form, that they are very brittle, partially translucent, generally they have smooth surfaces, and are incapable of being cut with a knife or tools; such shells are called *porcelanous*, from their resemblance to porcelain, they include most of the univalve shells, such as the whelks, limpets, and cowries. Most of these can only be worked upon after the manner of the lapidary, with emery and other gritty matters harder than themselves, by which means they are cut and polished, as will be explained in speaking of that art; by analysis, porcelanous shells are considered closely to agree with the enamel of the teeth.

The nacreous shells, thus named from *nacre*, the French for mother-of-pearl, are most commonly known in the shells of the pearl-bearing oyster of the Indian Seas, (*Ostræa margaritifera*,) but they include the generality of the bivalve shells, as the various oysters, muscles, &c.; within they are smooth and iridescent, without they have a rough coat or epidermis.

These kinds contain a larger proportion of animal matter, which is considered to be arranged in alternate layers with the carbonate of lime; and as these shells also are impenetrable to water, they neither shrink nor swell. The pearl shells are less frangible and hard than the porcelanous shells, and they admit of being sawn, scraped, and filed, with ordinary tools; but they are harsh, scratchy, and disagreeble under the operation.

The beautiful iridescent appearance of the pearl shells is attributed to their laminated structure, which disposes their surfaces in minute furrows, that decompose and reflect the light; and owing to this lamellar structure, they also admit of being split into leaves, for the handles of knives, counters, and the purposes of inlaying. As the pieces are very apt to follow, and even to exceed the curvature of the surface, splitting is not much resorted to, but the different parts of the shell are selected to suit the several purposes as nearly as possible; and the excess of thickness is removed upon the grindstone in preference to risking the loss of both parts in the attempt to split them.

The usual course in preparing the rough pearl shell for the arts, is to cut out the square and angular pieces with the ordinary brass-back saw, and the circular pieces, such as those for buttons, with the annular or crown saw, fixed upon a lathe mandrel. The sides of the pieces are then ground flat upon a wet grindstone, the edge of which is turned with several grooves, as the ridges are considered to cut more quickly than the entire surface, from becoming less clogged with the particles ground off. The pieces are finished upon the flat side of the stone, and are then ready for inlaying, engraving, and polishing, according to the purposes for which they are intended. Cylindrical pieces are cut out of the thick part of the shell, near the joint or hinge, and rounded upon the grindstone, ready for the lathe, in which they may be turned with the ordinary tools used for ivory and the hard woods.

The following are considered by an experienced dealer to be the respective qualities of the pearl shells. The Chinese, from Manilla, are the best; they are fine, large, and very brilliant, with yellow edges. Singapore, fine large shells, dead-white. Bombay, a common article. Valparaiso, also common, with jet-black edges. South Sea pearl shells, common, with white edges.

The very beautiful dark-green pearl shells, are known as ear-shells or sea-ears; they are unlike the others in form, being more concave, and with small holes around the margin, and are the coverings of the *Haliotis*, found in the Californian, South African, and East Indian Seas. Cameos are cut in the conch shell, *Strombus Gigas*, of the southern coast of America, and the West Indian Islands.

Mr. E. H. Bond states that he has seen the Chinese work the largest of known shells, the *Chama Gigas* of Linnæus, the *Tridacna Gigas* of Lamarck, into snuff-bottles, tops of walking-sticks, bangles, (a kind of bracelet,) and similar articles, some of which he possesses. The shell is a bivalve and not nacreous, generally white, sometimes pale blue; it may be beautifully polished, and is less readily scratched than mother-of-pearl; its localities are the Indian Seas, New Holland and the Red Sea, but the largest are obtained from Sumatra, one pair from whence, described in Sir Joseph Banks' MSS. Library, is said to weigh, the one valve 285, the other 222 pounds, but the more usual weight is about 100 pounds each valve. Mr. Bond considers the useful portions of the shell, already prepared, might be obtained from China.

In the bones of animals, the earthy and animal matters are more nearly balanced; they are therefore less brittle than the shells, but prior to being used they require the oil with which they are largely impregnated to be extracted by boiling them in water, and bleaching them in the sun, or otherwise. This process of boiling, in place of softening, robs them of part of their gelatine, and therefore of part of their elasticity and contractibility likewise they become more brittle, and having a fibrous structure, they break in splinters.

The forms of the bones are altogether unfavorable to their extensive or ornamental employment; most of them are very thin and curved, contain large cellular cavities for marrow are are interspersed with vessels that are visible after they are worked up into brushes, spoons, and articles of common

turnery. The buttock and shin bones of the ox and calf, are almost the only kinds used. To whiten the finished works, they are soaked in turpentine for a day, boiled in water for about an hour, and then polished with whiting and water.

Bone is far less disagreeable under the tools than the pearl shell, but it is nevertheless hard, harsh, and chalky; the screws cut on bone are imperfect and soon injured. It is harder, often whiter, but much less pleasant to work than ivory, which beautiful material will be treated of separately.

Horn.—In the English language we have only one word to express two quite different substances; namely, the branched bony horns of the stag genus, and the simple laminated horns of the ox genus, and other kindred genera.

The bony horns are called in the French *bois*, from their likeness to the branch of a tree; they are annually renewed.

The other sort of horn, to which the French appropriate the term *corne*, and which is the subject of our present inquiry, is found on the ox, the antelope, the goat, and sheep kinds.

These two kinds will be considered separately.

The stag-horn closely resembles the ordinary solid bones, both in its chemical characters, and also in structure, as it is spongy and cellular in its central parts. The horn is sawn into pieces, filed to the required shapes, and used without any further preparation, the natural rough exterior of the horn being left in the original state; its appearance is neat and ornamental, and from its uneven surface is very suitable for the handles of knives, and other instruments requiring to be held with a firm grasp.

When short pieces of stag-horn are used entire, as for the handles of table-knives, the hollow cellular part is concealed by the addition of the metal cap, and those parts of the white internal substance, which are necessarily exposed, are browned with a hot iron, or the flame of a blowpipe, so as nearly to match the other parts.

The horns of the ox tribe are deposited in annual layers upon the bony cores that project from the foreheads of the animals; whence it results, that the general form of the horn, (neglecting its curvature,) is conical, the portion beyond the core is solid, and the other extremity tapers off so as to terminate at the base in a single plate, or extremely thin edge.

Horn consists almost entirely of animal matter, chiefly membranous—namely, coagulated albumen with a little gelatine, and an inconsiderable portion of phosphate of lime; had the horns much more earth they would be brittle like bones, had they much more gelatine they would be soluble like jelly or glue; as they are constituted, the quantity of gelatine is only sufficient to allow them to be considerably softened by a degree of heat not exceeding that of melted lead, after which they may be cut open with knives or shears, flattened into plates, divided into leaves, and struck between dies like metal. Their gelatine serves as a natural solder, so that neighboring surfaces, when perfectly free from greasy matter, may be permanently joined together by moisture, heat, and pressure: the union becomes perfect, but horn being a cheap material, the process of joining it is seldom practised.

The straight conical horn of the rhinoceros is also occasionally used; it is solid, and formed as of a group of hairs cemented together: the transverse section of the upper part of the horn exhibits small dots. The horns of the chamois and antelope, and those of some other animals, are generally looked upon as natural curiosities, and are only polished exteriorly, without any strictly manufacturing process being applied to them.

The first step in operating upon horn is the separation of the bony core, which is effected by macerating the horns in water for about a month, when, from the putrefaction of the intermediate membrane, the core may be readily detached; this is not thrown away, but burnt to constitute the bone earth used for the cupels for assaying gold and silver.

The solid portion or tip of the horn is usually sawn off, and the remainder, if not cut into short lengths, is softened by immersion for half an hour in boiling water; it is then held in the flame of a coal or wood fire, until it acquires nearly the heat of melted lead, when it becomes exceedingly soft, after which it is slit up the side with a strong pointed knife, and opened out by means of two pairs of pincers applied to the edges of the slit; and lastly, the "*flats*" are inserted between iron plates previously heated and greased, which are squeezed tight in a kind of horizontal frame or press by means of wedges; wooden boards may be used.

For general purposes, as for combs, the pressure should be moderate, otherwise, in the language of the workman, it *breaks the grain*, or divides the laminæ, and causes the points of the teeth to split; but great pressure is purposely used in the manufacture of the leaves for lanterns, which are afterwards completely separated with a round-pointed knife, scraped, and polished. The heat and pressure when applied to the light-colored horn render it almost transparent.

An improved mode of "opening horn" was invented by Mr. J. James, by which the risk of its being scorched or frizzled over the open fire is entirely removed; he employs a solid block of iron with a conical hole, and an iron conical plug: these are heated over a stove to the temperature of melted lead, and the horn, after having been divided lengthwise with a saw or knife, is inserted in the hole, the plug is gradually driven in with a mallet, and in the space of about a minute the horn is softened and ready for being opened in the usual manner.

In making drinking-horns, and some few other turned works, the material is cut to the appropriate length, brought to the circular form, and allowed to cool in the mould; the process is similar to that just described, although the old methods of the open fire and wooden cones are commonly used. The horn is then fixed in the lathe by its larger end, and turned on its inner and outer surface, and the groove, or *chime* for the bottom, is cut with an appropriate tool. A thin plate, previously cut out of a flat piece of horn with a crown-saw, is dropped into the horn, and forced into the groove, after the horn has been sufficiently heated before the fire to allow the necessary expansion; in cooling, the contraction fixes the bottom water-tight.

As an illustration of the peculiar properties of horn, and a mode of its employment in the lathe, may be mentioned the expanding snake: this toy is well known to consist of a conical piece of horn, the

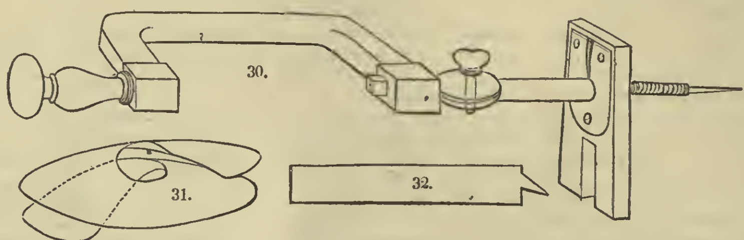
one end of which is carved to represent the head, and the remainder is cut into a single spiral shred, so as to admit of great expansion, in imitation of the body of the reptile. I find the elastic portion of the one before me to measure, when compressed, barely one inch and a quarter in length, and that it expands to upwards of three feet and a half, or thirty-five times: no mean proof of the elasticity of the material.

In making this trifle, the material is first turned to a conical form, after which a hole of about one-eighth or one-sixth of an inch diameter, is pierced from the tail almost through the head; the horn is then soaked for about two days in cold water to soften it, and the spiral incision or screw is made at one single cut, by means of a tool extending from the centre to the circumference; the cutter is not required to be very thin, as the shaving will bend away to make room for the same. One of the three following modes of proceeding is recommended in the *Manuel du Tourneur.*

First, by the employment of a sliding rest, adapted to cutting screws, by which the tool is *traversed,* or guided mechanically along the horn during the rotation of the mandrel of the lathe; and to prevent the fracture of the toy during its construction, a stick of wood, with a button on the end of it, is put up the aperture, to receive and support the spiral as it is produced.

Another method is by the employment of a lathe with a *traversing* or screw-cutting mandrel, upon which latter the horn is fixed, the tool being kept *stationary* in the slide-rest. Both methods require expensive apparatus, the principles of which will be explained in the article on screw-cutting tools.

The third plan is extremely simple; and appears, on inspection, to have been the one pursued in this instance: it is ascribed to the German toy-makers. The horn is prepared as before, but the lathe and slide-rest give way to the ordinary carpenter's brace, which carries the piece of horn, as in Fig. 30. A



small tool is fixed in the vice or bench; it consists of a piece of wood, to which is screwed a hardened steel plate about one-twelfth of an inch thick; it has a hole equal to the diameter of that in the horn, for the passage of the supporting wire; the plate is divided radially, the one edge is sharpened very keenly, and bent so much in advance of the other, that their *difference* of level or agreement, shall be equal to the intended *thickness* of the continuous shaving of the body of the snake, and therefore the projecting edge assimilates to the mouth of a plane: the last processes, in every case, being to carve the head and to attach a little piece for the end of the tail.

It is necessary the coils of the snake should be of a conical form, or dished, as in Fig. 31, instead of being quite flat, as it increases the strength of the toy; this is accomplished by making the cutting edge of the tool *oblique* to the axis of the snake; Fig. 32 shows the tool for the lathe. The several details are too simple to require further explanation.

The handles for knives, razors, and other works moulded in horn, are thus made: the horn is first cut into appropriate pieces with the saw, and when heated these are pared with a knife or spokeshave, to the general form and size required; in this state horn works as easily as a piece of deal: after having been pared, the pieces are pressed into moulds.

An idea of the moulds will be conveyed by imagining two dies, or pieces of metal, parallel on their outer surfaces, and with a cavity sunk entirely in the one, or partly in each, according to circumstances: the cavities made either straight, curved, twisted, rounded, bevelled, or engraved with any particular device, according to the pattern of the work to be produced.

The pressure is applied to the dies, by enclosing them in a kind of clamp, made like a very strong pair of nut-crackers, but with a powerful screw at the end opposite to the joint; the mould, dies, and horn, are dipped into boiling water for a few minutes, and then screwed as fast as possible immediately on removal from the same, and in about twenty minutes the work is ready for finishing; some handles are made of two pieces joined together.

On referring to French authorities, I find it stated that horn, steeped for a week in a liquor, the active ingredient of which is caustic fixed alkali, becomes so soft that it may be easily moulded into any required shape. Horn shavings subjected to the same process become semi-gelatinous, and may be pressed in a mould in the form of snuff-boxes and other articles. Horn, however, so treated, becomes hard and very brittle, probably in consequence of its laminated structure being obliterated by the joint action of the alkali and strong pressure.

Horn is easily dyed by boiling it in infusions of various colored ingredients, as we see in the horn lanterns made in China. In Europe it is chiefly colored of a rich red-brown, to imitate tortoiseshell, for combs and inlaid-work. The usual mode of effecting this is to mix together pearlash, quicklime, and litharge, with a sufficient quantity of water and a little pounded dragon's blood, and boil them together for half an hour. The compound is then to be applied hot on the parts that are required to be colored, and is to remain on the surface till the color has struck; on those parts where a deeper tinge is required, the composition is to be applied a second time. This process is nearly the same as that employed for giving a brown or black color to white hair; and depends on the combination of the sulphur, (which is

an essential ingredient in albumen,) with the lead dissolved in the alkali, and thus introduced into the substance of the horn. The horn which is naturally black is less brittle than that which is so stained.

Tortoiseshell comes next under consideration. The animal which produces this beautiful substance is a marine tortoise, called the *Testudo imbricata*, or hawk's-bill turtle.

The usual size of the full-grown animal is about a yard long and three quarters of a yard wide; its covering consists of thirteen principal plates, five down the centre of the back, and four on each side, and in a tortoise of the above size, the largest, or main-plates, weigh about nine ounces, and measure about thirteen by eight inches, and one quarter of an inch thick at the central parts; but they are thinned away at the edges where they overlap, owing to the deposition of the substance of the shell in annual layers, each extending beyond the previous one. Very rarely, the shells are three-eighths thick and proportionately heavy. Others are very thin, and appear to consist of only one single layer; this is supposed to occur when the animal loses a plate by accident, or that it is stripped and thrown back again into the sea whilst alive; such shells are usually very light-colored and are called "yellow belly." There are also twenty-five small pieces of shell which envelop the edge of the animal, but these can only be applied to very small purposes.

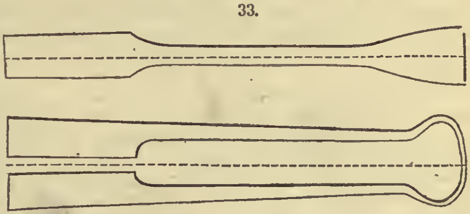
Some of the tortoiseshell is of very dark-brown tints running into black, and interspersed with light gold-colored dashes and marks, these are considered the best; others are lighter, even to pale red-browns, yellow, and white: the last are not valued, the yellow are used for covering the works of musical snuff-boxes, and the light red and brown shells are manufactured into ladies' combs, for exportation to Spain, where they obtain double the price of those made of the darker colored tortoiseshell. The shell of the turtle is also used, but it has not the transparent character of the foregoing; the colors are lighter, less beautifully marked, and it is little valued.

The treatment of tortoiseshell is essentially the same as that of horn, but on account of its very much greater expense, it is economized so far as possible. Before the shells are worked they are often dipped in boiling water to *temper* them; three or four minutes commonly suffice, but they require a longer period when they are either thicker or more brittle than usual: excess of boiling spoils the colors of the shells, renders them darker, and covers the outside with an opaque white film. Others, flatten and temper the shells with hot irons, such as are used by laundresses: the shell is continually dipped in cold water to prevent its being scorched; but as a general rule the less tortoiseshell is subjected to heat, or to being pulled about, the better, as from its apparent *want of grain* or fibre, it becomes in consequence very brittle.

Many of the works in tortoiseshell are made, partly by cutting them out of the shell, and partly by joining or adhesion, called by the French *souder*. Thus in the Manuel du Tourneur, the artist is directed to form the ring of tortoiseshell for the rebate of a box, by cutting out a long narrow slip of the shell; the ends are then to be filed with a clean rough file to thin feather edges, to the extent of three quarters of an inch of their length, the one on the upper and the other on the lower surface, to constitute the lap or joint; the slip is dipped into boiling water, and when softened it is bent into an oval form with the intended joint on the flat side, the ends are held in firm and accurate contact with the finger and thumb, and the piece is dipped into cold water to make it retain the form.

A pair of tongs is required, such as those in Fig. 33, with flat ends measuring about one inch wide and three or four long, and that spring open when left to themselves, but fit perfectly close and even, when compressed; these are made warm. In the mean time the ends of the ring are sprung asunder sidewise, to bring the *scarfs* or parts to be joined to the inner and outer surfaces respectively, that they may be retouched with the file to remove any small portion of grease which may have been accidentally picked up, and the joint is restored to its proper position. A piece of clean linen is then soaked in clean water, squeezed dry with the fingers, folded in ten to twenty thicknesses, to about the size of one and a half inch wide, and three or four long; the ends are now folded together, placed on each side the joint, the whole is inserted between the tongs, and fixed moderately tight in the jaws of an ordinary vice. The softening and consequent adhesion of the shell, will be known by the flexibility of the ring when the loose part is wriggled about with the fingers; the work is either allowed to cool in the vice, or after a time is dipped into cold water.

33.



The success of the process will depend on three different circumstances; the parts to be joined must be entirely free from grease and dirt, on which account the surfaces should not be touched after being filed; the temperature of the tongs should be just sufficient to color writing-paper of a pale orange tint; and moisture or vapor must be present, apparently to liquefy the gelatine of the tortoiseshell at the surfaces of union.

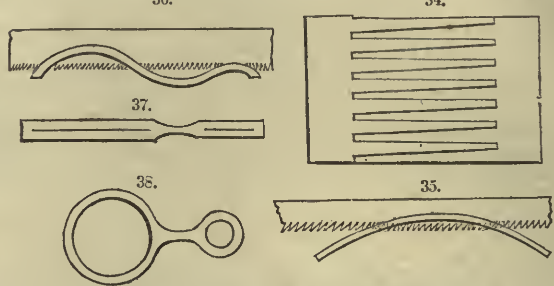
The ring, when cold, is pressed with the fingers into the circular form or even into an oval in the opposite direction, which would cause the ends of the joints to start, if the soldering were imperfectly performed; should this happen, the application of the moistened rag and heated tongs must be repeated until the result is perfect; the ring is made circular by warming it in boiling water, and gently forcing it on a wooden cone of small angle.

Another mode, the invention of an amateur, is also described; the strip of shell is chamfered off at the ends and bent round a piece of wood, a compress of linen in six or eight folds is put upon the joint, and the whole is tightly bound round with string, and immersed in boiling water for ten minutes. The contraction of the string, and the expansion of the wood, from being wetted, supply the needful pressure, and the process is said to be quite successful.

Moulding and soldering tortoiseshell, are also performed under water in various other ways for

example, in attaching the back of a large comb, to that piece which is formed into the teeth, the two parts are filed to correspond, they are surrounded by pieces of linen and inserted between metal moulds, connected at their extremities by metal screws and nuts; the interval between the halves of the mould, being occasionally curved to the sweep required in the comb. Sometimes also the outer faces of the mould are curved to the particular form of those combs in which the back is curled round, so as to form an angle with the teeth; the joint when properly done cannot be detected either by the want of transparency or polish at the part.

Considerable ingenuity is shown in turning to economical account the flexibility of tortoiseshell in its heated state; for example, the teeth of the larger description of combs are *parted*, or cut one out of the other with a thin frame-saw, when the shell equal in size to two combs with their teeth interlaced as in Fig. 34, is bent like an arch in the direction of the length of the teeth as in Fig. 35. The shell is then flattened, the points are separated with a narrow chisel or *pricker*, and the *two* combs are finished whilst flat, with coarse single-cut files, and triangular scrapers; and lastly they are warmed, and bent on the knee over a wooden mould, by means of a strap passed round the foot, in the manner a shoemaker fixes the shoe-last. Smaller combs of horn and tortoiseshell are parted whilst flat, by an ingenious machine, invented by Mr. Kelly. It has two chisel-formed cutters placed obliquely, so that every cut produces one tooth, the repetition of which completes the formation of the comb. Ivory and boxwood combs cannot be thus parted; they are cut in the old way, one tooth at a time, by various contrivances of double saws, as will be explained.



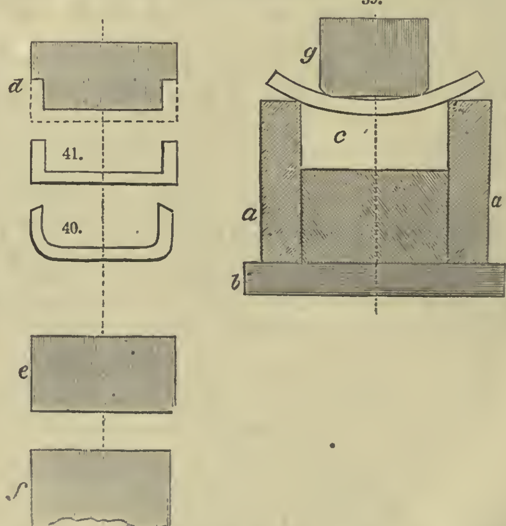
36. 37. 38. 34. 35.

In making the frames for eye-glasses and spectacles, the apertures for the glasses were formerly cut out to the circular form, with a tool something like a carpenter's centre-bit, or with a crown-saw in the lathe; the disks were in either case preserved, to be used for inlaying in the tops of boxes, and the outside of the frame was then shaped with saws and files. This required a piece of tortoiseshell of the entire size of the front of the spectacles, but a piece of a third that width is made to answer for inferior spectacles, as the *eyes* are *strained*, or *pulled*. A long narrow piece of the material is cut out, and two slits are made in it with a thin saw; the shell is then warmed, the apertures are pulled open, and fashioned upon a taper triblet of the appropriate shape: Figs. 36, 37, and 38, explain this method; the groove for the edge of the glass is cut with a small circular cutter, or sharp-edged saw, about three-eighths or half inch diameter, and the glass is sprung in when the frame is expanded by heat.

Tortoiseshell is also manufactured into boxes and a variety of moulded works, but the process calls for extensive preparations, and is not often followed by the amateur.

The construction of tortoiseshell boxes requires a copper, with a fireplace beneath; a trough with cold water; and a press and moulds. The former may be compared to the ordinary coining press, or to a strong rectangular frame, usually of wrought-iron, with a screw in the centre of the upper cross-piece; the base of the press is fitted into a square recess in the centre of the bench, fixed so firmly to the floor or wall, as to resist the efforts of two or three men at the end of a lever five or six feet long, whose entire force is sometimes required in tightening the mould. For the convenience of transferring the heavy press, from the hole in the bench to the hot or cold water, a crane, the centre of which is equally distant from the three, is added to the establishment.

The mould required for a round box consists of a thick wrought-iron ring *a a*, Fig. 39, turned interiorly to the diameter of the box; it stands loosely upon a plate *b*; it is accurately fitted with several pieces, commonly of brass, as *c* the bottom die, *d* the top die for a plain box, *e* a plain block for flat plates, and *f* a die engraved with any particular device to be impressed upon the work.



39.

In the *Manuel du Tourneur* the methods of making four different kinds of boxes are minutely given. Thus in the "*Boites à feuilles*," the best kind, in which the cover and bottom part are each made out of a single leaf of shell; the circular pieces are to be cut out of the shell as much larger than the size of the box, as the vertical height in addition to the diameter; so that a box of three inches diameter and one inch deep would require pieces of four and five inches respectively for the cover and bottom

The round plate of shell is first placed centrally over the edge of the ring, as in Fig. 39; it is slightly squeezed with the small round-edged block *g*, and the entire press is then lowered into the boiling water; in one quarter, or half an hour, it is transferred to the bench, and *g* is pressed entirely down, which bends the shell into the shape of a saucer, as at Fig. 40, without cutting or injuring the tortoiseshell, after which the press is cooled in the water-trough. The same processes are repeated with the die *d*, which has a rebate turned away to the thickness of the shell, and perfects the angle of the box to the section Fig. 41, ready for completion in the lathe; it is however safer to perform each of these processes at twice, with two boilings.

When the shell is insufficiently thick, two pieces are joined together, and should they from the nature of the shell be of irregular thickness, the thick and thin parts respectively are placed in contact; for such cases the dies *c e*, of a larger mould, are used. The piece *d* is adapted to boxes of various depths, or to the tops or bottoms respectively, by slipping loose rings upon it to contract the length of its smaller part.

When the box is required to have a device, an engraved die *f* is substituted in place of *c*. The same tools are also used for horn boxes, and for the embossed wooden boxes, but the latter process is mostly performed in the dry way, the warmth being supplied by heated plates, put above and below the two parts of the mould which are then compressed, and the whole is allowed to cool in the air.

The *Manuel* describes the construction of inferior boxes, "*Tabatières de morceaux*," in which small pieces of tortoiseshell with bevelled edges are carefully fitted together with the file and arranged along the bottom and up the sides of the mould; or else they are first pressed into a flat plate, and made into a box as a separate process; but the joints, from the manner in which they are made, can scarcely ever escape observation.

The "*Boites de très-petits morceaux*" are made of still smaller fragments, which are often cemented on a thin leaf of shell to ensure their better union; and lastly, the "*Boites de drogues*" are made of the fine dust and filings, which are passed through a sieve, and treated in other respects much in the same manner as the foregoing, but these boxes are quite opaque and brittle; a thin hoop of good tortoiseshell is sometimes inserted in the mould, to form the rebate of the box, which alone is then transparent; at other times, the shavings are mixed with mineral coloring matters, to imitate granite, lapis-lazuli, and other stones.

After the lapse of ten days or a fortnight, it sometimes happens the box shows a tendency to recover its primary form, that of a flat plate, and from being cylindrical on the edge, it becomes in a slight degree conical and larger without. After being again returned to the mould, boiled, and pressed, its figure is in general permanent.

This disposition is turned to useful account in restoring the fitting of a box that may have become loose, as by dipping the lower part, or the rebate, into warm water, it will expand and fill out the lid, but it requires care that it be not overdone.

The tortoiseshell boxes usually made, are those which are veneered upon a body or fabric of wood, for which purpose the plates are scraped and filed to a uniform thickness, and glued on much the same as veneers of wood; generally fine glue is the only cement used, but various compositions are resorted to by different manufacturers. To improve the appearance of the shell, and to conceal the glue and wood beneath, the back of the veneer is rubbed with a mixture of lampblack, vermilion, green, chrome, or white, in fish glue; the colors are applied over the entire surface, or partially to modify the effect, and thus prepared the veneers are glued upon the boxes.

In tortoiseshell works inlaid with mother-of-pearl and gold or silver plates or wire, the substances to be inlaid are first prepared; and for pearl shell a paper is pasted on a thin piece of pearl, the pattern is drawn thereupon, and the small pieces are cut out with a fine buhl-saw: gold and silver plates are sometimes also thus sawn out.

A plain mould similar to Fig. 39, but rectangular, and with plain dies, as *c* and *e*, is used; a few shavings of tortoiseshell are first placed on the piece *c*, to make a bed or cushion, then a piece of paper to prevent them from adhering to the thin leaf of tortoiseshell, which is next inserted in the mould. The small pieces of pearl shell, &c. to constitute the pattern, are then carefully arranged in their intended positions, and the top plate *e* is very carefully lowered into the mould above the pieces, so that it may not misplace any of them. The mould is then slid into the press, slightly squeezed, and plunged into the copper for an hour, carried to the bench and screwed moderately tight; the work is now examined to see that nothing is misplaced, it is returned to the caldron for a time, and the final squeeze is given by the entire force of three men, after which, whilst still under pressure, the whole is plunged into the cold water. The tablet is then fit to be smoothed and glued on the wooden box.

It will be readily conceived, that the force required depends upon the dimensions of the work; pieces of three or four inches square require all the appliances described; whereas the little ornaments upon razors and knives, may be pressed in with much slighter apparatus, such in fact as were previously described as being used in moulding them. In cutlery, a different method is generally resorted to, which applies equally well to ivory and pearl shell, substances which cannot be submitted to the softening and moulding processes employed for horn and tortoiseshell.

The cutlery works which are dotted all over with little studs of gold or silver, are drilled from thin pattern plates of brass or steel in which the series of holes have been carefully made; the drill or "*passer*" has an enlargement or stop, which, by encountering the surface of the pattern plate, prevents the point of the drill from penetrating beyond the assigned depth into the handle; the holes in the ivory or pearl shell are then filled with silver or gold wire, which is either filed and polished off level with the general surface, or allowed to project as little studs.

For small ornaments they use pattern plates or templets of hardened steel, pierced with the exact form. The cutting tool somewhat resembles an ordinary breast-drill eight or ten inches long, and like it, is used with the breast-plate and drill-bow; but the extremity of the tool is cleft, or made in two branches, which, left to themselves, spring open to the extent of an inch or more; each half of the tool

has a shoulder or stop, which bears upon the surface of the steel guard-plate, as in the drill, and a rectangular cutting part that protrudes through the shield-plate as far as the required depth of the recess, and is sharpened both at the end and side, or at the ends only.

When the elastic tool or "*spring-passer*" has been compressed so as to enter the guard-plate, it is put in motion, and flounders about in all directions, so far as it can expand, and routs or cuts out the shallow recess; the small ornaments are punched out, fixed by two rivets, and smoothed off; these processes are very expeditious, and produce accurate copies of the respective pattern-plates employed. The tortoiseshell, when unnecessarily thick for a single scale for a penknife, is sawn to serve for two; and the colors are brightened up by placing a piece of Dutch leaf beneath the same; they are finally polished on the various wheels used by the cutler. Tortoiseshell has been manufactured into hollow walking-sticks, and even bonnets.

Whalebone may be considered as a kind of horn; which latter substance it resembles perfectly, both in its chemical and principal physical properties; and is particularly interesting as forming the transition from horn to hair.

It is the substitute for teeth in the Greenland whale, and in the black southern whale; but is not found in any of the cetaceous animals that have teeth.

From the roof of the mouth hang down on each side the tongue about three hundred plates of whalebone, all the blades on one side being parallel to each other and at right angles to the jaw-bone. The average length of the middle blades is about nine feet, but they have occasionally occurred of the length of fourteen or fifteen feet.

The general color of whalebone is a dusky grayish black, intermixed with thin stripes or layers of a pale color, which are often almost white—very rarely the entire flake is milk-white.

The preparation of the whalebone for use is very simple. It is boiled in water for several hours, by which it becomes soft enough to be cut up while hot, in lengths of different dimensions, according to the use to which it is to be applied. Whalebone that has been boiled, and has become cold again, is harder and of a deeper color than at first; but the jet-black whalebone has been dyed, and by the usual processes it takes very bright and durable colors.

Whalebone is now principally used for the stretchers for umbrellas, and as a substitute for bristles in common brushes; it is also plaited into whips, and solid pieces of mixed shades are twisted for walking-sticks; but it does not admit of being soldered or joined together like tortoiseshell. Whalebone also furnishes a very neat and durable covering for pocket-telescopes. Narrow pieces of the material are grooved or made into ribs, by drawing them like wire through a corresponding aperture in a steel plate, after which they are wound round the tube, and "*tucked under*" the rings at the extremities. Broad flat strips of the party-colored whalebone, (the light portions of which absorb the green dye,) are also used: these are secured by narrow black bands which overlap the two edges, and other bands are wound around the ends also.

Ivory, the tusk or weapon of defence of the male elephant, and of which each animal has two, is placed by the chemists intermediately between bone and horn, and its mechanical characters corroborate the position. It is generally considered that the male elephant alone possesses tusks, commercially known as elephants' teeth, but this appears questionable, as by many the female is reported to have tusks likewise, but of smaller size, and some consider the latter produce the small solid tusks called "ball ivory," used for making billiard balls.

Ivory has less gelatine than bone; but as it leaves the animal in a state fit for use, without the necessity of removing any of its component parts for its purification, its elasticity and strength are not impaired by such abstraction. Ivory is not therefore so brittle as bone, neither does it splinter so much when broken, but its greater ultimate share of animal matter leaves it more sensible to change of form and size.

The shape of the tusk is highly favorable to its use, as it is in general solid for above half its length, and of circular or elliptical section; it is entirely free from the vessels or pores often met with in bone, and although distinctly fibrous, it cannot be torn up in filaments like horn, nor divided into thin flexible leaves, as for miniatures, otherwise than by the saw.

Its substance appears very dense, and without visible pores, as if beautifully cemented by oil or wax; and notwithstanding that it possesses so large a share of lime, it admits of being worked with exquisite smoothness, and is altogether devoid of the harsh, meager character of bone. It is in all respects the most suitable material for ornamental turning, as it is capable of receiving the most delicate lines and cutting, and the most slender proportions.

The general supply of ivory is obtained from the two present varieties of the animal, the Asiatic and the African: they are considered by physiologists to be distinct species, and to be unlike the extinct animal from which the Russians are said to obtain their supply of this substance; which, although described as *fossil* ivory, does not appear to have undergone the conversion commonly implied by the first part of the name, but to be as suitable to ordinary use as the ivory recently procured from the living species. An extract from the interesting account of "The Elephant of the Lena" is subjoined as a note.*

* "The Mammoth, or Elephant's bones and tusks, are found throughout Russia, and more particularly in Eastern Siberia and the Arctic marshes. The tusks are found in great quantities, and are collected for the sake of profit, being sold to the turners in the place of the living ivory of Africa, and the warmer parts of Asia, to which it is not at all inferior."

"Almost the whole of the Ivory-turner's work, made in Russia, is from the Siberian fossil ivory; and sometimes the tusks, having hitherto always been found in abundance, are exported from thence, being less in price than the recent. Although, for a long series of years, very many thousands have been annually obtained, yet they are still collected every year in great numbers on the banks of the larger rivers of the Russian empire, and more particularly those of farther Siberia."—The Naturalist's Library, 1836. Mammalia, vol. v., p. 133.

The Mammoth teeth are but rarely exposed for sale in this country. I only learn of two; the one weighed 186 pounds, was 10 feet long, of fine quality, and except the point, which was cracked, was cut into keys for pianofortes; the other also was large, but very much cracked and useless. Of the latter I have a specimen: the substance of the ivory between the

The hippopotamus, or river-horse, supplies the ivory used by the dentist, which is imported from the East Indies and Africa; the animal, in addition to twenty grinders, has twelve front teeth, the whole of which agree in substance with ivory, but not in their size or arrangement. The six in the upper jaw are small, and placed perpendicularly; in the lower jaw of the hippopotamus the two in the centre are long, horizontal, and straight, the two next are similar, but shorter; but the two external *semicircular* teeth are those so highly prized by the dentists on account of their superior size, and are those usually referred to when the "*sea-horse*" or hippopotamus tooth is spoken of, although the animal is in reality a quadruped inhabiting rivers and marshy places.

The circular hippopotamus teeth are covered exteriorly with a thick coat of enamel, which entirely resists steel tools, and will even strike fire with that metal; it is usually removed upon the grindstone* in order to arrive at the beautiful ivory within, which, owing to the peculiarity of its section, is better adapted to the construction of artificial teeth than the purposes of turning; the other teeth are tolerably round, and fit for the lathe.

The ivory of the hippopotamus is much harder than that of the elephant, and upwards of double the value; in color it is of a purer white, with a slight blue cast, and is almost free from grain. The parts rejected by the dentists are used for small carved and turned works.

In texture it seems almost intermediate between the proper ivory and the pearl shell; as when it is turned very thin, it has a slightly curdled, mottled, or damasked appearance, which is very beautiful; the general substance is quite transparent, but apparently interspersed with groups of opaque fibres, like some of the minerals of the chatoyant kind.

The teeth of the walrus, sometimes called the sea-cow, which hang perpendicularly from the upper jaw, are also used by the dentists; the outer part, or the true ivory, nearly resembles the above, but the oval centre has more the character of coarse bone; it is brown, and appears quite distinct. The long straight tusks of the sea-unicorn or narwal, which are spirally twisted, also yield ivory; but they are generally preserved as curiosities. These two kinds are principally obtained from the Hudson's Bay Company.

The masticating teeth of some of the large animals are occasionally used as ivory; those of the spermaceti whale are of a flattened oval section, and resemble ivory in substance; but they are dark-colored towards the centre, and surrounded by an oval band of white ivory: like that of the aquatic varieties generally, they are not much used.

The grinders of the elephant are occasionally worked; but their triple structure of plates of the hard enamel, of softer ivory, and of still softer cement, which do not unite in a perfect manner, render them uneven in texture. Owing to the hardness of the plates of enamel, the grinders are generally worked by the tools of the lapidary; they are but little used, and when divided into thin plates are disposed to separate, from change of atmosphere, the union of their respective parts being somewhat imperfect. They are made into small ornaments, knife-handles, boxes, &c.

The tusk of the elephant is, however, of far more importance than all these other kinds of ivory, and appears to have been extensively used by the Greeks and Romans. Amongst the former, Phidias was famous for his statues, thrones, and other works of embellishment, made in ivory combined with gold, an art described as the *Toreutic.* In reference to the construction of ivory statues, *Monsieur Quatremère de Quincy*, in his great work on ancient sculpture,† advances some curious speculations of their having been formed upon centres or cores of wood, covered with plates of ivory; and also that the ancients were enabled to procure larger elephants' teeth, or possessed the means of softening and flattening out those of ordinary size, from which to obtain the pieces presumed to have been thus employed.

These questionable suppositions, particularly the last, scarcely seemed called for, as solid blocks of ivory of the sizes commonly met with, would appear to be sufficient for the construction of colossal figures, in the mode ingeniously demonstrated by *M. de Quincy* in his plates 26 to 31. It is much to be regretted that none of these statues have descended to our times.

One of the constituent parts of ivory being animal matter, we should naturally expect it to be less durable than the inorganic materials, in which numerous fine specimens of ancient art still exist in great comparative perfection. Ivory appears not to suffer very rapid decay, in the lengthened deposition in the frozen earth of Siberia, nor when immersed in water; but various specimens in the British Museum, apparently less favorably situated, and in contact with the air, exhibit the effect of time, the ivory being decomposed and divided into flakes and pieces which exhibit its lamellar structure in a very satisfactory manner.

Elephants' teeth differ considerably in their size, weight, and appearance. The outsides of the African teeth run through all the transparent tints of light and deep orange, hazel, and brown, and some are almost black. Those from Asia are similar, although generally lighter, and frequently of a kind of opaque fawn, or stone-color; they have seldom the transparent character of the African teeth; and they commonly abound in cracks of inconsiderable depth, from which the others are comparatively free.

Some teeth are as long as from eight to ten feet, and as heavy as 150, rarely 180 lbs. each tooth; sometimes they are only as many inches long, and about one inch in diameter, and of the weight of five or six ounces, and even lighter; the teeth less than from 10 to 14 lbs. are called "scrivelloes." In section, the tusks are rarely quite circular, sometimes nearly elliptical, seldom exceeding the proportions of four to five, but commonly less exact than either of these forms; Figs. 43, 44, and 45, are accurately reduced from sections of teeth; the largest tusk the author has met with measured eight and a quarter inches the longest, and seven inches the shortest diameter of the irregular oval.

---

cracks appears quite of the ordinary character, although the interstices are filled with a dry powder resembling chalk. Both teeth were *solid unto within six inches of the root.*

* The enamel of the hippopotamus is much thicker, but similar to that of the generality of masticating teeth, which is found upon analysis to agree very nearly with the hard porcelanous shells. The enamel is sometimes scaled off by driving a thin chisel between it and the ivory; and I learn, the flame of the blowpipe is likewise frequently used for the purpose of separating it. Several of the other teeth have enamel, but the semicircular tooth by far the most abundantly.

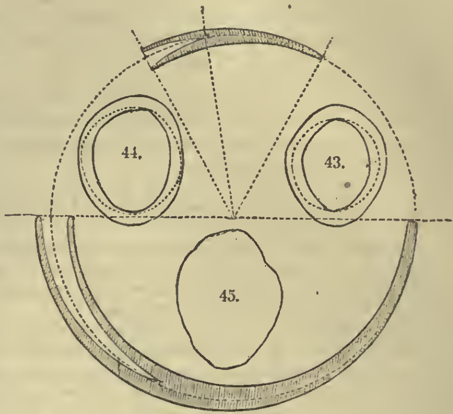
† Le Jupiter Olympien, ou l'Art de la Sculpture Antique. Paris, 1815.

The curvature of the teeth is sometimes as much as the half-circle, as in Fig. 46, and occasionally even so little or less than the sixth, as in Fig. 42; they are sometimes finely tapered off, especially in the African teeth, at other times their ends are very much worn away,—in rare instances, to the extent of a third of their apparent length, and generally more so on the one side of the centre than the other.

Other teeth end very abruptly, as if they had been broken and repointed before they left the head of the animal, in which they are generally inserted for about one-fourth their length.

The teeth are hollow about half-way up, and a speck, sometimes called the nerve, but in reality the apex of the successive hollows, is always visible throughout the length of the tusk to its extreme end, the tooth being formed by layers deposited on a vascular pulp after the manner of teeth generally.

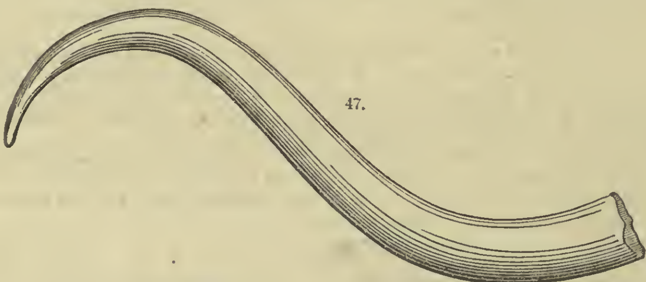
42.



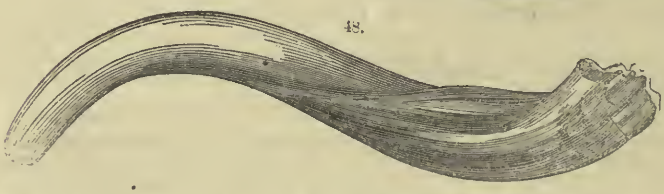
46.

The inner and outer surfaces of the teeth are in general tolerably parallel, and exteriorly they are curved in the one direction only, so as to lie nearly flat on the ground; but occasionally they are much curved in both directions, as represented in Figs. 47 and 48; the smaller is beautifully formed, and resembles in shape a handsome bullock's horn, the other is furrowed throughout its length, and appears the result of disease or injury.

The choice of ivory in the tooth is admitted by the most experienced to be a very uncertain matter; of course, for the purposes of turning, a solid cone would be the most economical figure, but as that form is not to be met with, we must be satisfied with the nearest approach that we can find to it, and select the tooth as nearly straight, solid, and round as possible, provided the other prognostics are equally favorable.



47.



48.

The rind should appear smooth and free from cracks, and if the heart should be visible at the tip, the more central it is the better; by the close inspection of the tip, from which the bark is always more or less worn away, it may be in general learned whether the tooth is coarse or fine in the grain, transparent or opaque, but the color of the exterior coat prevents a satisfactory judgment as to the tint or complexion of the ivory within.

After the most careful scrutiny on the outside of the tooth, however, the first cut is *always* one of a little anxious expectation, as the prognostics are far from certain, and before proceeding to describe the preparation of ivory, I will say a few words of its internal appearance when exposed by the saw.

The African ivory, when in the most perfect condition, should appear, when recently cut, of a mellow, warm, transparent tint, almost as if soaked in oil, and with very little appearance of grain or fibre; it is then called transparent or green ivory, from association with green timber; the oil dries up considerably by exposure, and leaves the material of a delicate, and generally permanent tint, a few shades darker than writing-paper.

The Asiatic ivory is of a more opaque dead-white character, apparently from containing less oil, and on being opened it more resembles the ultimate character of the African, but it is the more disposed of the two to become discolored or yellow. The African ivory is generally closer in texture, harder under the tools, and polishes better than the Asiatic, and its compactness also prevents it from so readily absorbing oil, or the coloring matter of stains when intentionally applied.

The rind is sometimes no more than about one-tenth of an inch in thickness, and nearly of the color

of the inner ivory, but occasionally it is of double that thickness, dark-colored, and partially stains the outer layers. As we do not find all specimens of the most perfect kind, we must be prepared to expect others, especially amongst the larger teeth, in which the grain is more apparent, but it generally dies away towards the centre of the tooth, the outside being the coarser; the regularity of the grain sometimes gives it the appearance of the engine-turning on a watch-case.

In some teeth, the central part will appear of the transparent character, the outer more nearly white; and the transparent teeth often exhibit, at the solid parts, white opaque patches, which are frequently of a long oval form. Amongst the white ivory, the teeth are often found to be marked in rings alternately light and dark colored; these are called "*ringy* or *cloudy*."

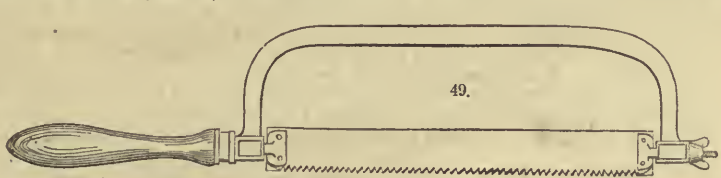
In those teeth in which there appears to be a deficiency of the animal oil, the intervals between the fibres occasionally assume the chalky character of bone, and are disposed to crumble under the tools unless they are very sharp; in this they resemble the softer parts of woods when worked with blunt tools; sometimes the ivory is not only coarse but dark or brown, and the two defects not unfrequently go together.

The cracks occasionally penetrate further than they appear to do when viewed from the outside, and more rarely a very considerable portion of the tooth is injured by a musket-ball, although the gold and silver bullets, said to be used by the Eastern potentates, are exceedingly scarce, or else transmuted into iron, of which metal they are commonly found, and less frequently of lead. The ball generally lacerates the part very much, and a new deposite of bony matter is made that fills up all the interstices, incrusts the hollow, and leaves a dotted mottled mass extending many inches each way from the ball, and which completely spoils that part for any ornamental purpose.

Preparation of Ivory.—On account of the great value of ivory it requires considerable judgment to be employed in its preparation, from three conditions observable in the form of the tusk; first, its being curved in the direction of its length; secondly, hollow for about half that extent, and gradually taper from the solid state to a thin feather edge at the root; and thirdly, elliptical or irregular in section. These three peculiarities give rise to as many separate considerations in cutting up the tooth with the requisite economy, as the only waste should be that arising from the passage of the thin blade of the saw: even the outside strips of the rind, called spills, are employed for the handles of penknives, and many other little objects; the scraps are burned in retorts for the manufacture of ivory black, employed for making ink for copperplate printers, and other uses; and the clean sawdust and shavings are sometimes used for making jelly.

The methods of dividing the tooth either into rectangular pieces, or those of circular figure required for turning, are alike in their early stages until the lathe is resorted to: I propose, therefore, to begin with the former. The ivory saw, Fig. 49, is stretched in a steel frame to keep it very tense; the blade generally measures from fifteen to thirty inches long, from one and a half to three inches wide, and about the fortieth of an inch thick; the teeth are rather coarse, namely, about five or six to the inch, and they are sloped a little forward, that is, between the angle of the common hand-saw tooth and the cross-cut saw. The instrument should be very sharp and but slightly set; it requires to be guided very correctly in entering, and with no more pressure than the weight of its own frame, and it is commonly lubricated with a little lard, tallow, or other solid fat.

49.



The cutler generally begins at the hollow, and having fixed that extremity parallel with the vice, with the curvature upwards, he saws off that piece which is too thin for his purpose, and then two or three parallel pieces to the lengths of some particular works, for which the thickness of the tooth at that part is the most suitable; he will then saw off one very wedge-form piece, and afterwards two or three more parallel blocks.

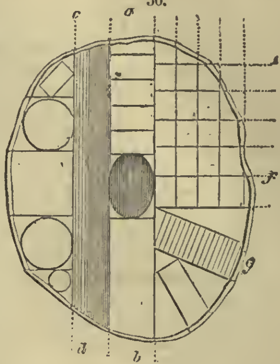
In setting out the length of every section, he is guided by the gradually increasing thickness of the tooth; having before him the patterns or gages of his various works, he will in all cases employ the hollow for the thickest work it will make. As the tooth approaches the solid form, the consideration upon this score gradually ceases, and then the blocks are cut off to any required measure, with only a general reference to the distribution of the *heel*, or the excess arising from the curved nature of the tooth, the cuts being in general directed, as nearly as may be, to the imaginary centre of curvature. The greatest waste occurs in cutting up very long pieces, owing to the difference between the straight line and the curve of the tooth, on which account the blocks are rarely cut more than five or six inches long, unless for some specific object.

In subdividing those blocks which are entirely solid, no great difficulty is experienced: in those which are nearly solid, as in Fig. 50, the first step is to cut a central slice just thick enough to avoid the hollow, unless the pieces *a b* are required to have some particular size; *c d* would serve for leaves for miniatures or veneering, and the remainder would be cut up of any required sizes, as sketched beyond *c d*. For square pieces of similar size, the block is cut into parallel slabs; for bevelled pieces, as the taper handles of knives and razors, the slabs are cut out wedge-form, the thick end of one against the thin end of the next, as at *e f:* these slabs are afterwards divided with parallel or inclined cuts, either with the frame or the circular saw.

In flat works, such as razor and knife handles, the broad surfaces, if cut radially, would show the edges of the rings or layers of the ivory; but cut parallel with the curve or as the tangent, the grain is

much less observable, and the ivory appears finer. In the keys for pianofortes this is particularly attended to; the finest broad keys are always cut upon the flat side of the oval, as at *f*, those upon the long diameter are cut into the narrow pieces called tails, (used between the black keys,) and the intermediate parts are cut obliquely as at *g*; this causes much waste.

50.



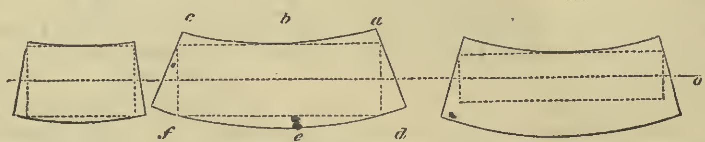
For such pieces as have large hollows, more management is necessary, as the thickness and curvatures of the material have to be jointly considered. When the hollows are thin, they are cut into squares or handles as large as the substance will allow; but on account of the circular section of the tooth, some of the pieces, if not all, must necessarily be angular or wedge-form; as regards pieces for the lathe, this is of little consequence.

In all cases the entire division of the block or ring should be determined upon, and carefully marked in pencil upon the end of the piece, before the saw is used.

When the tusk is cut up exclusively for turnery-work, the first cut is more generally made where the hollow terminates, which spot is ascertained by thrusting a small cane or a wire up the tooth; and every cut is directed as nearly as possible at right angles to the curve of the tusk, or to the centre of the circle, as before described. Unless the tooth is very far from circular, it is usual to prepare the principal quantity into cylinders or rings, as large as they will respectively hold, and the diagrams, Figs. 51, 52, and 53, are intended to explain the best mode of centreing the pieces, or placing them in the lathe.

If, as in preparing an ordinary block of wood, a circle were made at each end, and the work were chucked from the centres of the circles, as at *o*, Fig. 51, the largest cylinder that could be obtained would

53. 52. 51.



be that represented by the four sides of the dotted rectangle within that figure. Very much less waste would result from placing the centres so much nearer to the convex side, as to obtain the cylinder represented in Fig. 52, by allowing the waste to be equally divided between the points *a*, *c*, and *e*.

It is however more economical, to cut those teeth which are much curved into the shortest blocks, and the Fig. 53, which represents the proportions more commonly adopted, shows the small comparative degree of waste that would occur in a piece of half the length of the others, when centred in the most judicious manner.

The first process in preparing to rough-turn the block, is to fix it slenderly in the lathe between the prong chuck and the point of the popit-head, and its position is progressively altered by trifling blows upon either end, until when it revolves slowly, and the common rest or support for the tool is applied against the most prominent points *a*, *e*, and *c*, respectively, the vacancies or spaces opposite to each, at *d*, *b*, and *f*, shall be tolerably equal; so that, in fact, about a similar quantity may have to be turned away from the parts *a*, *e*, and *c*, for the production of the cylinder, represented by the dotted lines within the figure.

The centres having been thus found, they should be made a little deeper with a small drill; and then the one end of the block being fixed upon the prong chuck, the opposite extremity, supported by the centre, is turned for a short distance slightly conical, ready for fixing in a plain boxwood chuck, or a brass chuck lined with wood, to complete the rough preparation, unless indeed it is entirely performed upon the prong chuck.

With the decrease in length, less attention is requisite in the centreing, on account of the interference of the curvature of the tooth, and the pieces may be at once rasped to the circular form, and then chucked either in a hollow chuck, or else by cement or glue, against a plain flat surface.

When the blocks of ivory are long and much curved, a thin wedge-form plate may be sometimes sawn from the end, in preference to turning the whole into shavings; the end is turned cylindrically for a short distance, just avoiding to encroach on the lower angle of the block, and as soon as practicable, a parting tool is used for cutting a radial notch for the admission of the saw, which may be then employed in removing a thin taper slice. The process is at any rate scarcely attended with more trouble than turning the material into shavings, and thin pieces are retained for a future purpose, such in fact as these represented beyond the dotted lines at the ends of the figures.

The hollow pieces of ivory are treated much in the same manner as those which are solid, and into which latter condition they are sometimes temporarily changed, by rasping a piece of common wood, such as beech, to fit into the hollow, driving it in pretty securely, but so as not to endanger splitting the ivory; the work is then centred as recently explained, the chuck and centre being in this case received in the wood.

With the hollow pieces, the process of turning must be repeated on their inner surfaces, for which purpose a side cutting tool, with a long handle for a secure grasp, should be used: the tool should be held very firmly, so as to withstand the jerking intermittent nature of the cut, until the irregularities are reduced.

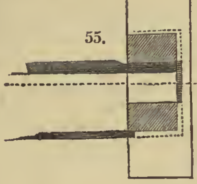
For this purpose the sliding-rest is very desirable, as the tool is then held perfectly fast without effort

on the part of the individual, and if the chucking be correctly done, the greatest possible economy of the material is attained; the hand tools succeed very well on the outer surface, as the rest or support upon which they are then placed is so close to every point of the exterior surface, that they may be held securely with less effort, although the sliding-rest is nevertheless desirable there also.

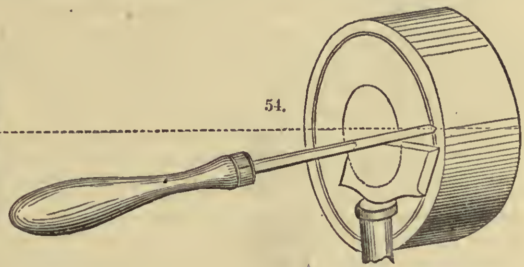
When the ivory hollow is thin, and far from circular, the material would be turned entirely into shavings, in attempting to produce a circular ring; the circular dotted lines in Figs. 43 and 44, are intended to explain this. Fig. 43 might be turned into an oval ring; but it is more usual to cut such irregular hollows into small square and round pieces, as explained.

When thin rings or short tubes are required, they are frequently cut one out of the other in the lathe, in preference to wasting the material in shavings; this is done with the parting tool, as in Fig. 54; an incision being made of uniform diameter from each end, and continued parallel with the axis, until the

55.



54.



two cuts meet in the centre; very short pieces may be thus divided from the one end only. When the rings are large and thin, it is desirable to plug them at one or both ends, with a thin piece of *dry* wood, turned as a plug to fill the diameter, and prevent the ivory from becoming oval in the course of drying.

Fig. 55 explains the mode of preparing such an object as a snuff-box out of a solid block; that is, with the ordinary parting tool entered from the front, and the inside parting tool entered from within; the incisions of which meet and remove a series of rings. The dotted lines represent the paths of the respective tools, the shaded parts the ring obtained, and the black lines the tools themselves. An aperture must necessarily be made in the centre, of a diameter equal to the extreme width of the tool; but after the removal of the first, or central ring, a tool of considerably larger size may be used to extract a much wider ring; and a little tallow or oil applied to the parting tools, will, in a great measure, prevent the shavings of the ivory from sticking to them and impeding their progress.

Ivory requires a similar drying, or seasoning, to that recommended for wood; as when the pieces cut out of the tooth are too suddenly exposed to hot dry air, they crack and warp nearly after the same manner as wood, and the risk is the greater the larger the pieces; and on this account ornaments turned out of ivory or wood, especially those composed of many parts, should not be placed upon those chimney-pieces which, from their size, are so close to the fire as to become heated thereby in any sensible manner.

Notwithstanding the difference between the component parts of wood and ivory, and that the latter does not absorb water in any material degree, it is subject to all the changes of size and figure experienced by the woods, and in one respect it exceeds them, as ivory alters in *length* as well as *width* whereas from the former change wood is comparatively free.

The change, however, is very much less in the direction of the length than the width; this is particularly experienced in billiard-balls, which soon exhibit a difference in the two diameters, if the air of the apartment in which they are used differ materially from that in which the ivory had been previously kept. The balls are usually roughly turned to the sphere for some months before they are used, to allow the material to become thoroughly dry before being turned truly spherical; and in some of the clubs they even take the precaution of keeping the rough balls in their own billiard-room for a period, to expose them to the identical atmosphere in which they will be used.

It may be asked, what means there are of bleaching ivory which has become discolored; the author regrets to add that he is unacquainted with any of value. It is recommended in various popular works to scrub the ivory with Trent sand and water, and similar gritty materials; but these would only produce a sensible effect, by the removal of the external surface of the material, which would be fatal to objects delicately carved by hand, or with revolving cutting instruments applied to the lathe.

Perhaps it may be truly advanced, that ivory suffers the least change of color when it is exposed to the *light*, and closely covered with a glass shade. It assumes its most nearly white condition when the oil, with which it is naturally combined, is recently evaporated; and it is the custom in some thin works, such as the keys of pianofortes, to hasten this period, by placing them for a few hours in an oven heated in a very moderate degree, although the more immediate object is to cause the pieces to shrink before they are glued upon the wooden bodies of the keys. Some persons boil the transparent ivory in pearlash and water to whiten it; this appears to act by the superficial extraction of the oily matter as in bone, although it is very much better not to resort to the practice, which is principally employed to render that ivory which is partly opaque and partly transparent, of more nearly uniform appearance.

It is imagined by some that ivory may be softened so as to admit of being moulded like horn or tortoiseshell: its different analysis contradicts this expectation; thick pieces suffer no change in boiling water, thin pieces become a little more flexible, and thin shavings give off their jelly, which substance is occasionally prepared from them. Truly, the caustic alkali will act upon ivory as well as upon most

animal substances, yet it only does so by decomposing it; ivory, when exposed to the alkalies, first becomes unctuous or saponaceous on its outer surface, then soft, if in thin plates, and it may be ultimately dissolved, provided the alkali be concentrated; but it does not in any such case resume its first condition.

Ivory is not in all cases used in solid pieces, to which the foregoing remarks principally apply; but is frequently cut into thin leaves and glued upon fabrics of wood, for the manufacture of small ornamental boxes, and works of various kinds, after the manner of the veneers of wood, or the plates of tortoiseshell; it is also used in buhl works, combined with ebony. Such thin plates are usually cut out of the solid block, parallel with the axis of the tooth, as at *c d*, in Fig. 50, with a fine feather-edge veneer saw; but the mode introduced in Russia for cutting veneers spirally from a cylindrical block of wood, with a knife of equal length, (as if the veneer were uncoiled like a piece of silk or cloth from a roller,) has been latterly applied to the preparation of ivory into similar veneers, converting the cylinder of ivory into one ribbon, probably by the action of a reciprocating-saw.*

The modes pursued in these veneered works are analogous to those to be described in the article in reference to woods; it is, therefore, only necessary to add a few words on the white-fish glue, or "Diamond cement," as it is sometimes called, which is very often used for ivory-work, both in attaching ivory to ivory, and ivory to wood.

This cement is made of isinglass, (which is prepared from the sound, or swimming-bladder of the sturgeon,) dissolved in diluted spirits of wine, or more usually in common gin. The two are mixed in a bottle loosely corked, and gently simmered in a vessel containing boiling water: in about an hour the isinglass will be dissolved and ready for use; when cold, it should appear as an opaque, milk-white, hard jelly; it is remelted by immersion in warm water, but the cork should be at the time loosened, and it may be necessary, after a time, to add a little spirit to replace that lost by evaporation. Isinglass, dissolved in water alone, soon decomposes.

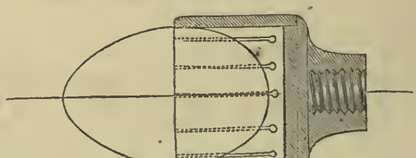
Factitious ivory and tortoiseshell have been prepared in France in thin plates or veneers.

Having adverted to many animal substances suitable to the mechanical arts, obtained from various inhabitants of the land and water, let me, in conclusion, mention some that are obtained from the feathered tribes—namely, the eggs of birds; which, although of limited application in the arts of embellishment, have at all ages served as models or standards of beautiful form.

They may be made to answer in a very perfect manner for the bodies of vases, the feet and upper parts of which are turned out of wood or ivory; for this purpose the egg-shells have been commonly used in their entire state, a hole having been made at the top and bottom for the extraction of their contents, and the attachment of the remaining parts. I have now the pleasure to bring before the reader a method of cutting the shells of the eggs of our various domestic fowls, and other birds, for the formation of vases with *detached* covers.

In the accompanying drawing is represented the nose of a lathe, with an egg chucked ready for cutting. Fig. 56 is the section of a chuck for holding the eggs to prepare them for the chuck represented in Fig. 57.

56.



57.

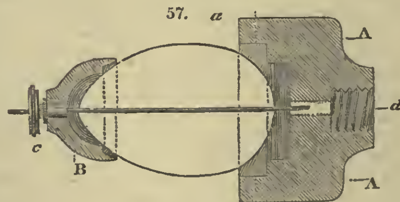


Fig. 56 is what is generally termed a spring chuck, and is made by rolling stout paper, thoroughly moistened with glue, upon a metal or hard-wood cylinder, the surface of which has been greased to prevent the paper adhering to it, and upon which it must remain until perfectly dry, when it may be removed, and cut or turned in the lathe as occasion may require.

This sort of chuck is very light, easily made, and well adapted for the brittle material it is intended to hold. Before fixing the egg in it, the inner surface should be rubbed with some adhesive substance, (common diachylon answers exceedingly well;) when this is done, the egg should be carefully placed in the chuck, the lathe being slowly kept in motion by one hand, whilst with the other the operator must adjust its position, until he observes that it runs perfectly true; then, with a sharp-pointed tool he must mark the centre, and drill a hole sufficiently large for the wire in the chuck, Fig. 57, to pass freely through.

When this is done, the egg must be reversed, and the same operation repeated on the opposite end; its contents must then be removed by blowing carefully through it: it is now ready for cutting, for which purpose it must be fixed in the chuck shown in Fig. 57, which is made as follows:

A is a chuck of box, or other hard wood, having a recess turned in it at *a b*, into which is fitted a piece of cork, as a soft substance for the egg to rest against. B is a small cup of wood, with a piece of cork fitted into it, serving the same purpose as that in A. A piece of brass, *d*, is to be firmly screwed into the chuck A, and into that a steel wire, screwed on the outer end.

* Monsieur H. Pape, of Paris, pianoforte manufacturer, has taken out patents for this method of cutting ivory spirally into sheets. A specimen, 17 inches by 38 inches, and about one-thirtieth of an inch thick, glued upon a board, may be seen at the Polytechnic Exhibition in Regent-street, and M. Pape advertises to supply sheets as large as 30 by 150 inches. He has veneered a pianoforte entirely with ivory.

ANIMAL STRENGTH. Of all the first movers of machinery, the force derived from the strength of man or other animals, was first used; and at present, in a multitude of cases is still the most convenient. As horses were formerly employed for the same purposes as water-wheels, wind-mills, and steam-engines now are, it has become usual to calculate the effect of these machines as equivalent to so many horses; and animal strength becomes thus a sort of measure of mechanical force.

When an animal is at rest, and exerts its strength against any obstacle, then the force of the animal is greatest, or the animal when standing still, will support the greatest load. If the animal begins to move, then it cannot support so great a load, because a part of its strength must be employed to effect the motion, and the greater the speed with which the animal moves, the less will be the force exerted on the obstacle, or the less will be the load which it is able to carry, for the greater will be the portion of its strength directed to the movement of its own body; and there will be a speed with which the animal can move and carry no load, but where the whole of its strength is employed in keeping up its velocity.

It is clear that in the first and last of these cases, the useful effect of the animal is nothing, in a mechanical point of view. There must however be a certain relation between the load and speed of the animal, in which the useful effect is a maximum. It has been found that the mechanical effect of any animal at work during a given time, is greatest when the animal moves with one-third of the greatest velocity with which it can move unloaded, and the load which it bears is four-ninths of that which it can only move. The mechanical effect of any animal depends upon the load which it carries, and the speed with which it moves, conjointly; and thus to find the mechanical effect of an animal, we have only to multiply the load by the speed; hence the mechanical effect of a man carrying a load of 60 lbs., and moving at the rate of 3 feet in the second, is $3 \times 60 = 180$. When a man goes up a stair unloaded, his quantity of action is the greatest possible, but his useful effect is nothing. When he is loaded his quantity of action is less, but his useful effect is more than formerly. In fact, it was found by Coulomb, that the greatest useful effect was produced when the weight which the man bore was 0·756, or $\frac{3}{4}$ of his weight; or assuming the weight of the man to be 150 lbs., the load would be $112\frac{1}{2}$ lbs.

When a man travels unloaded on a level road for several days, he can hardly walk more than 31 miles a day, which gives for the quantity of a man's action in this way 7700 lbs., carried 1094 yards. The quantity of action of a man walking up a stair, is to that when he walks on a level road, as 1 to 17.

The following table exhibits the average amount of mechanical effect produced by men and animals in different applications; the animal working with a mean velocity and effort during an average day's work, thereby producing the maximum effect.

Nature of the work.	Effort exerted.	Velocity per second.	Effect per second.	Duration.	Mechanical effect per day.
	Pounds.	Feet.		Hours.

Desaguliers and Sweaton state the strength of a horse to be equivalent to five men; French writers to seven; Dr. Gregory to six. It is however to be remarked in comparing the strength of a horse with that of a man, that the most advantageous way to apply the strength of the one, is the least advantageous to the other. The worst way to apply the strength of the horse, is to make him carry a weight up a steep hill, while the structure of man fits him very well for that purpose.

When a horse is employed in a gin, as is often practised in grinding and threshing mills, it is desirable to give as great a diameter as possible to the circle in which the animal walks. In practice it may be stated, that the diameter of the gin walk ought not to be less than 25 or 30 feet.

According to Desaguliers, a horse's power is equivalent to 44000 lbs. raised one foot high in one minute of time. During 8 hours, according to Watt, 33000 lbs.

ANNEALING. Glass, cast iron, and steel, together with other substances, when heated, and then allowed suddenly to cool, become hard and brittle, a circumstance which often renders them unfit for the purposes for which they are intended. To obviate this inconvenience, these bodies are, when heated, allowed gradually to cool, and this process is called annealing. Glass vessels after having been blown, are placed in an oven called the *leer*, which is situated immediately over the great furnace, where they are allowed to remain gradually cooling for a greater or less time according to their thickness. The best way of annealing steel, is to render it red hot in a charcoal fire, taking care that the metal be completely covered, and then allowing the fire to go gradually out of its own accord. Cast iron cannot be managed in this way, as, being bulky, the expense of charcoal would be enormous; it is therefore usual to employ turf or cinders, the process being otherwise conducted the same way as with steel. In annealing cast iron, it is not desirable that the metal should be brought to any more than a red heat, as otherwise the smaller pieces, and thin bars might not only bend, but even melt. In annealing cast iron when the pieces are numerous, and the fire too small, or, when it is suspected that the heat of the fire when left to itself may become too great, the pieces are, when red hot, buried in dry saw dust, and in that state allowed to anneal. One great advantage of annealing cast iron, is, that if it is afterwards subjected to a partial heating, it is less liable to warp than it would otherwise be. The character of cast

iron is not in any way altered by annealing, except that it is rendered more malleable. Cast iron when employed in cutlery, is commonly bedded in some poor iron ore, or some substances which give out oxygen, and kept in a state little short of fusion for twenty-four hours; it is then found to be in a state not unfit for some kinds of edge tools and nails, and to retain a considerable portion of that malleability imparted to it by annealing. It is remarkable, that annealing makes copper hard and brittle, and that sudden cooling has the contrary effect. See IRON.

ANNIHILATOR. See FIRE ANNIHILATOR.

ANTHRACITE COAL. See COAL.

ANTIMONY, a metal usually found in a crude state combined with sulphur, of a bluish-white color crystalline texture, brittle and easily pulverized.

Manufacture.—The smelting of this metal is very simple. The crude ore is picked by hand; the pieces are broken to the size of an egg; and by means of a hand hammer, the gangue, such as quartz, barytes, or carbonate of lime is removed. These pieces may be heated in an earthenware pot, in the bottom of which is a small aperture. The sulphuret of this metal, melting at a very low heat, will flow out from the gangue, and may be gathered in another pot set below. The operation used to be performed in this manner; but as it is expensive, the ore is at present melted in a reverberatory furnace, the hearth of which is very concave, and formed of sand. In the centre of the hearth, at its deepest part, there is a tap-hole which communicates with one of the long sides of the furnace. The ore on being sorted, is spread over the hearth of the furnace, and is there melted. The tap-hole is stopped by dense coal-dust, while the reduction is going on.

Uses of Antimony.—Besides its employment in medicine, it is much used for forming alloys; of these type-metal, and anti-friction-metal—which is type-metal with the addition of copper—are those most used. Eighty parts of lead and twenty of antimony form type metal; to this commonly five or six parts of bismuth are added. Tin 80 parts, antimony 20, is music metal; it is also composed of 62.8 tin, 8 antimony, 26 copper, and 3.2 iron. Plate pewter also contains from 5 to 7 per cent. of antimony; 89 tin, 7 antimony, 2 copper, 2 iron, is one of these compositions. Britannia metal contains frequently an equal amount of antimony. Queen's metal is 75 tin, 8 antimony, 8 bismuth, and 9 lead. Antimony and tin, melted together in equal parts, form a moderately hard, brittle, but very brilliant alloy, which is not soon tarnished, and is frequently employed for small speculums in telescopes. Crude antimony is employed for purifying gold.

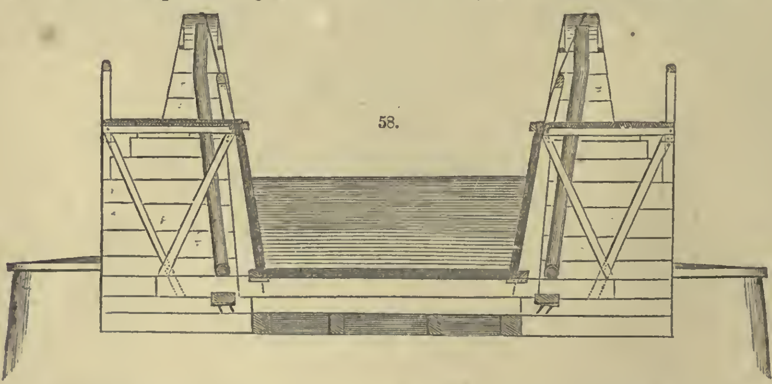
AQUEDUCT, a conduit for water: as an illustration of an Aqueduct for the conveyance of a canal across a river we instance the Aqueduct Wire Suspension, over the Alleghany River at Pittsburg, constructed under the superintendence of John A. Roebling, at the western termination of the Pennsylvania Canal. This work consists of 7 spans, of 160 feet each, from centre to centre of pier. The trunk is of wood, and 1140 feet long, 14 feet wide at bottom, 16½ feet on top, the sides 8½ feet deep. These, as well as the bottom, are composed of a *double* course of 2½ inch white-pine plank laid diagonally, the two courses crossing each other at right angles. The bottom of the trunk rests upon transverse beams, arranged in pairs, four feet apart; between these, the posts which support the sides of the trunk are let in with dovetailed tenons, secured by bolts. The outside posts which support the sidewalk and tow-path, incline outwards, and are connected with the beams in a similar manner. Each trunk post is held by two braces, 2½ × 10 inches, and connected with the outside posts by a double joint of 2½ × 10. The trunk-posts are 7 inches square on top, and 7 × 14 at the heel; the transverse beams are 27 feet long



and 16 × 6 inches; the space between two adjoining is 4 inches. It will be observed that all parts of the framing are double with the exception of the posts, so as to admit the suspension rods. Each pair of beams is supported on each side of the trunk by a double suspension rod of 1⅛th inch round iron, bent in the shape of a stirrup, and mounted on a small cast iron saddle, which rests on the cable. These saddles are connected on top of the cables, by links, which diminish in size from the pier towards the centre. The sides of the trunk set solid against the bodies of masonry, which are erected on each pier and abutment as bases for the pyramids which support the cables. These pyramids which are con-

structed of 3 blocks of a durable, coarse, hard grained sand-stone, rise 5 feet above the level of the sidewalk and towpath, and measure 3×5 feet on top, and $4 \times 6\frac{1}{2}$ feet at base. The ample width of the tow and foot path is therefore contracted on every pier; but this arrangement proves no inconvenience, and was necessary for the suspension of the cables next to the trunk.

The caps which cover the saddles and cables on the pyramids rise 3 feet above the inside or trunk railing, and would obstruct the free passage of the tow-line; but this is obviated by an iron rod which passes over the top of the cap and forms a gradual slope down to the railing on each side of the pyramid.

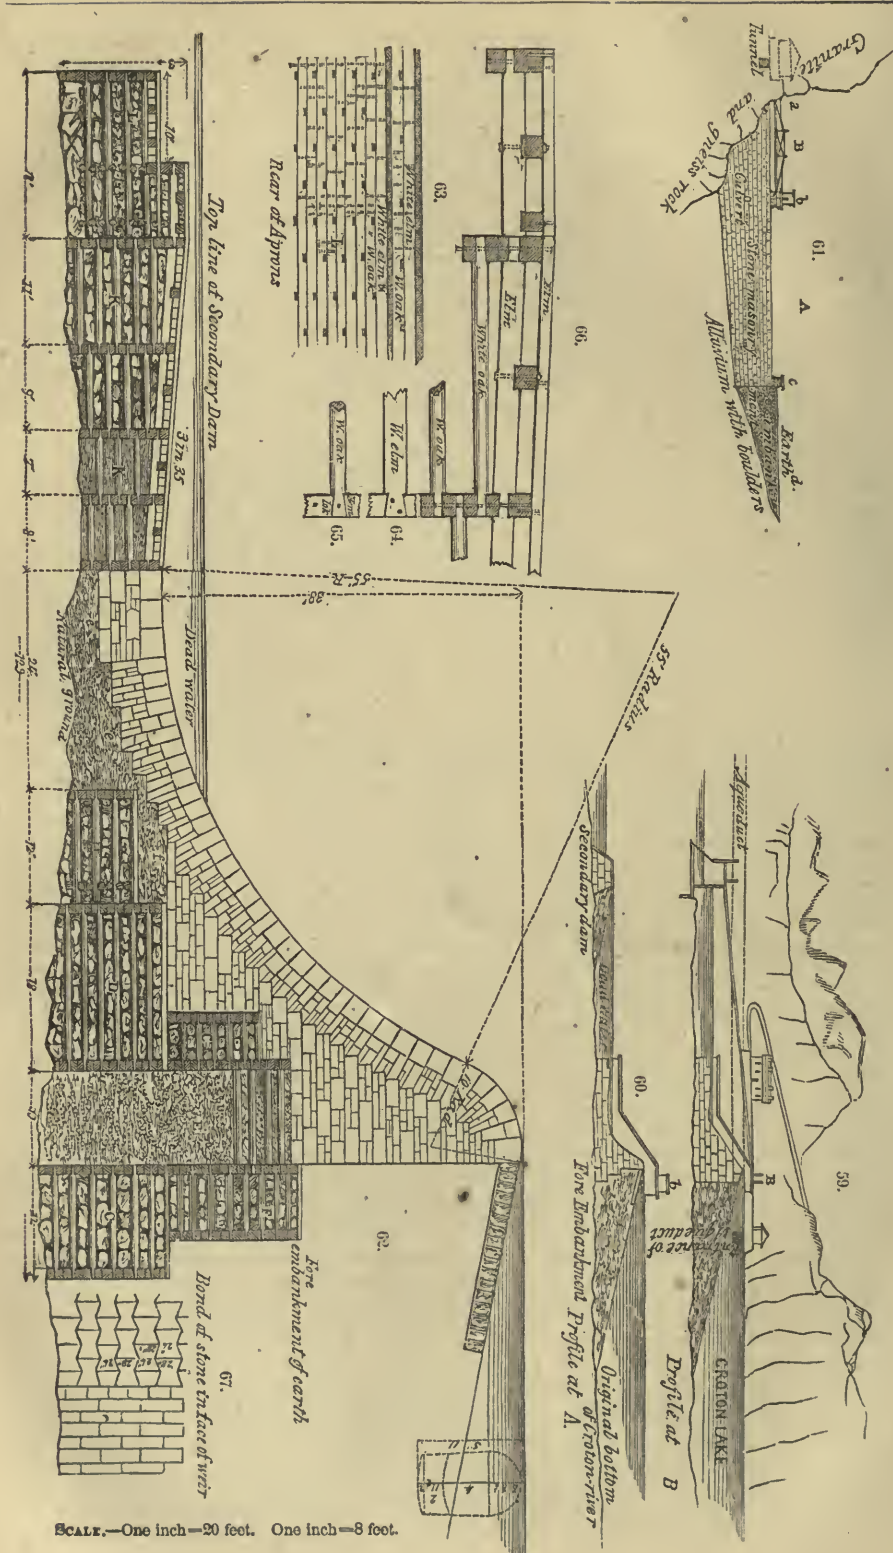
The wire cables, which are the main support of the structure, are suspended next to the trunk, one on each side; each of these two cables is exactly 7 inches in diameter, perfectly solid and compact, and constructed in one piece from shore to shore, 1175 feet long; it is composed of 1,900 wires of $\frac{1}{8}$th inch thickness, which are laid parallel to each other. Great care has been taken to insure an equal tension of the wires. Oxidation is guarded against by a varnish applied to each wire separately; their preservation, however, is insured for certain by a close, compact, and continuous wrapping, made of annealed wire, and laid on by machinery in the most perfect manner. The extremities of the cables do not extend *below* ground, but connect with anchor chains, which in a curved line, pass through large masses of masonry, the last links occupying a vertical position: the chains below ground are imbedded and completely surrounded by cement. Where the cables rest on the saddles, their size is increased at two points by introducing short wires, and thus forming swells, which fit into corresponding recesses of the casting. Between these swells the cable is forcibly pressed down by three sets of strong iron wedges, driven through openings which are cast in the side of the saddle.

AQUEDUCTS, for the water supply of cities. The Aqueduct of Spoleto, constructed in 741 by Theodoric, king of the Goths, to communicate with the town of Spoleto, is situated on the summit of a mountain. It is one of the handsomest structures of the kind, and remains entire to the present day. In crossing the river *De La Morgia*, the channel-way is supported upon two tiers of Gothic arches, the lower containing ten grand arches, and the latter thirty. The length of this arcade is 800 feet, the breadth 44, and the height 420. The Aqueduct of Caserta, built in 1753 by Charles III. of Naples, is also an expensive and gigantic structure; one of its arcades consisting of three tiers of arches, 1724 feet long, and 190 feet in height. In France, that which conducts the waters of St. Clements, and Du Boulidou to Montpelier, is perhaps the most beautiful. It was built under the superintendence of M. Pitot, and required thirteen years for its completion. The principal arcade is 90 feet high, and consists of two tiers—the lowest containing 90, and the upper 210 arches. That of Arcueil deserves next to be noticed. It was originally built by the Emperor Julian, A.D. 360, to bring water to Paris, and supplied the palace and hot-baths, but was destroyed by the Normans. After it had been in disuse for 800 years, it was rebuilt in 1634; again repaired in 1777; and fresh sums have lately been devoted to the same purpose by the city of Paris. The arcade over the valley of Arcueil consists of 25 arches, is 72 feet high, and 1,200 feet long. The Aqueduct of Lisbon, completed in 1738, is about three leagues in length, and in some part of its course has been excavated through hills; but near the city it is carried over a deep valley, for a length of 2,400 feet, by several bold arches, the largest of which has a height of 250 feet, and a span of 115 feet.

AQUEDUCT, CROTON, for the supply of the City of New York. The Croton River rises in Putnam County in three springs, whose rivulets unite near Owentown; its water is increased by the surplus of several lakes, which collect the water of the country by different small streams above and under ground. The route for the conduit canal commences near the village of Mechanicsville, runs along the left shore (looking downward) of the Croton, and the left shore of the Hudson River, and crosses Harlem River by High Bridge to the city. The execution of the work was intrusted to Mr. John B. Jervis, a practical and experienced engineer, who had been previously engaged in the execution of state canals.

The line of the aqueduct was portioned off into 4 divisions of 10 to 11 miles extent each, by Mr. Jervis the chief engineer. 1st division contained the dam, and stretched some distance below Sing-Sing, the 2d to Cook's run, the 3d to Fordham Church, and the 4th to the distributing reservoir. The whole amount of the work was given out in 99 Sections, one after the other, under contract.

THE CROTON DAM.—At the above-mentioned point, the dam was erected in order to raise the water, and to form the Croton lake. Fig. 61 shows the profile of the river. At first a length of only 90 feet was given for the dam B, and this part was erected after the profile of Fig. 59, with a construction similar to that of Fig. 62, extending then only from *a* to *b*, Fig. 61, occasion for which was given by the rock lying here affording a good foundation: the remainder of the river profile to *d*, was to be filled with an earth embankment. A considerable freshet, however, carried away this embankment when partly completed, and it was resolved to extend the stone dam 180 feet further, to *c*. For the erection of this part, A, Figs. 61 and 62, the bottom of the river was cleared from mud and boulders, and the piers C and D, of 12 inch hemlock timber, successively built up; the walls were connected together by ties, and filled with stone closely packed in; the top was covered with six-inch plank of white pine, and treenailed: upon this planking, the timber-piers F and G were erected, but only F covered with plank. While erecting those piers, the space E was filled with concrete, and the piers near the top connected with ties. Both these piers, together with their filling of concrete, being the armature of the dam, served at the same time for a coffer-dam against the water above. Against G, another timber pier was in like manner constructed, with but one timber wall; in place of the other, anchors of round timber were laid in, and with the ties joggled together. The timber of these piers is of hemlock, 12 inches by 12, the ties of white oak, 7 inches thick at the smaller end, framed with single dovetails 4 inches thick, Fig. 65, and fastened with one-inch treenails, which are placed 10 feet from centre to centre. The pier-timbers, Figs. 63 and 66, are treenailed 30 inches deep, with 2-inch treenails of white oak. These nails are sometimes put nearer together, and the ties likewise. The planking is of white pine. When the timber piers had reached a certain height, the piers K K, of four compartments, were put down, two of which, the nearest to low water, were packed out with stone; the two others were filled with concrete, and formed the coffer-dam against the water below the dam. The courses were of 12 by 12 inch hemlock; the ties of oak, 8



SCALE.—One inch=20 feet. One inch=8 feet.

inches at the smaller end, and 6 feet apart from centre to centre; the treenails of the squared timber the same. The uppermost of them are made of elm and white oak, treenailed every 3 feet, 30 inches deep, 2½ inches in diameter. The upper ties, Figs. 64 and 66, are of elm 12 inches square; to this course of ties a bed timber of white elm is joggled and secured by iron screw-bolts, Fig. 66. Across these bed timbers or caps, an apron-planking of 6-inch elm is fastened by 1½-inch locust (robinia pseudo acacia) treenails of 13 inches in length. Against the rear of this timber pier the one marked L was erected; against the back-water only, it has a regular timber wall, Fig. 63: the ties are secured by anchors. A part of the apron planking of this pier is laid horizontally in connection with the apron of the pier K; the remainder is put three feet lower, Fig. 62. After the pit had been laid dry by pumps, the ground and the space at *f* were filled in with concrete and levelled off. On this bed the body of the dam was by degrees erected of hydraulic stone-masonry, according to the bond, Fig. 67, and the courses of face-stone for the weir laid down. This face-work is of granite, cut with such closeness as to allow the stone to be laid with a joint not exceeding three-sixteenths of an inch. The masonry is laid in horizontal courses to 3 feet from the extrados of the face-work, where it is in courses corresponding with the radii. In front of the lip of dam below the head-water, a fore-embankment, Figs. 59, 60, and 62, was formed of earth, and its upper part secured with a dry stone-pavement 2 feet thick.

In the part of the dam first erected, B, Fig. 61, at *b*, and Fig. 60 at *b*, a waste-weir is constructed, in order to draw off the water of the lake from a greater depth; it consists of a well with culverts having two sets of gates, all of which are protected with a small stone-house, Figs. 60 and 61, at *b*; which can be reached by the bridge B, Figs. 59 and 61.

At a distance of 300 feet from the lip, a secondary dam, Figs. 59 and 60, is constructed; it is erected of round timber, filled up with dry stone. The object of this secondary dam is to divide the head of water, and by means of the water-basin formed by it, to break the body of water running over the weir, and to keep the wood-work of the timber-piers K and L, under water. Near the left shore a waste-weir is constructed in this dam, in order to let off the water from the basin when required.

By the construction of the Croton dam the water was raised 40 feet, whereby the river passed its shores and formed the Croton lake: this is the collecting-reservoir of the aqueduct, containing in it, at a depth of 6 feet, 500000000 gallons of disposable water, above the level that would allow the aqueduct to discharge 35000000 gallons per day;—sufficient for 1750000 inhabitants, at the rate of 20 gallons daily per head, including manufactories, shipping, watering streets, gardening, baths, &c. The flow of the Croton is about 27000000 gallons in 24 hours, at the lowest stages, which continues, with moderate rains, from two to three months in the year. Whenever the wants of the city may require the above-mentioned amount, it will be necessary to draw from those 500000000, daily, 8000000 to make up these 35000000. The amount of the reservoir would thus afford a supply for 62½ days. Never has the water in summer been so low. The supply of the Croton from its daily flow, aided by the reservoir, may therefore be taken, with great confidence, at 35000000 gallons; and when the day arrives that will require a larger quantity, it may be obtained by constructing other reservoirs further up the stream, where there are abundant facilities for such purposes.

Profile of the Aqueduct.—At the first consideration of the adopted plan, to conduct water from the Croton river, an open trapezoidal canal was proposed. The flow of the water over earth and rock might, however, impregnate the conduit-water therewith;—and as a good deal might sink into the bottom, it became necessary to make the bed waterproof; to do this with tight earth seemed insufficient, though brick with concrete under it might answer. The open canal remained, however, exposed to the sun and to evaporation, as well as to the wading of cattle, to bathing, and to being filled up with earth, boulders, and snow washed in; and might, in fine, freeze out in winter; it became necessary, therefore, to cover it, as had been found indispensable already, at deep-cuts, and in the vicinity of villages. A protection with a kind of wooden roof was some time under discussion, (seeming economical,) having the deep-cuts and tunnels arched. This mode of roofing, however, did not seem impenetrable to frost and heat; it was resolved, at last, to arch the whole, notwithstanding the great expense.

The artificial Croton lake stretches more than 5 miles on the line of the original bed of the river, which makes the total length of the whole work amount to 50 miles.

The regulation of all the measurements in heights and depths was taken from a grade-line or planum which is 7 inches below the intrados of the inverted arch at the bed of the aqueduct, being the base-line or basis-surface of the aqueduct-masonry, in cuttings into the natural ground.

Length, Inclination, and Grade.—The fall of the aqueduct on the continent is 0.021 per hundred, or 1.1088 feet per mile. The roofing-arch follows accurately this inclination, except a distance of 2276 feet next the dam, which runs horizontally at the height of the lip of the dam. At the entrance, 2.93 feet were added to the height, which brought this to 11 feet 5 inches in the clear, (Fig. 62.) From the lower intrados the inclination is 0.0113 per 100, or 0.59664 feet per mile, at a distance of 4.949 miles, where it meets the general inclination and the profile of the aqueduct, as shown in Figs. 68, 69, 70 This arrangement, which, in a certain way, can be considered as an extension of the lake, renders it possible to draw water from a depth of 11 feet 5 inches, and to carry it, under influence of its head, with less fall, over this distance. At the level of the lip of the Croton dam the aqueduct has still a capacity to draw off 35000000 gallons every 24 hours, as experiment has shown.

Table of Lengths and Inclinations.

	Distances in Miles.	Distances in Feet.	Fall in feet.
From the dam to the meeting of the general inclination...	4.9490	26130	2.9507

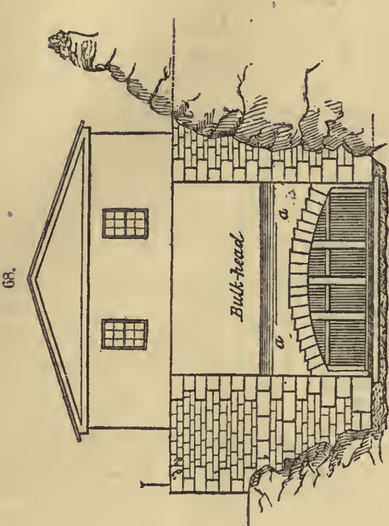
of the Croton lake and that of the distributing-reservoir	....	....	51.1702
When to this extension of the aqueduct that of the large mains is added, which is about..............................	4.0000		
we have the following as the entire length of aqueduct from its head to the distribution of the water, viz.:—	44.5620		

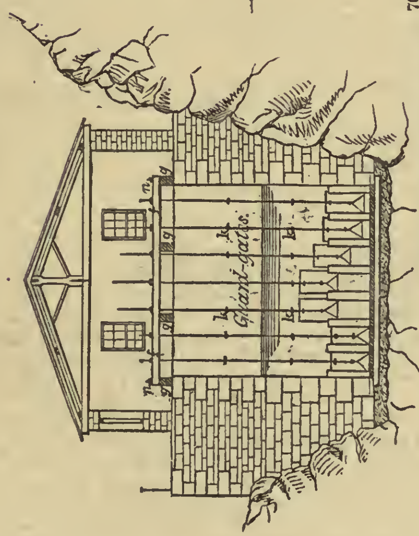
Construction of Aqueduct-canal.—Where the masonry of the aqueduct is cut in level ground or side-hills, a course of concrete 3 inches high is laid under the whole extent of masonry; under the extrados of the inverted arch, as high as the shape of the extrados required. Where water-veins were met, and in loose ground, or where the depressed ground made foundation walls necessary, the concrete bedding was put 12 inches high as broad as the clear width of the aqueduct; but under the side walls only 6 inches. In both cases each of the side walls was carried up 13 inches high perpendicularly, by which the spring-line of the inverted arch was reached; after this the inverted arch was turned ½ a brick 4 inches thick, the stone part of the side walls carried up 4 feet high, and on both sides plastered ⅜ inch thick with hydraulic mortar. When these walls had set, the inner facing, ½ a brick 4 inches thick, was carried up; at last the roofing-arch, 1 brick 8 inches thick; then the spandril-backing, over which and the upper part of the extrados, plaster of ⅜ inch thickness was laid on and smoothed off with the trowel. Where suitable stone was to be had near, the side walls could be carried up; also the roofing-arch, which in this case was turned 12 inches thick; this, however, has been carried into execution in but few instances. The courses of masonry were levelled off every 12 inches, and no stone put in which reached through the wall or raised over the course of 12 inches; granite, or gneiss of the most sound quality, was used.

The hydraulic mortar at tunnels, deep-cuts in earth and rock, had the proportions of 1 part cement to 3 sand; upon foundation-walls, however, 1 part cement to 2½ sand in volume; the same proportion for concrete. The sand for concrete, containing coarse and fine grains, was first mixed with water, then there was added to it from 2 to 2½ broken stone of the size of 1¼ inch, or the same amount of coarse gravel, and worked till the mass became uniform, and the broken stone completely covered and bedded in the mortar. Immediately after this preparation the concrete was laid and settled with a stamper till the surface had the appearance of an even floor: the courses were laid not over 6 inches thick. For brick masonry the proportion of cement to sand was 1 to 2; the mortar for vertical joints was put to the brick before laid, the brick forced into its bed in such a manner, that from horizontal and vertical joints the mortar readily is forced out like sausages; the superfluous mortar was then taken off and the joints smoothed immediately: only bricks of superior quality were admitted, No. 1 for the inverted arch and the facing, No. 2 for the roofing-arch.

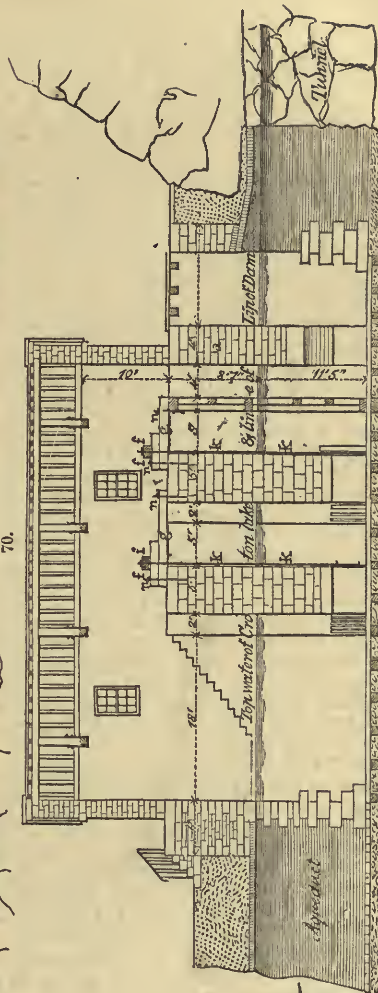
Culverts.—In order to carry off rivers, creeks, and field-waters, underneath the aqueduct, culverts were constructed at a suitable depth. Their fall or inclination was 1 in 20; and where the upper end happened to be below the surface of the ground, generally the case at side-hills, a well was constructed, Figs. 76 and 79. The culvert, Figs. 79, 80, and 81, is one of the smallest dimensions, with bottom and roof of stone slabs; that of Figs. 76, 77, and 78, is a large one, bottom and roofing are of smooth, well-wrought stone, the side-walls only faced with it, while the backing of this face-work is of rough masonry

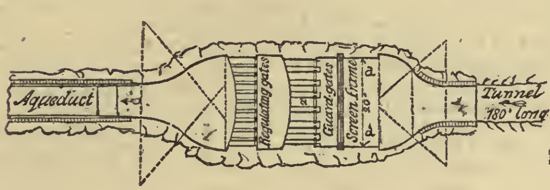
68.



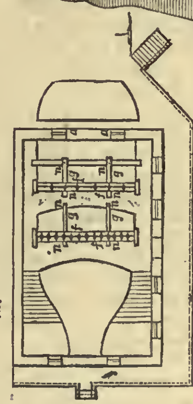


70.





72.



SCALE.—1 inch = 40 feet.

In the body of the foundation-wall of the aqueduct, an arch of dry stone without mortar was rolled over the extrados of culvert, Fig. 78; after this the foundation carried further up. The fall-well at the arched culverts is round in plan, Fig. 77.

The Gateway.—From the effluence of the lake, Figs. 59 and 61, a tunnel is cut through solid rock 180 feet in length. It has no facing of masonry, and in dimensions is kept somewhat larger than the general aqueduct, only below the gateway, Fig. 70, it takes the dimensions as marked, Fig. 62, except the height, which is here greater. The ground is uncommonly favorable for the construction of the gateway, offering rock-foundations throughout. As shown, Fig. 71, the channel of the aqueduct is widened, and the water runs through an arch in the bulkhead *a a*, then passes the screen-frame, a set of guard-gates, and a set of regulating gates. The screen, formed of oak slabs, six inches by one, allowed a quantity of fish to pass through the one-inch spaces into the aqueduct. In order to prevent this, a fine brass netting was put over the screen, through which only very small fish could pass; to prevent which other artificial preparations will be required. Below the wall with the regulating gates, the width of the water-way is reduced to the general width of the aqueduct, by an ogee curve, in order to let the water into the proper aqueduct without any loss of fall.

The guard-gates with their frames are of cast-iron, made as shown in Fig. 37; *a* is the frame lined with metal. The sill is marked here let in stone, but in the case under description it is cut something into the wooden floor; *b* is the shover with the consols *c c* through which the wrought-iron rod *d d* passes—the latter has a screw cut at its upper end; *e e* is a nut, which is let into the caps *f f* and screwed. By turning right or left with a key put on the die, the rod rises or lowers, and the gate is opened or shut. On account of the considerable length of the rod, the guides *k k*, Figs. 69 and 70, are put on; they consist of cases of wrought-iron, leaded into the stone of the wall. The regulating gates with their frames are of gun metal, in order to obtain a superior tightness. The caps *f f*, Fig. 70, are secured upon the saddles *g g* by bolts. In turning to the left the female, whereby the shover is raised, the saddles with the caps press upon the base and are kept closer and closer upon their bed; in screwing right, however, they press upward. To prevent their loosening and lifting, the screw-bolts *n n n* are put in; they reach down through two courses of stone, and there they are bent; some of them are secured to the caps of the screen-frame. In shutting the gates by turning to the right, the bolts *n n* secure the caps *f f* to their places and prevent their lifting. The masonry in all parts of the gateway is of rough gneiss in hydraulic mortar, faced with well-hammered stone: the partitions between the gates are of cut stone. To keep the gates and utensils secure, a stone house is erected over the gateway.

Line of Aqueduct.—Having left the gateway, the aqueduct makes its way upon the left bank of the Croton river. After a course of one mile, it crosses Lounsberry's brook, over a culvert of 6 feet in width, 66 feet in length, the bottom of which lies 44 feet below the top of the back-filling of aqueduct. After crossing some little brooks with small culverts, the line leaves this river, having followed it for 5 miles, turns to the left and crosses the valley of India creek 6 miles from the dam; the culvert for the passage of this stream is 8 feet wide, 142 feet long, and its bottom is 58 feet below the top. A little distance further, the aqueduct is tunnelled through two hills of solid rock. The first passage, called Benvenue farm tunnel, is 720 feet in length; the second, Acker's brook tunnel, is 116 feet long. Half a mile further is another tunnel of 276 feet in length, called Hoag's hill tunnel, cut through rock. From here to Sing-Sing, several small valleys and ravines of from 20 to 32 feet in depth are crossed by the aqueduct. Immediately after the last one, there is another tunnel worked through rock, called Sing-Sing tunnel.

Sing-Sing Kill Bridge—was commonly called, while in construction, the passage of the aqueduct across the valley of the Kill river. Although the Kill is merely an unimportant brook, by frequent freshets it has worn out a large chasm, the depth of which from the top of the aqueduct to the rock bottom is 82 feet; the width measured at the top is 536 feet. Parallel to the river runs a street of the village of Sing-Sing, over which an aqueduct bridge of 20 feet in width was constructed; a little further the line of the aqueduct cut off the dwelling-house from the rest of the farm of Mr. Sing, where a passage-way 7 feet wide was constructed. Across the stream an arch of 88 feet span was required. The abutment walls of this bridge are 20 feet thick, on solid rock-foundation. The arch is constructed over an half oval, 33 feet in height, 4 feet thick at the spring-line, and 3 feet at the keystone; the granite and gneiss for it was cut with much accuracy, not allowing the joints to be over three-sixteenths of an inch thick. The spandrils were carried up solid, sloping upward, thence with hance walls and alternating openings, till 3 inches over the highest point of extrados: these openings were arched over with half a brick. Across those openings, the hance walls were connected together by bond stone. On the top of the small brick arches, a rubble masonry of 6 inches in height was laid, and the whole levelled off; on this the concrete course of 9 inches height to the extrados of the inverted arch of aqueduct. As far as the clear width of the bridge arch and its abutments extended, the construction of the aqueduct was so altered, that the side-walls were carried up 5 feet high instead of 4, as in ordinary aqueduct, and the arch was turned over a segment of 7 feet 7 inches long, 2 feet 8½ inches high. Bottom and side walls were provided with a lining of cast-iron in form and dimensions, worked in with the masonry; whereby the aqueduct was rendered absolutely water-tight above these constructions. The same iron lining was applied also at the before-mentioned street bridge. Between the attic wall and the side wall of the aqueduct, spaces were left, covered over, above the attic wall, carried up in connection with the side walls of the aqueduct, and covered with a coping stone, the whole then filled over with earth. The spaces serve not only for protection against frost from without, but also for carrying off the water falling from the sky on the back-filling, down into the hollows. Upon the extrados of the bridge-arch, the drainage water runs over the tangental surface of the spandril-backing into the dry foundation wall. The surface over which the water drains is well plastered with hydraulic mortar. The exterior masonry of both the bridges is of well-hammered stone. Throughout the structure hydraulic mortar was used. For the distance of aqueduct between the bridges and back of them to the side-hills, the rock bottom was prepared with steps, and a foundation wall of dry stone-masonry carried up The exterior faces of some thickness into the wall were laid in hydraulic mortar, and the joints pointed with the trowel.

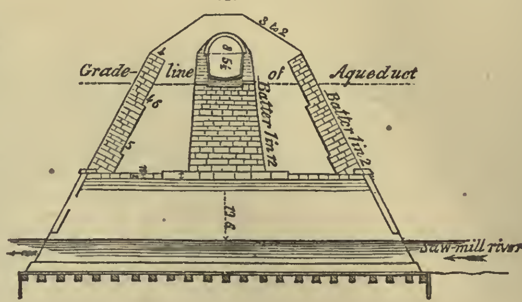
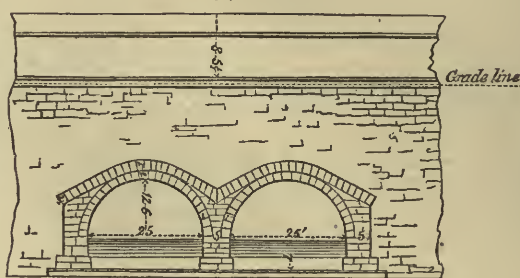
SCALE.—1 inch = 40 feet.

Continuation of the line of Aqueduct.—Below some streets running across Sing-Sing, the aqueduct proceeds further on for a mile, on quite favorable ground, and when on the land of the State prison farm, it enters into the great State prison farm tunnel, made 416 feet long, partly in rock, partly in earth. At some distance further, it is met by the small State prison farm tunnel, 375 feet, in earth: 9½ miles from the dam, after having passed Hale's brook tunnel of 260 feet in length, the aqueduct crosses the valley of Hale's brook; its culvert is 6 feet in width, 131 feet long, and 49 feet below the top of the back-filling of the aqueduct. One mile further, the line crosses Rider's brook, over a culvert 100 feet long, 6 feet wide, and 34 feet under the top of the aqueduct: 10 miles from the dam, the aqueduct crosses over the highway leading from Sing-Sing to Tarrytown by a bridge of 20 feet span. Proceeding further on, the aqueduct encounters some high land, through which a tunnel of 186 feet is driven; it is 11½ miles from the dam, designated Austin farm tunnel. From here the ground has various depressions of from 20 to 30 feet under the top of the aqueduct.

73.



74.



75.

At Mill river, 13 miles from the dam, the crossing-work is imposing. The depression of the valley is 87 feet below the top; the culvert or aqueduct bridge is 25 feet in width and 172 feet in length. In the extension of the next two miles, in the vicinity of Tarrytown, at five valleys in succession, small culverts of various dimensions are constructed; then the aqueduct passes a tunnel of 246 feet in length, mostly through rock, called White Plains tunnel; then Requa's brook is crossed, over a culvert of 25 feet below the top; and after this the classical ground of Washington Irving's farm and Irving's run, the latter with a small culvert.

The next structure is at Jewell's brook, and its ravine, 17½ miles from the dam; the culvert is 6 feet wide, 148 feet long, 62 feet below the top. A farm-road which could not be removed, was made to run under the aqueduct at a heavy expense; its arch is 14 feet in width, 141 feet long. Across Wilsey's brook, 18½ miles from the dam, the culvert is 49 feet below the top, 6 feet wide, and 137 feet long. Half a mile further there is a tunnel near Dobbs' Ferry, 262 feet, driven through earth, and designated Dobbs' Ferry Tunnel. Crossing Storms' brook, the depth of culvert is 40 feet, the clear width 6 feet, and the length 137.

From here the aqueduct passes several small valleys of from 10 to 15 feet in depth. At Cook's run the culvert is 4 feet wide, 132 feet long, and its bottom is 42 feet below top of aqueduct. Dyckman's brook, 22 miles from the dam, has a culvert of 8 feet in width, 120 feet in length, and is 35 feet below the top of back-filling. Then the line crosses various unimportant valleys and creeks, with small culverts, and arrives in the vicinity of the village of Yonkers, where, on account of the greater inland extension of low ground, an abrupt curve to the left was required, followed at a short distance by another to the right. The aqueduct passes through the Sawmill river tunnel, which is 684 feet, driven partly through earth, partly through rock; then it crosses the river itself, over which a bridge of two arches of 25 feet each has been erected. Fig. 73 is the cross-section of aqueduct at this point, with the longitudinal section of bridge; Fig. 74 the cross-section of bridge with the longitudinal section of aqueduct; and the last, Fig. 75, is the horizontal projection of one of the flanks; close to it is the passage for the turnpike-road, 20 feet in width, arched over a semicircle. The next work is a culvert over Nodine's run; after which a hill of considerable height is encountered, behind which the valley of Tibbit's brook comes in the way. The tunnel under this hill is 810 feet long, driven through solid rock, and called Tibbit's brook tunnel. The culvert for the brook is 6 feet wide, 107 feet long, and its bed is 40 feet below the top of the aqueduct: it is 26 miles from the dam. At some distance several small brooks are crossed: one is O'Brien's run; the largest is Acker's brook, which passes 37 feet below the top of the aqueduct. The last two miles of the line are very nearly straight, the high land offering so favorable ground, that the upper filling of the aqueduct just disappears under the surface. Here the aqueduct arrives at the strait which separates Manhattan Island from the continent.

Harlem River Bridge.—The valley of Harlem river slopes down from the before-mentioned high land, at a point which is 33 miles distant from the Croton dam, first at 20 degrees, to a piece of table-land 25 feet above tide-water, stretching over a distance of 300 feet, whence, by a second slope, it

reaches the water's edge. The tide-water has here a width of 620 feet. The bank of the island being of solid gneiss-rock, rises with a slope of 35 degrees to the height of the top of the aqueduct. The slope of this rock below water, as far as it could be examined, is steeper, and disappears under a deposite of mud mixed with sand and boulders. It is supposed this rock has connection with that of the opposite shore. In the basin formed by its depression below the strait is deposited a mass of white marble, Fig. 100, upon which the gneiss and alluvium of sand, mixed with pieces of rock and boulders, are found, upon which mud is deposited, consisting chiefly of vegetable matter.

At first it was intended to carry the conduit-water over the valley in a siphon, through iron pipes,—on the side of the continent, following the surface of the ground to the water's edge, across the water of the river upon a stone embankment, from the centre of the river, ascending to that point of the island where the aqueduct starts again. Through the body of that part of the embankment, next the island bank which is sloping up, an arch of 120 feet in width, 60 feet high, was intended, through which a passage was to be kept open for navigation with sloops and schooners of 200 tons burden. The execution of this work was already contracted for, the dredging-machine in operation, when the landholders of both the banks of the river started a lawsuit against the measure; and an act from the legislature of the State was obtained, according to which, the aqueduct was to be carried below the bottom of the sea, or above its surface at such a height, that openings of 100 feet above high-water, 80 feet in width, had to be left in order to carry on the navigation. Notwithstanding estimates and comparisons of the two methods showed a surplus in cost of 200,000 dollars for the latter, its erection was preferred.

This bridge has 15 arches, 8 of which are 80 feet in width each, by 100 feet in height above flood-tide, placed in the water, and upon both the shores 7 arches of 50 feet span each; the two abutments were founded on the gneiss rock, three upon the marble, seven on piles, the rock being without reach below the latter. With this arrangement, the conduit-water was carried across to the island in a siphon of 12 feet depression.

The manner intended of carrying the water below the bottom of the sea should here be mentioned. Following the slopes of the banks and the valley, 4 pipes of 3 feet diameter each, were to be laid 4 feet under the surface of the ground, below the bottom of the Strait; 2 tunnels, parallel to each other, 12 feet wide, 8 feet high each, 12 inches thick at bottom arch, put upon concrete, side walls and centre wall 4 feet thick each, roofing arches 16 inches thick; the extrados of both these arches covered with a course of concrete of 2 feet thickness, and the whole structure, top and sides, covered again with a stone pavement 12 inches thick, set in hydraulic mortar; the stone pavement was kept 24 feet below low-water. Each of the tunnels contained 2 pipes; the tunnels were provided with entrances, in order to examine them. It was intended to carry out the work by means of a coffer-dam on each side. The estimated cost was 636738 dollars.

In order to reach the foundation of every pier for the high bridge, a coffer-dam was put down, the coffer or box made for each of the piers of such a height as the depth of water at its site required, together with the thickness of the mud-deposite, and 3 feet border above high-water.

In order to take the water out of the aqueduct, and let it into the pipes, and after passing over the bridge, re-discharge the same into the aqueduct, 2 gate-chambers, *a* and *b*, Fig. 100, are placed. Fig. 113 shows the ground-plan, Fig. 112 the longitudinal section, and Fig. 111 the cross-section of the influence gate-chamber, (entrance into the siphon;) *c c* is a basin, the bottom of which is level with the deepest line of the intrados of the inverted arch; *d d* are the gateways, *e e* the two pipes; the influx of the water can be regulated by the two cast-iron double gates *k k; f g h* is a waste-weir, whereby the waste water or the whole content of the aqueduct may be let off; *f* is the gateway, *g* the waste-weir well, *h* the sewer. The construction of the latter for the first 30 feet in length, is shown by Fig. 115; following the slope downward, it is funnelled into the shape and construction of Fig. 114, which leads to Harlem river. Fig. 111 is the section of gateway for the waste-weir; Fig. 112 the elevation of front with the gates *l l*. All the gates are of shape and construction as shown at Fig. 69. The rod-caps of waste-weir are connected by the bolts *m n*, Fig. 111, with the consols *n*; but the rod-caps of the gateways by the bolts *m n*, which are kept down and secured in the pier below, by the crosspiece *n*. Over the entire structure, a stone building is erected, arched with bricks, and covered with 3-inch greywacke slabs. The effluent-gate *b*, Fig. 111, at the island extremity of the bridge, is of the same arrangement in reversed order, but without waste-weir; it receives the water from the pipes of the siphon, and discharges it again into the aqueduct.

Several times the question has been asked, why this bridge, being in a certain way considered a construction of luxury, has not been carried up to the full height, reaching the water-line of aqueduct, with the construction of the latter as upon the Sing-Sing Kill bridge? The pipes could have been spared; the erection of the gate-chambers rendered needless; and what is most important, 2 feet of height had been saved, 117 feet head being left in the city, instead of 115. The reply may be:—a greater height of the structure would have required a larger and more compact model for the piers, or a more careful choice of material, and a more costly workmanship of the same; also a greater height for the attic walls upon the bridge arches; and in fine, the construction of the aqueduct itself with iron lining. All this, without doubt, would have accumulated the cost by 75000 dollars, a sum of some moment in the cost of the water-work. Considered as a monument, the bridge, as above constructed, has a sufficient height.

The beginning of the construction of this bridge had been greatly delayed. It was desirable to use the aqueduct sooner than the bridge possibly could be finished. Down the descent of the valley, then upon the embankments enclosing the coffer-dams—which by degrees had formed an unbroken embankment across the salt-water strait—then up the island-shore to the aqueduct, a 36-inch pipe was put down, through which the conduit-water provisionally was led across the valley, and the aqueduct opened on the 4th of July, 1842. The construction of the bridge went on but slowly.

Continuation of the Line of Aqueduct.—A short distance from the effluence-gate the aqueduct passes over a ravine of 30 feet in depth, immediately after which a tunnel had to be driven 234 feet through solid rock. This lies about 33½ miles from the dam, on the land of the deceased Monsieur Etienne Jumell, on that account called Jumell tunnel. Close by this tunnel is a ravine of 38 feet in

depth, and another 43 feet deep. Proceeding further 34¼ miles from the dam, the aqueduct enters into the line of 10th Avenue. Without any obstacles of consequence, it proceeds hence to the vicinity of Manhattanville, and 35 miles from the dam passes through Manhattan-hill tunnel, the longest of the whole line—worked 1215 feet through rock.

Manhattan Valley.—Having left the tunnel, the ground slopes down to a depth of 105 feet, and rises up again to grade-line; measured here, the length amounts to 4180 feet. For conducting the water across this valley, first an aqueduct of arcades was proposed, with arches of brick supported by piers of rough stone-masonry, and the aqueduct upon these in its common shape. This method of crossing would have preserved 3 feet of head-pressure for the conduit-water, but at an expense of $1200000, while the passage in pipes cost only the fifth of that sum; this was a matter of some moment, and it was concluded, therefore, to make use of 4 pipes of 36 inches each. At the end of the last-mentioned tunnel an influent-gate, similar to that of Fig. 112, was erected, only of a greater width of basin—4 pipes being required; otherwise of the same arrangement, leaving out the waste-weir. At the brow of the opposite height, called Asylum-hill, is the effluent-gate, of the same construction entirely with the influent-gate; it receives the conduit-water from the pipes, and lets it into the aqueduct again. Between

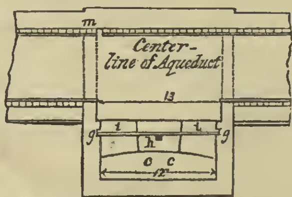
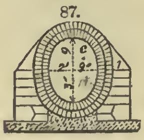
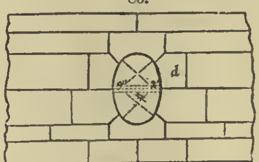
84.



87.



86.



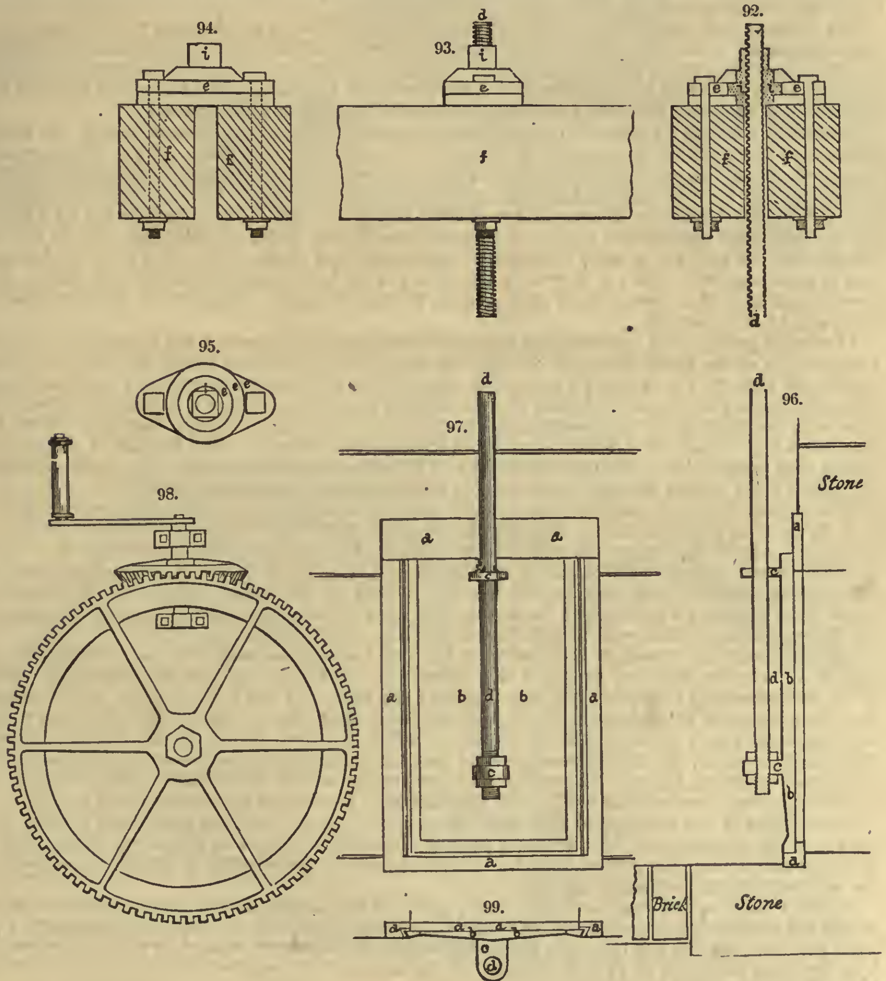
those two gates the siphon is placed, the pipes of which are partly laid in the ground; and where depressions of the ground occur, upon an embankment of earth, throughout covered with earth 4 feet high

In order to empty the pipes of the siphon when required, in cases of repair or removing deposites of sand at the deepest depression of the valley, here, just in Manhattan-street, provisions were made for a waste weir for that purpose at each pipe; waste-pipes were put in; those pipes pass through the stop-cock vault and discharge into the waste-weir well. When one of the pipes is to be emptied, both of its upper ends are closed first by the respective gates in the gate-houses, then the stop-cock in the stop-cock vault drawn open; the content of the pipe makes now its way through a pipe into a sewer, which about 2000 feet from here discharges into the Hudson river.

Continuation of the Aqueduct-line.—The declivity of the aqueduct being from here only 9 inches per mile, the water rises back as far as this from the receiving reservoir, which is merely 2.1727 miles off. To the thickness of the side-walls of the aqueduct, by degrees, 4 inches have been added, making in all, 3 feet below, and 2 feet 4 inches at the spring-line; in the same way the walls were carried higher up to 1½ feet above the spring-line of the roofing-arch. A short distance from the effluent-gate the line goes through its last tunnel, called Asylum-hill tunnel; this has a length of 640 feet, mostly broken through rock. Further on, for the greatest part of a mile, it was necessary to construct

the aqueduct thus, that its sides and back-filling reached the height of 30 feet; at the end of this, for a little distance, the ground rises again to such a height that the upper-filling of the aqueduct just disappears below it, then another valley comes in the way.

Clendenning Valley is the name given to the depression of ground which stretches across the highlands of the island. The most favorable passage for the aqueduct is offered by a line drawn 150 feet west from the axis of 9th Avenue, to which the aqueduct-line, coming from the 10th Avenue, is connected by an ogee-curve. The valley here has a length, or rather width, of 2000 feet, measured from the commencement of the upper-filling of the aqueduct, at the brow of the hill, to its disappearance on the opposite side; its greatest depth is 50 feet below the upper-filling. Looking on the map, it shows that this part of the island is laid out in streets and blocks. At this place it was designed that the streets, after being cut through and opened, should cross over the aqueduct; but, under such a considerable depression of ground as this, it was not practicable; and it was concluded to pass 6 of



these streets, viz., the 101st, 100th, 99th, 98th, 97th, and 96th, underneath. The first 5 of these streets are 60 feet wide; but 96th, being a principal street, is 100. For their passage aqueduct-bridges were applied, of 3 arches each for the first 5; a main arch 30 feet in width in the centre for the road-way; and two side arches, for the sidewalks, of 9 feet span each, over 101st and 97th streets; but of 10½ at the bridges over 100th, 99th, and 98th streets. During the construction of those bridges it was thought, by the new Water Commissioners, only some of those bridges might be required for passage for the space of 50 or even 100 years, in consequence of which the passages for 101st, 97th, and 96th streets were beforehand left out; the bridges for 100th, 99th, and 98th streets will then be spoken of here.

The dimensions of the different parts of these bridges are the same among all, with exception of the height of the pier-shafts only, which is determined by the various levels of pavement in the streets, but making only a difference of some inches. The foundation of all the piers is placed partly on rock, and partly on alluvial ground; the piers themselves, as well as the arches, being constructed of gneiss rock; the former of well-hammered stone, the latter of cut-stone. The spandrels of the arches are car-

ried up solid to the line tangental to the extrados. From here hance-walls are carried up alternating with openings, the latter being covered over with stone slabs, at a height of 3 inches over the extrados: here the whole is levelled off by a rubble-masonry of stone 6 inches thick. Upon this level a course of concrete 9 inches thick is bedded, on which the aqueduct with its iron lining is erected; on the outsides of the side-walls of aqueduct, spaces of 6 inches in width are left, in order to separate the masonry of the aqueduct from the attic-walls, and to carry the water, draining through the earth-filling, over the extrados and the spandrel-backing. The spaces of aqueduct between the various streets, and beyond them to the extremities of the valley, are supported by a dry stone-wall; stone of large size, to the thickness of 2 feet, were laid upon their broadest beds over the whole course, the interstices filled in with smaller ones, and all levelled off with smaller and smaller broken stone to the height of 2 feet, on which the following course was laid in the same manner; on a width of one foot back from the outside, this masonry was laid in hydraulic-mortar, and the joints pointed. This part of the aqueduct has a very substantial appearance.

The Aqueduct line continued.—Over a distance of seven-eighths of a mile, upon which a curve of 90 degrees is turned to the left, in three various radii, the aqueduct of masonry discharges into the receiving reservoir; upon that curve the ground has a depression of about 40 feet, and the over-filling of the aqueduct is supported by protection-walls. Here then is the termination of the aqueduct as far as it is constructed of masonry; and only some appurtenances still remain to be mentioned.

In order to keep the air which is confined in the closed aqueduct, in communication with the atmosphere, ventilators, Fig. 90, are erected at distances of every mile; buttresses *a a*, Fig. 91, are carried up on each side of the aqueduct, between which the roofing-arch is carried round 12 inches thick instead of 8 inches. In the centre of the arch thus fortified, a circular opening is left bordered with bricks or stone; upon this border the chimney-like ventilator, Fig. 90, is erected, secured at the top by a lattice. The third of those ventilators is always of larger dimensions and provided with a door to pass into the interior, Figs. 89 and 88, in order to facilitate examination and repair of the inner parts of the aqueduct in cases required. The one shown by Fig. 90 is put up before crossing Clendenning valley. The greater number of them are made of white marble, the rest of gneiss. There are of the latter kind 11 in all, and 22 of the former.

At suitable points of the aqueduct line waste-weirs are put in to draw out the water when required. There are six on the whole line, with exception of that in the gate-house before Harlem river bridge. A gateway, Figs. 82, 83, 84, and 85, is formed according to the marked dimensions; the waste-water passes through a pair of gates, *b b*, falls into the well *c c*, and discharges over *d* into the sewer *e e*. The gates with the gateway are constructed entirely as shown in Fig. 97, and already described. When the water rises higher than 5 feet 9 inches, measured from the deepest point of the intrados of the inverted arch, it runs over the lip of the breast-wall *f f*, and falls likewise into the well *c*. By means of timber or planks *i i*, put against the post *h*, and slipping in the rabbits *g g*, provision is made to keep the water in the aqueduct higher at pleasure, consequently over the mentioned 5 feet 9 inches. In the platform at *k*, an opening, provided with a trap-door, is left, through which the planks *i i* can be put in and taken out. Above all, a stone house has been erected. From without, the platform can be reached by the door and over a small stair. At *m*, Figs. 84 and 85, a rabbit is cut in the side-walls of the aqueduct, into which timber may be slid in order to shut off the same. Those waste-weirs at their places serve likewise for ventilators; the one just described is put at 142d street: those on the continent are of the same description, with unimportant differences adapted to locality.

The Receiving-Reservoir, is built between 7th and 6th avenues, and 86th and 79th streets; its area is 37.05 acres, including the top of the embankment, or 31 acres of surface of water. By means of an embankment it is divided into two divisions; the north one has a depth of 24 feet, measured down from the top of the embankment, and is filled with 20 feet of water; the southern division is 29 feet deep below the top of the embankment, 25 feet of which is water. Those depths, however, are not throughout the same; the rock-bottom near the southern embankment lies lower than this—near the northern embankment, higher. The contents of water amount to 150000000 gallons. Each division can be used as a single reservoir for itself, while the other may be emptied for inspection and repair.

At the influx of the aqueduct at 85th street, west side of the reservoir, the street-level is equal with the top of the embankment. All the other parts of embankment had to be carried up more or less in order to reach the top, the ground being lower; and at efflux of the reservoir in 80th street, east side of the reservoir, it is 38 feet below the top.

All the embankments are of earth, the interior puddled with clayish earth or loam. The sides on the streets and avenues are protected by dry walls of stone, their outside being laid in lime-mortar and the joints pointed, Figs. 127 and 128. The inside slopes of the embankments washed by water, are protected by a dry stone pavement of 15 inches thick. At the bottom of the reservoir the bare rock or earth is left without any artificial contrivance.

In order to keep the surface of both the divisions at a level, a connecting or communicating-pipe, Fig. 125, has been placed, of which Fig. 123 is the section; the pipe is bedded upon rock, surrounded and supported by concrete: halfway a stop-cock is put for shutting and opening the pipe; over this cock a circular well is erected, and carried up to the top of the embankment. Upon the top of the well two caps are placed, on which a nut is screwed, like that at Fig. 94, *i*; by means of which, in connection with the screw-bar, the stop-cock can be drawn and shut.

When the water has reached its height in the reservoir—viz. 4 feet below the top of embankment—and the rising still continues, the surplus water falls by itself into the waste-weir well. Through the same way 3 feet more water can be drawn off from the surface when required, by taking out the timbers. Over the top of this waste-weir well, a bridge with a brick arch is erected, for the passage on the top of the division-embankment.

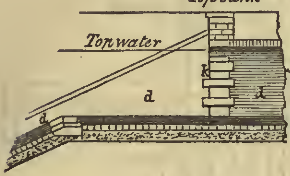
The influent-gate, Figs. 120 and 121, receives the water from the aqueduct *a*, by the gate-chamber *b*, and lets it either directly by the gateways *e e e* over the sluice-channel *c c* into the northern division, or by

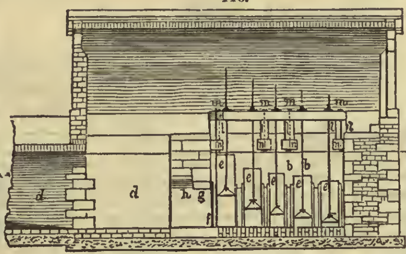
the gateways *f f f* through that part *d d* of the aqueduct which is built in the body of the western embankment leading into the southern division. The various apertures of the gateways of the two entrances are separated from each other by means of jambs of cut-stone 9 inches thick, covered over at the front, in the gate-chamber, with stone lintels, Figs. 116 and 119, at *g g*; in the rear at *h h*, however, the passages are arched over with half a brick, Fig. 119. The gates, with their frames, are made as shown at Fig. 97; the gate-caps rest partly in the walls and partly upon the posts *l l*. In order to prevent their rising, in screwing the gates, consols *n n* are projected, to which the gate-caps are secured by the bolts *n m*. By those two sets of gates, the water-influx to the divisions of the reservoir can be regulated completely.

Over the whole a stone building arched with brick has been erected, and covered with flags of grey wacke.

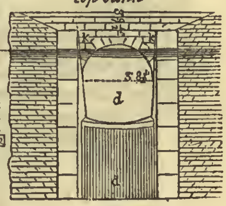
116.

117.

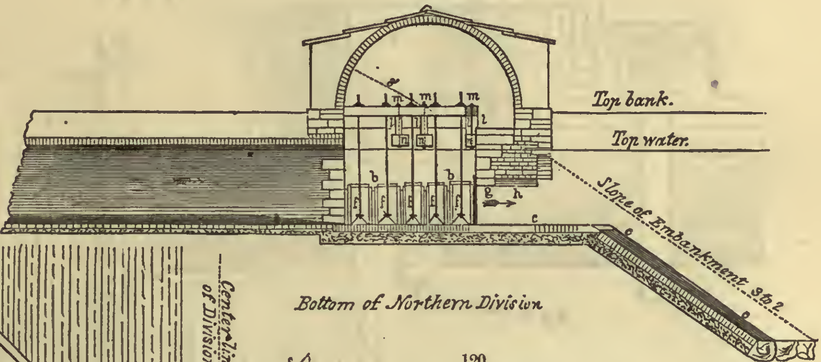




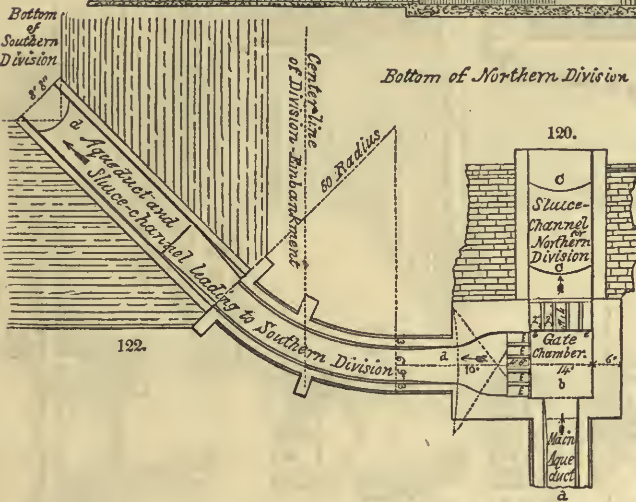
118.



119.

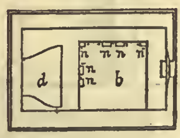


120.



122.

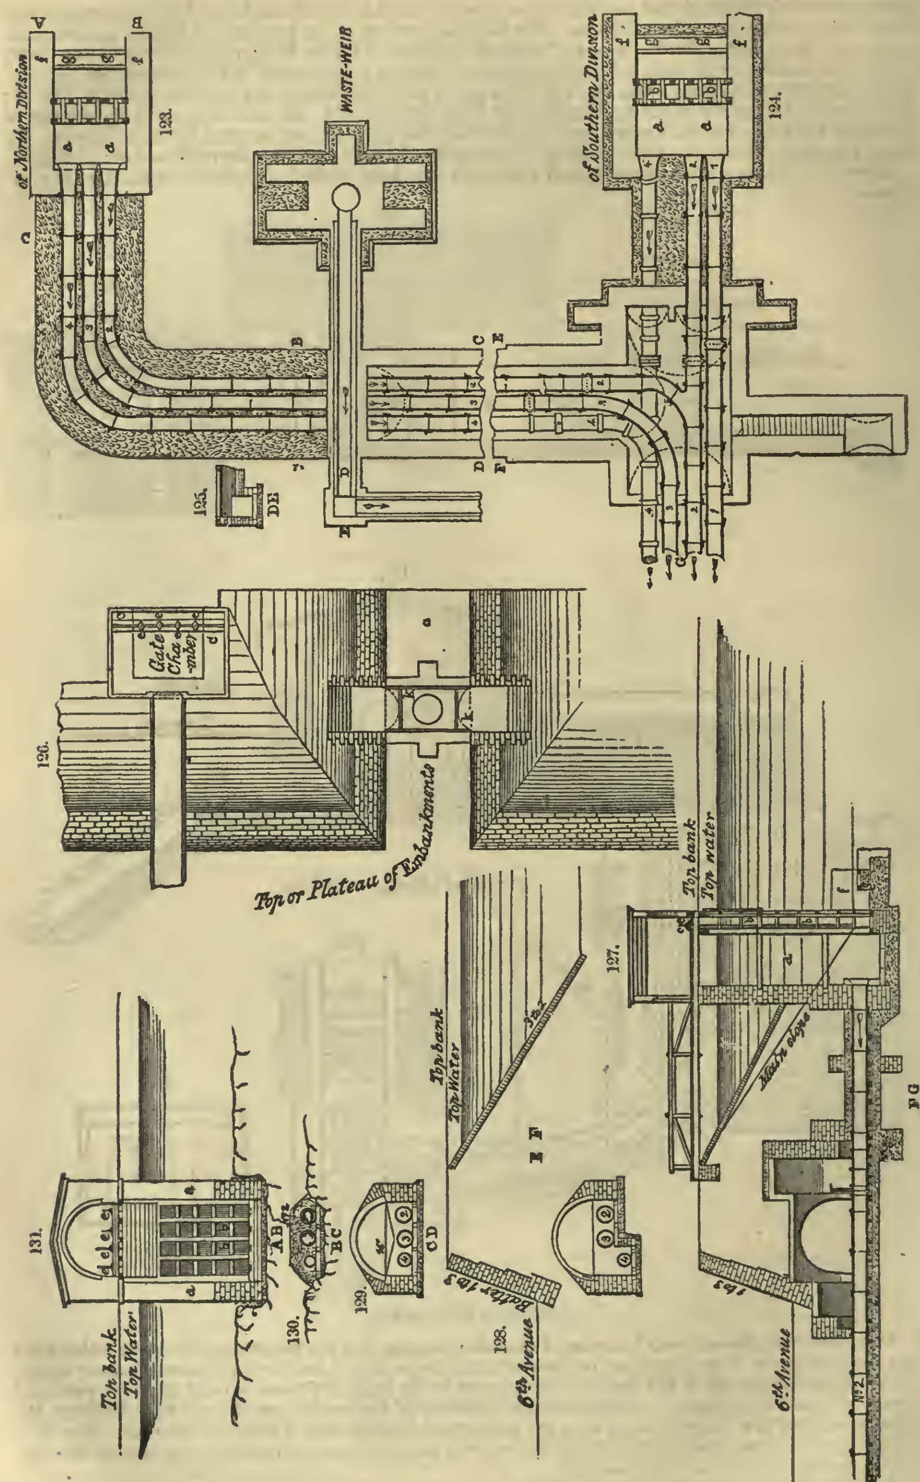
121.



Scale.—1 inch = 40 feet.

The efflux from the reservoir is arranged in such a manner, that the water may be drawn either from the one division or from the other, or from both at once, each division having its own separate outlet. Three pipes, coming out of the northern division, run in the body of the eastern embankment, protected by a vault built in the same. At the southern extremity of the vault, upon the axis of 80th street, the pipes are united to 3 others, leading from the southern division, making 4 after the junction. Nos. 1, 2, and 3, carry the water to the distributing reservoir for the lower part of the city; No. 4 is for the supply of the east side of the upper town.

The arrangement of efflux is thus. *a a a*, Figs. 123, 124, 126, 127, and 131, is a tower, erected with substantial stone walls; in the open side, fronting the reservoir, is put the gate-framing with the screen *b b*,



SCALE.—' inch — 40 feet.

the same consists of two frames, of 1.2-inch white pine timber; the outer is filled with 1-inch oak slats 6 inches wide, put 1 inch apart, Fig. 131; the upper part is covered with plank; the inner, or 2d frame, is left open as far as the just-mentioned planking reaches. Below this the gate-apertures are left—4 of such are in the tower, Figs. 123 and 127; at the tower, Fig. 124, they are of 2-inch pine plank, connected by pieces of plank nailed across and slid in wooden grooves; some of them are opened by sliding down, some by sliding up. Opening and shutting is effected by iron rods reaching up to the gate-caps *c c c*, Figs. 126, 127, and 131. On the top of each rod a screw is cut, which goes into the nut put upon the gate-caps; the nut and screw are shown by Fig. 93, at *d e* and *i*. Above this gate and screen-frame the tower is carried higher up and roofed over. Fig. 131 is the elevation of the tower-pavilion; Fig. 127, its section, and longitudinal section of bridge connecting the tower with the embankment. In the interior of the tower, Fig. 127, some timbers are put for support of the gate and screen-framing when the gates are

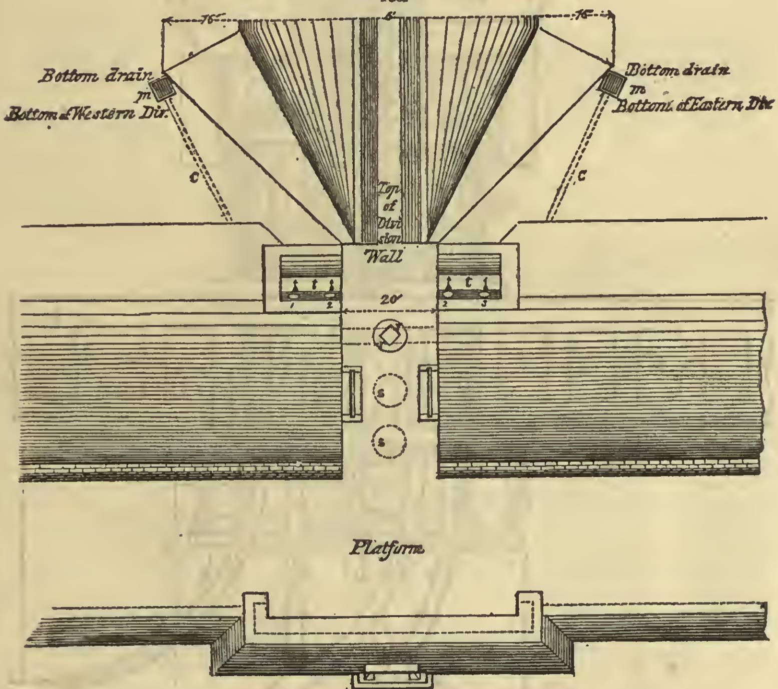
133.



42.d Street.

SCALE.—1 inch = 40 feet.

exceed. At the figure named, *f* shows the wing-walls of the tower, and *g* a breast-wall, being carried up against the bottom of the reservoir. Although Fig. 127 here is the section of Fig. 124, just as Fig. 131 is the elevation of Fig. 123, yet the arrangement and construction of the two are alike, except in some dimensions, which at Figs. 123 and 131 are smaller.

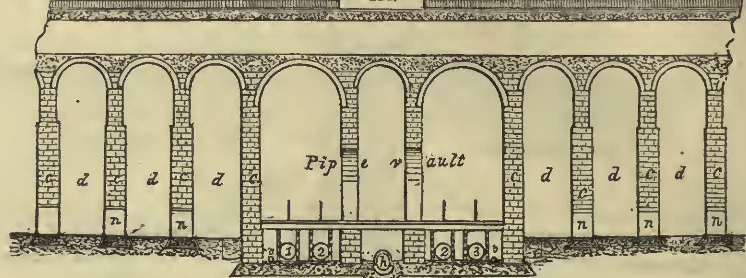
In the rear-wall of the tower are the mouths of the pipes; the latter for some distance are bedded in and covered over with concrete, Figs. 123, 124, and 130. When the pipes Nos. 2, 3, and 4, coming from the northern division, have passed the line of the waste-weir sewer, D E, Fig. 123, they enter into the pipe-vault, Fig. 129 and Fig. 128; here they join with the pipes Nos. 1, 2, and 4, and so pass on. The letters *h h* show the stop-cocks; at *i* is a passage with stairs starting down from the avenue. In order to prevent all sudden opening and shutting of the stop-cocks or sliding-valves, consequently the pushing

of the water, and to obtain a water-tight sit, a set of conical wheels and the crank, Fig. 98, were put in connection with the stop-cock.

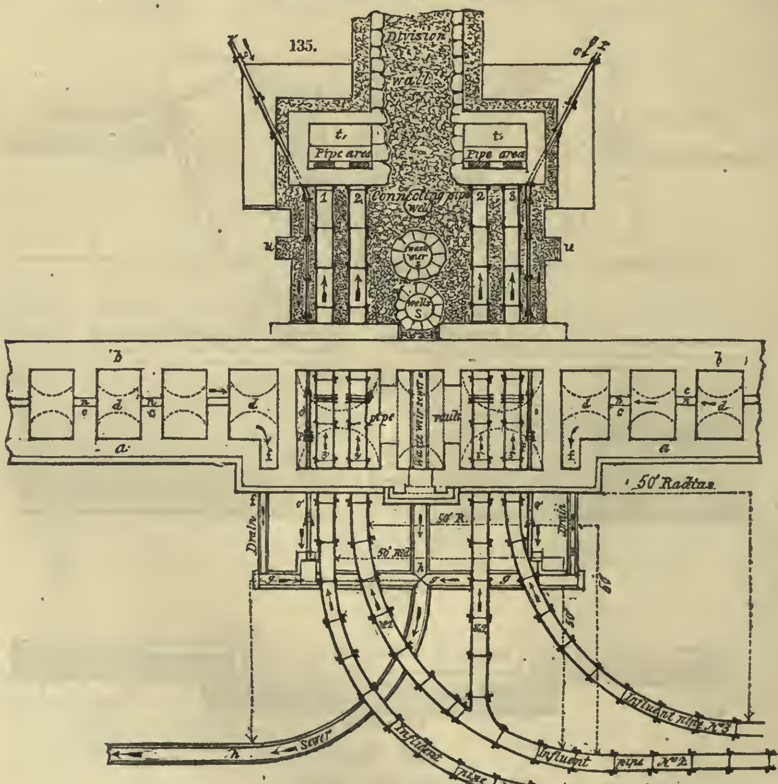
There are for the supply of the upper town, at the west side of the reservoir, two other effluent-gates, of similar description and equal heights with the corresponding ones in the same reservoir-division; yet they have their outlet through one pipe only. They are, together with the towers, of smaller dimensions in length and width.

The Aqueduct-Line continued.—From the mouth of the pipes at the 6th Avenue, the aqueduct, consisting here of three pipes, 36 inches each, 4 feet under ground, runs along 80th street, bends round the corner into 5th Avenue, proceeds here a distance of 2.176 miles across three depressions of ground and two

134.



135.



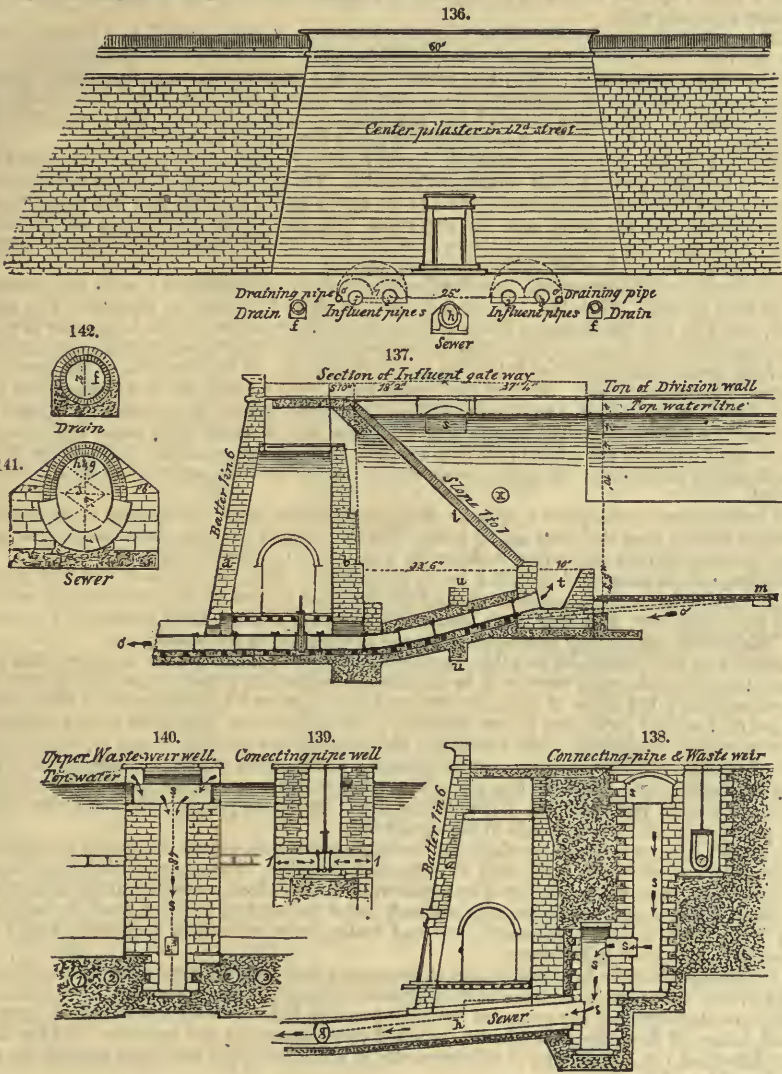
Scale.—1 inch — 40 feet.

heights. On the summit of the latter air-cocks are put, to allow the air to escape. At the lowest points of the depressions there are outlets, in order to get rid of the sand which might collect here.

The Distributing Reservoir is also divided into two divisions, an eastern and a western, by means of a division-wall. Each has a separate inlet and outlet, and may be used as a reservoir for itself, while the other division is emptied. It is erected on the top of Murray hill, the greatest part being above ground; as for instance—the corner marked by *x*, is 49 feet above the street; *y*, however, only 39 feet.

The outer walls *a a* of the reservoir, of 4 feet thickness, the inner of 6, connected together with the cross-walls *c c*, 4 feet thick, form the chief mass of the enclosure of the basin. The cellules *d d*, between the cross-walls, are arched over 12 inches thick with bricks; their spandrels, of some feet in height,

backed with stone masonry; then filled over and levelled off with concrete to a height of 6 inches above the highest point of the extrados of those brick arches. The division-wall is of concrete, faced with rough stone-masonry, Fig. 146. The bottom of the basin is puddled with earth, over which a course of concrete, 12 inches thick, is laid; the sides are puddled, and slope up 1 foot in 4, horizontally, for 16 feet in width; then 1 to 1 to the coping of the enclosure. The lower part of this slope is covered with a course of concrete, 12 inches thick; the steeper upper part is protected by a pavement 15 inches thick, laid in hydraulic mortar. The slopes of the division-wall have the same protection. The upper-filling of the cellule-arches is likewise of puddle, except 2 feet next the slope-pavement, and 2 feet below the flagging of the platform, Figs. 134, 137, 138, 144, 150, and 151, which will prevent the frost from penetrating into the puddle in parts not covered with water.



Scale.—1 inch = 40 feet.

The total length of the entire structure, measured at the top of the cornice, (not in its projection,) is 420 feet; so the width. The basin is 386 feet square, 42 feet deep, and when filled with water 38 feet, contains 21000000 gallons. In order to collect and drain off any water which might filter down through the embankment *i*, and through the walls *b b*, there are left in the cross-walls *c c*, small openings *n n*, Figs. 134, 135, 143, 144, 150, 151, by which the water may drain from cellule to cellule without the structure. Out of the northern side, the drain-water runs through the two sewers *f f*, Figs. 134, 135, 136, 141, 142, through the receiving-sewer *g g*, to the street-sewer *h h*. The southern part of the structure makes its drainage in an opposite direction—viz. through the drain-sewer *i* to the well *k*, Figs. 134, 135, from which it is carried off by the street-sewer of 40th street. Fig. 140 shows the lon-

gitudinal section of the sewer q, the cross-section of the well k, with the mouth of the street-sewer l, the construction of which is given by Fig. 139; the sewer $i\,i$ has a like construction as Fig. 142.

In order to draw off entirely the water from the bottom of each division, when required for cleansing or repairing them, 2 little wells are put in, $m\,m$, Figs. 133, 137, and a slight descent of the bottom towards them, from off all sides, arranged. In those wells the last of the contents collect, and is drawn away by pipes marked $o\,o$ in the above-mentioned figures. The pipes discharge the water into the receiving-sewer $g\,g$; by the stop-cocks $p\,p$, those pipes can be opened and closed.

In order to keep the water of both divisions on a level, a 36-inch connecting-pipe is put through the division-wall. Fig. 135 shows the ground-plan of the well in dotted lines. Fig. 133 is the top of the well, with a square opening formed by jutting over the coping-stone. Fig. 139 is the longitudinal section of pipe, stop-cock, and well.

For letting out from the reservoirs the superfluous water, a waste-weir well, in 2 descents, or for 2 cascades, has been constructed in the body of the division-wall. That water which falls from the opening of the bridge $s\,s$, Figs. 132, 137, 138, 140, covering the first well, fills the water-bag below, which is 8 feet deep; it passes through the opening s, makes then the second fall down the well s, fills its water-bag, and is carried off through the sewer $s\,h$ into the street-sewer of 42d street. The construction of the sewer h is shown by Fig. 141; it has here, as well as in g, a bottom and arch of stone.

The pipes 1, 2, and 2, 3, having made their curves running parallel with each other, they end in the pipe-areas $t\,t$, and the aqueduct itself terminates herewith. The just-mentioned figures show the course of the pipes: Figs. 136 and 140 the cross-section of the course at the entrance into the structure of the reservoir; and Fig. 134 the parts near the stop-cocks. Fig. 137 is their longitudinal section and section of the pipe-area: the same figure shows also the bedding and wrapping of concrete round the pipes in the embankment; it exhibits also the cut-off wall u.

For the effluence of the water into the distributing-pipes, an effluent-tower v, with gate-frame w, is erected for each division. Figs. 143, 145, show the ground-plan; Fig. 146, the elevation; Fig. 150, the side-view; and Fig. 151, the section. The gate-frame has a screen at the outside, in the rear of which is the gate-frame itself; both are supported by a breast-wall, over which the water falls upon the interior bottom of the tower, which is 8 feet below the top of that wall. In the rear wall of the tower is put the entrance into the city-main. Each of the towers has a pipe x and z, which are connected in the pipe-vault by the cross-pipe y; x runs to the eastern part of the town, z to the central part, and $t\,z$ to the west part, for distribution. The ground-plan shows the way in which all 3 pipes can be supplied by the one set of gates, or the other, or by both together. The arrangement for the outflow of water answers, therefore, completely, the purpose—to empty the one division, entirely, while the other remains filled.

At the lowest points of the pipes x, y, and z, draining-pipes with stop-cocks are put in, to let out into the sewer-pit $k\,k$ any sand that may collect here. The way to work the gates from the caps, as well as the upper structure of both the towers, is shown by Figs. 145, 146, 150, and 151.

The platform of the reservoir is guarded by an iron railing. At the elevation of 119 feet above the level of the sea, it commands a complete view of the west and east of Manhattan Island, as well as of the south part of the city, with New York bay, and at a greater distance in that direction, the Atlantic ocean. This view is exceedingly beautiful, and is one of the finest in the world.

Distribution of the Water.—From this reservoir, the distribution of the water is made. The above-mentioned three 36-inch pipes convey it to the lower town, which is built closer and closer the further down one goes; 134 miles of pipes of all sizes, between 36 and 4 inches, conduct it through the streets, and feed several public and private fountains; these pipes are laid down in the centre of the streets, or as near so as possible. The branchings and crossings are made by means of single or double sleeves cast together with a main-piece. The pipes are put together with faucet and spigot, 6 inches deep; at the smaller pipes, 4 inches. The pieces have a length of 9 feet, each piece making thus 9 feet run of water-conduit when put together. Before laying down, they were proved with the hydraulic press, with the pressure of 200 to 250 pounds to the square inch.

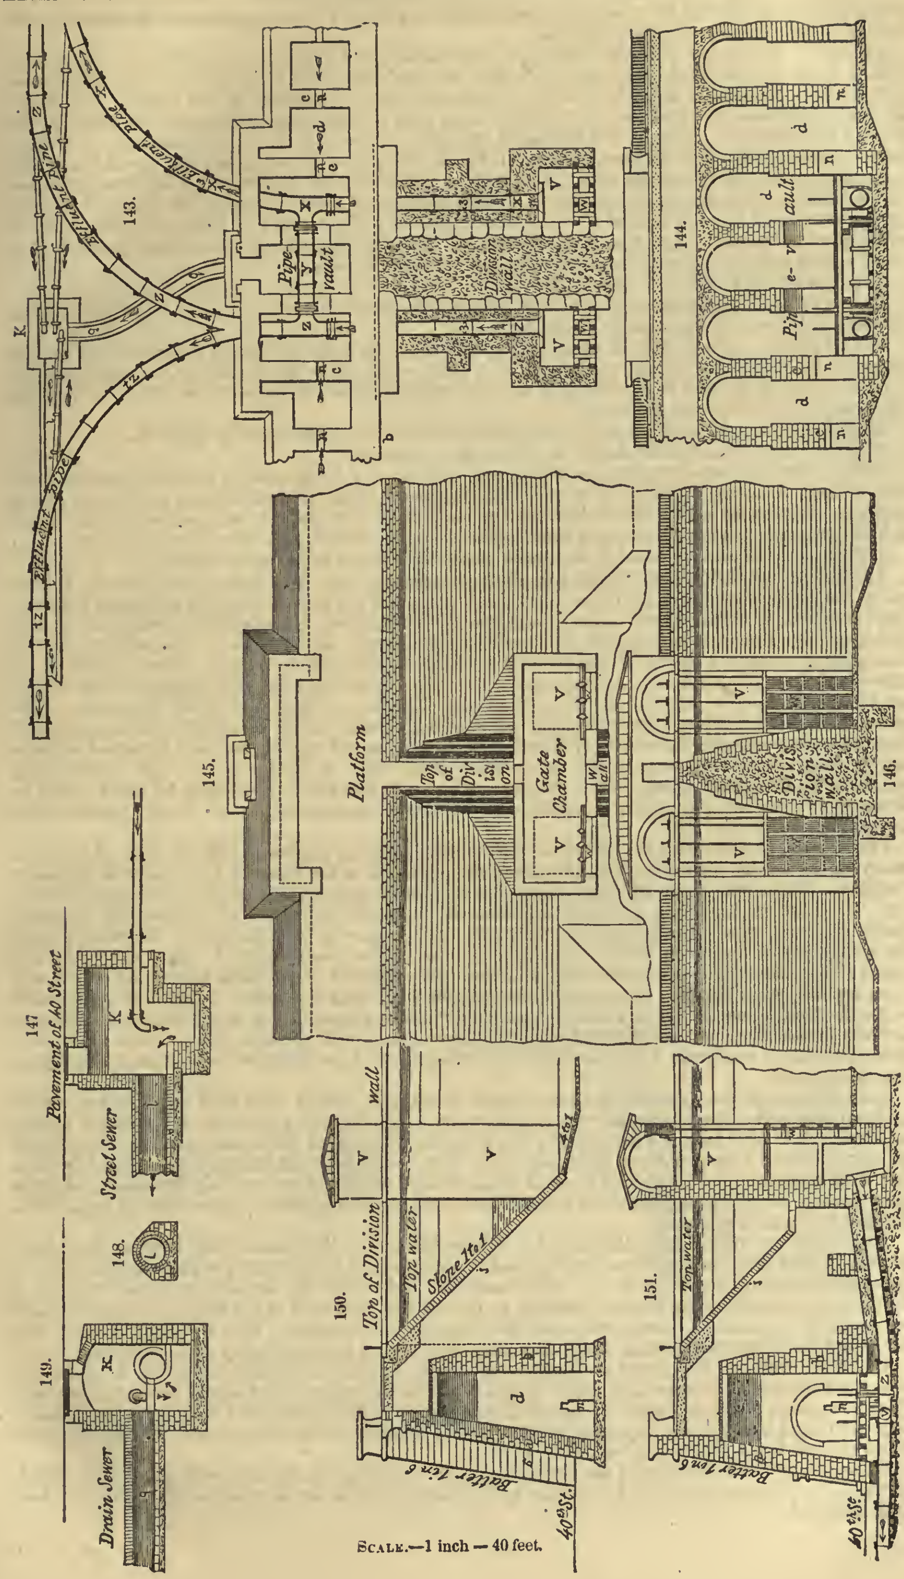
At the corners of streets where crossings and branchings occur, stop-cocks are put in, in order to cut off districts of pipes, when this is required for alteration or repair. Those pipes that run off from the street pipes, leading into the houses, are ½ to 1 inch wide, made of lead, connected to the main-pipes by boring. Such a house-pipe has either a mouth-cock under the outdoor steps, or leads to the kitchen, which in this country is in the basement. To feed bathing-tubs or bathing apparatus, a pipe sometimes rises to the upper-story bedrooms.

Pipes branching off for the hydrants, placed at convenient distances, are for the most part of cast-iron, branching off from the mains by sleeves; at the larger-sized pipes, by means of boring. The hydrants, as far as they are above ground, are protected by a cast-iron case to keep off frost, heat, and damage. For the extinguishing of fires, the engine-hose is screwed to the muzzle of the hydrants. At the harbor, pipes are branched out, terminating at the bulwarks, in order to supply the ships, and fill the water-casks on board by a hose.

The cost of this aqueduct amounts to 8575000 dollars, including purchase of land required, extinguishing of water-rights, and some unfinished works. This amount is within 5 per cent of that estimated by the chief engineer, Mr. John B. Jervis, and the percentage occurs chiefly below the estimate. To this is added 1800000 dollars, the cost for the distributing-pipes.

The first two millions had to be raised at an interest of 7 per cent, and are payable from 1847 to 1857. For the rest, 5 per cent is paid, and to be redeemed from 1858 to 1880. 647157 dollars was the discount for issuing the loan, which, together with the interest paid already during the construction of the work, brings the total expense to 12500000 dollars.

The annual interest for this capital amounts to 665000 dollars, which is collected by a direct water tax, and some indirect taxes; by means of an existing sinking fund, the capital will be redeemed by degrees. The water-tax amounts to 10 dollars for a house of middle size; manufacturers, hotels, bathing



SCALE.—1 inch — 40 feet.

establishments, distilleries, livery-stables, bakeries, sugar-refineries, breweries, slaughter-houses, etc., and ships, pay according to extension and size.

ARCHES. Arches are of various shapes, as Pointed, Elliptical Segmental, and Circular. The outer surface of the arch is called the *estrados* or back of the arch, the inner or concave surface, the *intrados*, or the soffit; the joints of all arches should be perdendicular to the surface of the soffits. The stones are called *arch stones* or voussoirs. The first course on each side are termed *springers*, which rest on the imposts or abutments. In case of a segmental arch, the course beneath the springers are called *skew-backs.* The extreme width between springers is called the *span* of the arch, and the versed sine of the curve of the soffit, the rise of the arch. The highest portion of the arch is called the *crown*, and the centre course of voussoirs the *key-course.* The side portions of arches between the springing and the crown, are termed *haunches* or flanks. All arches should be well sustained by backing on the haunches called *spandrel*-backing. The line of intersection of arches cutting across each other transversely is called a *groin* and the arches themselves *groined arches.* See Bridge.

ARCHIMEDEAN SCREW. See Screw.

ARCHITRAVE. The lower of the three principal members of the entablature of an order, being the chief beam resting immediately on the column.

ARCHIVOLT. A collection of members in the face of an arch, concentric with the intrados, and supported by imposts. *Archivolt* of the arch of a bridge—the curve line formed by the upper sides of the arch-stones in the face of the work; it is sometimes understood to be the whole set of arch-stones which appear in the face of the work.

AREOMETER. An instrument for measuring the density or specific gravity of fluids.

ARGAND BURNERS AND LAMPS. See Gas and Lamps.

ARRIS, the intersection or line, on which two surfaces of a body forming an exterior angle meet each other. Although the edge of a body may in general mean the same thing as its arris, yet, in building, the term arris is restricted to those two surfaces of a rectangular solid, on which the length and thickness may be measured, as in boards, planks, doors, shutters, and other framed joinery.

ARTESIAN WELLS, so called from a mode practised in Artois in boring for water.

ARTESIAN WELL OF GRENELLE, *Boring Apparatus of.* About the year 1824, M. Péligot, one of the superintendents of the hospitals at Paris, suggested the idea of sinking a well upon the Artesian principle, and workmen were sent from Artois for the purpose; whilst this was being effected, M. Mulot, a smith, became interested in the operation, and turned his attention to the subject; he was consequently employed by the Marchioness de Groslier to sink one at Epinay; success attended his efforts, and he was nominated to attempt one at Grenelle. The primitive soils, according to M. Arago, are but rarely stratified, or are found in regular beds. The fissures in granitic rocks, the crevices separating the contiguous masses, have but little width or depth, and do not frequently communicate with each other; in such soils the waters of filtration have but limited outlets, each film or thread terminating its course alone, without receiving any increase from others in their descent. The springs being numerous in the neighborhood, it was not thought probable that any vast quantity of water could be obtained, as the whole of the rain penetrating the earth was supposed to pass off through various openings in the sides of the hills.

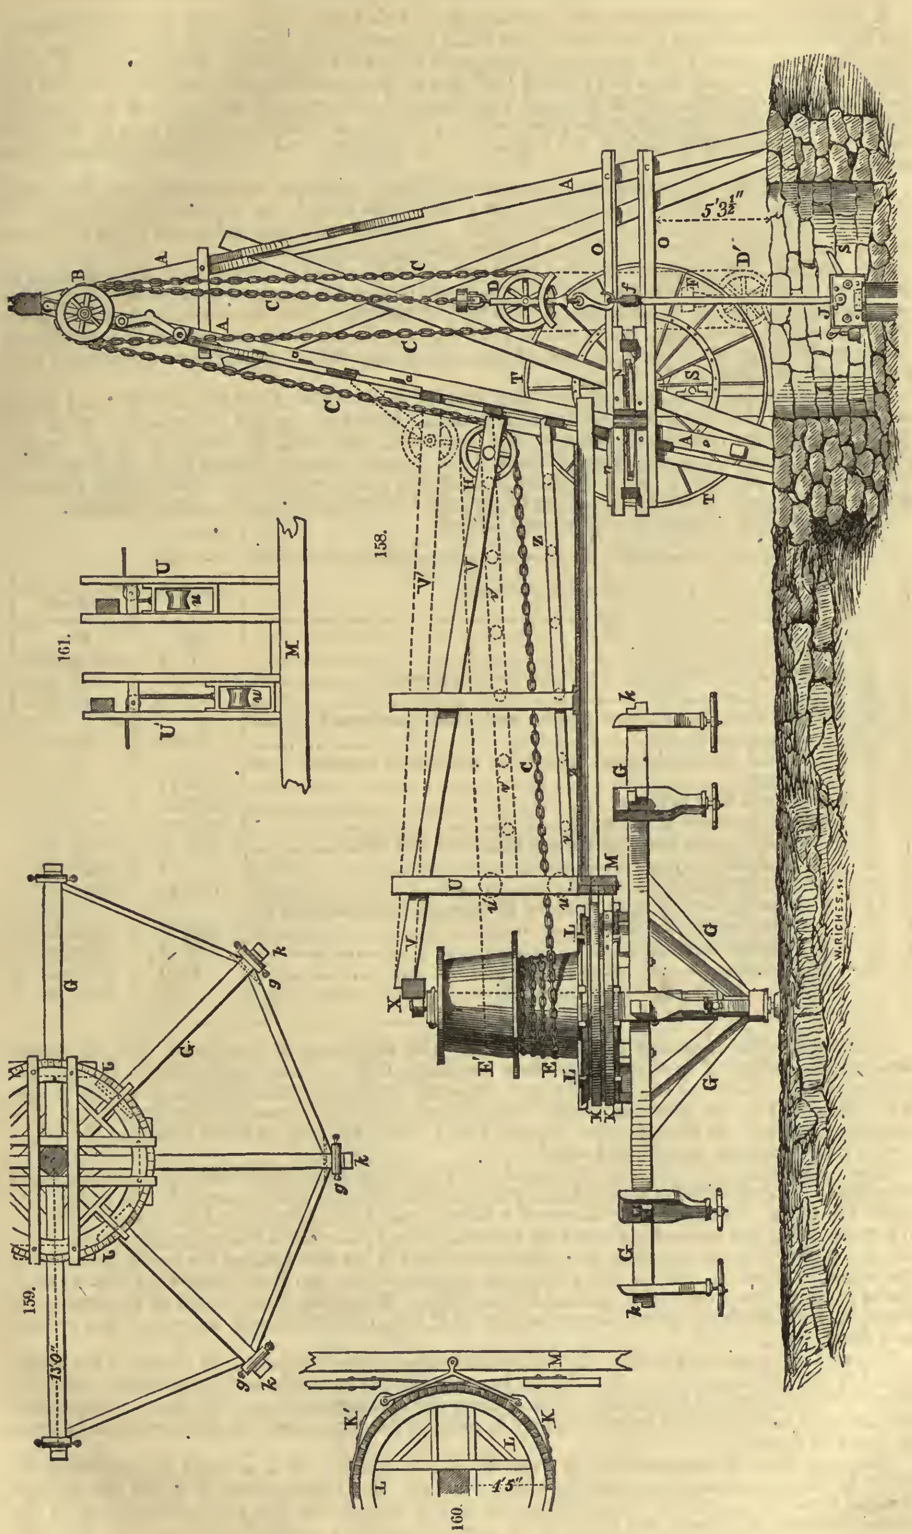
The secondary soils, which are composed of a variety of rocks, in general take the form of immense reservoirs or basins, the centre being considerably depressed, or the extreme boundaries of it greatly elevated. Within this basin, hills, and often mountains, arise, apparently destroying its original character. The stratification of the secondary formation is in regular beds, some of which are of enormous thickness, composed of sand or grit, and very permeable; these permeable beds, as they rise towards the extremities of the basin, become bare on the sides of the mountains and hills. The rain-water which falls on the earth, after penetrating it, forms one continued sheet, which pursues its course with great rapidity when the beds have a great declivity, and, reaching the lowest point, is accumulated in vast quantities. One chalky or calcareous stratum, which is furrowed out in all directions, and particularly in the upper portion, allows the pluvial water to pass with great facility, and also to circulate through the mass to a great depth: and in this peculiar stratum the wells both of Grenelle and Rouen have been bored.

The tertiary soils are stratified, and composed of many beds placed over each other, and separated by clean and well-defined joints, like the secondary, on which they rest; these basins are of less extent, and derive their form from the rectifying of the beds, the elements of which they are constituted being the same as those found on the neighboring hills. The several beds are arranged in a regular manner, and their separation is formed by a layer of sand, through which the water freely percolates; in these several sandy fissures it acquires force as it descends, and at great depths, its pressure being augmented, the flow is rendered constant.

These soils are undoubtedly the best for sinking Artesian wells, because they have at their base courses of sand lying on impermeable clays, and are less subject to dislocation or rupture than rocks of the older formation. Such strata are easily examined, and are usually found rising from the centre of the basin, and following an inverse direction to that of the inclination of the water, which, like a subterranean river, pursues a downward course till it meets with an outlet. They frequently become broken, when the water they contain weeps into small rivulets and is carried away on the surface.

Where the well has been bored at Grenelle, the upper stratum or tertiary deposite is 41 metres in thickness; the next is composed of chalk mixed with flint, 99 metres; then a gray chalk, without any silex, 25 metres; to this succeeded a gray chalk, in which were iron pyrites, 341 metres; then a wealden clay, gray sand, and a sandy clay, in which were found ammonites and other fossils; the whole depth bored through being 548 metres, or about 1798 feet.

Before giving the description of the apparatus used in boring this well, we will give a short sketch of the difficulties encountered and overcome by M. Mulot, to whom the direction of this great work had been intrusted.



158. 159. 160. 161.

M. Mulot commenced boring in 1833; he easily pierced the tertiary sands, which are at Grenelle 13C feet thick, but shortly after having reached the chalk, at the depth of 377 feet, the sides gave way and filled the bored space, which was cleared again, after fifty-seven days' labor; this happened in June, 1834. In May, 1837, the borer had reached 1246 feet, when the valved-spoon, together with a rod 262 feet long, fell to the bottom of the hole and were shattered to fragments; the weight of the mass was 100 cwt. Many contrivances were proposed—some even put in execution—but in vain, till M. Mulot had the idea of wearing the ends of the fragments, and thus extracted them, fifteen months after the accident.

In April, 1840, the instruments were wearing out rapidly, while they were making little headway through the hard chalk, when, being raised to a considerable height, the boring-screw fell, and was buried in the compact rock to the depth of 75 feet. It became necessary to bore all round it in order to free it, and after many months of labor this new obstacle was surmounted.

In December, 1840, the spoon detached itself from the rod, causing a little delay in the operations of M. Mulot, who bored a hole in the sides of the well and pushed the separated instrument into it. This was the last impediment to overcome, and the 26th of February, 1841, the rod suddenly sunk several feet; immediately a column of warm water 1797 feet high, equal to the pressure of 53 atmospheres, rose from the bosom of the earth, and poured upon its surface 800,000 gallons of water, having a temperature of 79 Fahrenheit.

But, besides boring, it was necessary to give support to the sides of the well, which would fall in, unless composed of material more consistent than earth. A tube of a certain calibre is first introduced, then another smaller one slipped within the first, and so on; but should the boring be deeper than expected, it would become necessary to withdraw these tubes in order to replace them by larger ones, because the last must be of sufficient calibre to allow the rod to work. At Grenelle it was necessary to draw off five series of tubes, and to bore larger holes to introduce tubes of a greater diameter.

The following is a table of the strata bored through.

	Nature of the Strata.	Thickness.	Depth beneath the soil.
		Feet.	Feet.
1	Foundation of a basin	7.21	on the surface
2	Alluvial soil, composed of rolled flints and gravel	24.40	7.216
3	Chalk	2.78	31.652
4	Plastic clay, lignites, iron pyrites, and sand, penetrated by sulphuret of iron	65.69	34.44
5	Marl and calcareous sand, containing nodules of compact limestone	36.11	100.13
6	Chalk and silex in lumps	312.89	136.25
7	Hard gray chalk with silex	652.92	449.14
8	Gray chalk, very hard, alternating with more soft chalk	423.18	1104.23
9	Green chalk	.98	1524.20
10	Blue chalk with clay	101.73	1526.0
11	Black and blue clay, with strata of green sand, containing iron pyrites and fossils	101.79	1658.51
12	Argillaceous sand	2.30	1780.28
13	Green sand	4.50	1792.57
	Water		1797.47

Description.—The apparatus consists of a crane with four beams A, iron-bound. At the summit there are four pulleys of cast-iron B, on these the chains C pass; these chains also go through two other moveable pulleys D D′. The chains C, attached by one end to the guide-strap of the pulleys D D′, are hooked by the other extremity on the conical drum E E′, around which they are wound in opposite directions. By these pulleys the iron bars F, 26.24 feet long, to which are attached the burrowing instruments, are lowered and raised.

To raise the rods, eight horses are harnessed at G, Figs. 158 and 159, which being set in motion, one of the chains passing through the pulley H coils round E, while the other chain is unrolled. The pulley D, to which the rod F is suspended by means of a hook, is raised, and brings up all the boring apparatus. When this pulley has reached the top of the crane the second pulley D′ is made fast; then the bar just raised is taken off by men standing on *a*; the hook is fixed to the next bar, and the horses are driven in the opposite direction. While the pulleys are exchanged, the top bar is seized by the crank J, placed at the orifice of the well to prevent it from falling. The cranks J are formed of two strong iron plates, between which are set two eccentric chaps J^1 J^2, which allow the rods to ascend, but prevent their falling back.

One man is necessary to lower the rod, which is accomplished by pulling or loosening the break, Figs. 158 and 159, at pleasure. This double break consists of two large hoops K K′, surrounding the drum L, which is covered with a thick sheet of iron; one of the extremities of the hoops is fastened to the horizontal beam M, while the other is kept in place by a square placed out of the works, and opened or closed by a lever.

The next thing to be considered is how the rod is turned. It is adapted to the wheel N, which is made to communicate with the wheel, Fig. 163. The toothed-wheel N, is for this purpose changed from the position it occupied, Fig. 158, to that represented Fig. 162, corresponding to the axis of the well; a square hole is made in the centre to receive a square bar of iron .2624 of a foot

square and 13 feet long, which is adapted by one extremity to the boring-rod, and by the other is suspended to the hook of the pulley D. When the wheel N is fixed to the rod it is adapted to its intermediate toothed-wheel P, fixed to a wooden frame close by the crane. The wheel P is put in connection with the great wheel Q, placed over the wheel R, to which two, and sometimes three horses are harnessed. The burrowing-rod is suspended by chains run into a ring *g*, Fig. 159, and coils round the drum S, Figs. 158 and 163′, situated on the other side. The wheel T serves to raise or lower the instrument.

When the wheel R is put in motion, the rod receives the movement of rotation imparted to N by the toothed-wheel P. The men at T allow the rod to descend slowly. The pulley D′ would be in the way during the operation, it is therefore fixed by a pin to the links of the chain.

Explanations of the Figures.—Fig. 158.—A vertical and longitudinal section of the apparatus in a plane passing through the axis of the well, and of the wheel used to lower and raise the borer.

Fig. 159.—A horizontal section of the wheel G, made above the breaks; the two conical drums around which the chains are wound, being omitted.

Fig. 160.—A horizontal projection of the drum L, and of the breaks.

Fig. 161.—A front view of the two frames U U′, placed in the horizontal beam, near the wheel G. Within these frames two smaller frames are made to slide; they have wooden rollers, *u* and *u′*, and are intended to support and guide the chains C, to the drums E E′. These chains, when slack, rest on the rollers *v v′*. The frames U and U′ have their superior part in contact with the beams V and V′, which are fastened by one extremity to the crane, and by the other to the strong bearer, X. The pillow of the axis of the wheel G, rests also on this bearer.

A flooring, Z, connects the wheel to the crane, and places within the reach of the workmen the parts just described.

Fig. 162.—Vertical and transverse section of the apparatus, whose plane is perpendicular to that of the section, Fig. 158.

Fig. 163′.—A view of the drum used for supporting and lowering slowly the borer as it sinks.

Fig. 165.—A profile view of the frame and wheel N.

Fig. 166.—A plan of this frame, which slides in grooves made in the beams O, Figs. 158 and 162, on small friction-rollers. The small flooring *n*, gives passage towards the centre of the wheel N, in order to adapt the rod in it.

Fig. 167.—Front view of the wooden support to the toothed-wheel P, Fig. 162.

Fig. 168.—A horizontal section of this support, and plan of the wheel.

Figs. 169 and 170.—A front and profile view of one of the moveable pulleys, D D′, with its guide-strap, giving attachment to the hook *d*, to which is suspended the borer by a ring.

Figs. 171 and 172.—An external view of the crank J, with a section following the line 1—2.

While the boring goes on, this is set over the orifice of the hole; to this end, two semicircular pieces *j′* are attached to the plates J, and rest on the ground. The rods pass between J and the nippers J^1, J^2. As long as the rods are raised the nippers yield; but as soon as they remain motionless, either to change the rods or for any other motive, the arcs through their eccentricity press against the bars and prevent their descent. To secure them further, their other sides are held by the force-screws j^2.

Figs. 185 and 186.—Rods united by means of pins, the heads of which are buried in the thickness of the bars. The end of one is fissured, in order to receive the end of another rod.

Figs. 187 and 188.—A ring which is attached to the rods by three pins.

Figs. 189 and 190.—A chisel, called Trepan, used to perforate the hard rocks which it is necessary to break and to crush at the same time. There are three edges, *a*, *b*, *c*. The edge *a* is double, *b* and *c* are turned in opposite directions. This implement will cut the rock and crush it in whatever direction it is turned.

Figs. 191 and 192.—A valved spoon, used in sands and clays almost rendered liquid by the water in which they are in suspension. It consists of a long cylinder in sheet-iron, open at both extremities, the inferior being strengthened by an iron ring with a sharp edge. A little above this ring there is a disk, at the centre of which a round hole has been perforated. This opening is perfectly closed by an iron ball. When the spoon is lowered into the hole the sand pushes away the ball, which, however, falls back by its weight, closes the orifice *b*, and allows the extraction of the sand. The ball is prevented from rising too high by the perforated disk *c*.

Figs. 193 and 194.—A vertical section and external view of the borer, used to enlarge the hole. It is very solid, and consists of a hollow cylinder, whose inferior extremity is furnished on its circumference with fluted knives, of which there are several of different dimensions.

Fig. 195.—A view of the underneath part of the preceding.

Fig. 196.—Shows the mode of attachment of a knife to the ring, and also a front view of the knife The knives are firmly attached to the inner ring, and are surrounded by another ring of greater diameter. The whole is traversed by a pin.

ASPEN, See Woods, *varieties of.*
ASH, See Woods, *varieties of.*
ASHLAR, hewn stone used for the facings of walls. If the work be so smoothed as to take out the marks of the tools by which the stones were first cut, it is called *plane ashlar;* if figured, *tooled ashlar,* or *random tooled,* or chiselled, or bousted, or pointed: if the stones project from the joints, it is said to be *rusticated.*

ASHLERING, in carpentry, the fixing of short upright quarterings between the rafters and the floor.

ASH-PAN. In locomotive engines, an iron box attached to the fire-box to receive the ashes from the fire.

ASPHALTUM. Native bitumen. Its chief application is in the construction of roads and pavements, for roofing, and for protecting buildings from dampness. Its application to roads and pavements in this country has been unsuccessful, but it is still in use in Paris and other European cities.

Asphaltum varies considerably in purity, according to the quantity of different earthy substances mingled with it. When nearly pure its color is almost black, or dark brown, and it does not soil the fingers: when rubbed it gives off a pitchy odor. In combination with other substances it forms a mastic, which is applied in a liquid state to kitchen and stable floors, pavements, &c. The principal ingredient in "The Calcareous Asphaltum" which is found at Seyssel near the Jura Mountains, is a dark brown bituminous limestone. The stone is reduced to powder and mixed with a portion of mineral tar when intended to be applied as a cement, as in covering roofs, lining tanks, &c.; but when intended for flooring or pavements, sea grit is used in addition. This is melted and run into moulds about 18 inches square, by 6 inches deep, or formed into blocks weighing from 112 lbs. to 130 lbs. each. In this state it is sold for use, and is remelted on the spot where required, in cauldrons heated on small portable furnaces, with the addition of 1 lb. of mineral tar to 1 cwt. of mastic.

The only kind of tar to be used in this mixture, is that with which the limestone is impregnated. If the mastic is required to be very stiff, as for paving kitchen floors, a smaller proportion of tar is to be used, with a larger proportion of grit. To convert fine asphalte into coarse, 30 lbs. of fine clean grit are to be added to 112 lbs. of mastic, with from 1 lb. to 2½ lbs of tar.

In applying asphalte to the floors of cellars and basements to exclude dampness, an inverted brick arch laid in asphalte as a cement should be used. Asphalted bricks are also prepared by heating them, and placing them in rows upon a flat surface between gauges, allowing a layer of mastic a quarter of an inch thick to be laid over them: the brick are then separated with a knife before the mastic is quite set. The brick are also prepared by dipping the ends in boiling mastic.

The thickness of asphaltum used for pavements varies from half an inch to an inch and a quarter, the former for floors and the latter for carriage-ways: half an inch or five-eighths is sufficient for roofs and the coverings of arches, and about a quarter of an inch is sufficient for the ground line of brick-work to prevent damp from rising. An asphaltnm surface admits of easy repair. By placing hot mastic upon the place requiring it, the fresh material will readily adhere to the old work if free from dust or moisture. Asphaltum is used in oil painting; for which purpose it is first dissolved in oil of turpentine, by which it is fitted for glazing and shading.

ASSAYING. This term is applied in a confined sense to the analysis or separation of the precions metals from other metals; and to the determination of the quantity or value of gold and silver in bullion, coin, plate or trinkets, but more generally to the operation which decides the quantity of a certain kind of metal contained in an ore, or in an alloy, if it is performed by heat chiefly, in contradistinction to analysis, or the operation by moisture.

ATMOMETER. An instrument for determining the rate of evaporation from a humid surface.

ATMOSPHERE; that gaseous fluid which surrounds the earth, according to Dr. Prout, 100 cubic inches of which composes the atmosphere at the surface of the earth, when the barometer stands at 30 inches, and at a temperature of 60 Fahrenheit, weighs 31.0117 grains, being thus about 815 times lighter than water, and 11,065 times lighter than mercury. Since the air of the atmosphere is possessed of weight, it must be evident, that a cubic foot of air at the surface of the earth, has to support the weight of all the air directly above it, and that therefore the higher we ascend up in the atmosphere, the lighter will be the cubic foot of air; or in other words, the farther from the surface of the earth, the less will be the density of the air. At the height of three and a half miles, it was found that the atmospheric air was only half as dense as it was at the surface of the earth. From the nature of fluids, it follows, that the air of the atmosphere presses against any body which comes into contact with it; because fluids exert pressure in all directions, upwards, downwards, sidewise, and oblique. From the nature of fluids it also follows, that the pressure on any point is equal to the weight of all the particles of the fluid in a perpendicular line between the point in contact, and the surface of the fluid. The amount of pressure of a column of air, whose base is one square foot, and altitude the height of the atmosphere, has been found to be 2156 pounds avoirdupois, or very nearly 15 pounds of pressure on every square inch. It is common to state the pressure of the atmosphere as equal to 15 lbs. on the square inch. If any gaseous body or vapor, such as steam, exert a pressure equivalent to 15 lbs. on the square inch, then the force of that vapor is said to be equal to one atmosphere; if the vapor be equal to 30 pounds on every square inch, then it is equal to two atmospheres; and so on, consequently, the atmospheric pressure is capable of supporting about thirty inches of mercury, or a column of water 34 feet high. It is found that the pressure of the atmosphere is not constant even at the same place; at the equator, the pressure is nearly constant, but it is subject to greater change in the high latitudes. In this country the pressure of the atmosphere varies so much, as to support a column of mercury sometimes so low as 28 inches, and at other times so high as 31, the mean being 29·5. This would make the average pressure between 14 and 15 pounds on the square inch. In scientific books generally, the pressure is understood in round numbers to be 15 lbs., so that a pressure exerted equal to one, two, three, four, &c. atmospheres, means such a pressure as would support 30, 60, 90, 120, &c. inches of mercury in a perpendicular column, or 15, 30 45, 60, &c. pounds on every square inch.

ATMOSPHERIC ENGINE. See CALORIC ENGINE.

ATMOSPHERIC PRESSURE, applied to pile driving by Dr. Pott's system. Atmospheric pressure has been applied to the erection of several beacons in the vicinity of the mouth of the Thames. The first experiment was upon the Goodwin Sands on July 16, 1845, and an iron tube of 2 feet 6 inches diameter was driven into the sand to a depth of 22 feet in two or three hours. A gentleman, present at the experiment, which was made by the Trinity Brethren, said, that the facility with which this large iron tube was made to descend could be compared to nothing better than shutting up a telescope. The method of operation is this: the tubes are in convenient lengths, with spigot and faucet joints, and one of them being placed perpendicularly, an air-tight cap is fixed to the upper end. This cap communicates with a powerful air-pump, by means of which the air is exhausted from the tube, drawing up the sand or shingle with the water which ascends, and the tube immediately descends from the effects of outward atmospheric pressure. The contents of the tube are then removed by the pump, which readily draws away the sand or shingle with the water which rises during their action, and the exhaustion process is then continued. The upper end of the tube having become level with the surface, the operation is stopped, the cap removed, a fresh tube is affixed and secured, and the same course pursued, and thus continued, until, with the greatest facility, this great length of tube penetrated what must have been exceedingly hard sand.

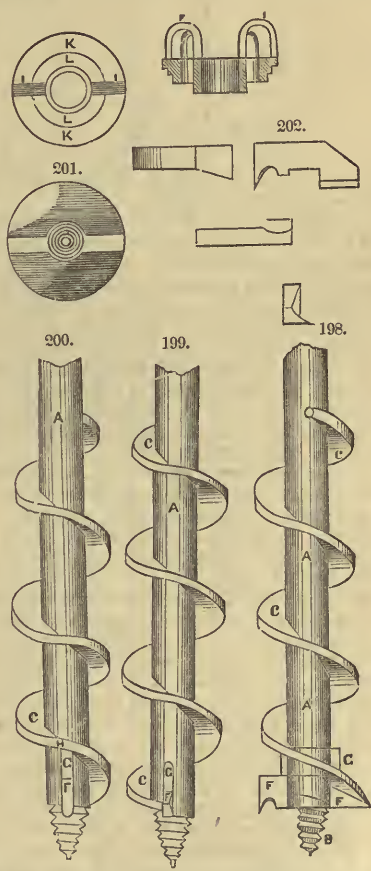
ATMOSPHERIC RAILWAY. See RAILROADS.

ATTRACTION. A tendency which certain bodies have to approach and adhere to each other. There are several kinds of attraction, as of gravitation, cohesion, capillary, chemical, electrical, &c.

ATWOOD'S MACHINE. See ACCELERATION.

AUGERS. See BORING TOOLS.

AUGER. Invented by Wm. Ash. An instrument to produce holes of various diameters, with the cutting and guiding parts detached, so as to change them at pleasure.



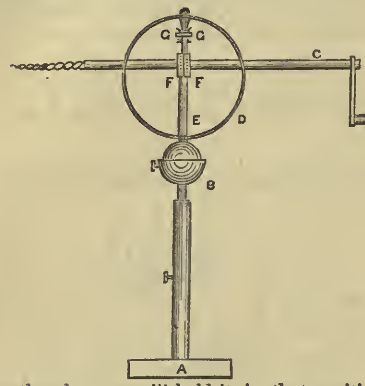
202. 201. 200. 199. 198.

Figs. 198, 199, 200, and 201, represent the auger in three different positions. Fig. 201 shows its end. A is the spindle; B the conical screw; C the worm fitted on the spindle. The upper end of the worm is made to bear against the stop D. F is the cutter fitted into a mortise in the spindle, fastened by the wedge-piece G. The cutter F, is shown above in four detached positions, Fig. 202. The lower end of the worm bears against the back of the cutter, and the wedge G rests also in a small notch cut in the face of the worm, as seen in Fig. 200. On taking out the wedge the cutter can be taken out, and also the worm, when another worm or cutter of a different size may be attached to the spindle. In this way the cutter can be taken out and sharpened at pleasure. Instead of the worm C, the guides, Figs. 203 and 204, are sometimes substituted. Fig. 203 is a vertical, and Fig. 204 a horizontal, section. This guide consists of a ring, K K, having a slightly conical screw-thread on the outside, from which extend two wings, I I, supporting a thimble, L. Through this thimble the spindle A passes, and the cutter being applied to bore the wood, the opening of the hole is only to be cut in the first place, then the ring of the guide is firmly screwed into that orifice; and in boring, the cutter will then be directed by the spindle sliding through the thimble. By the worm the chips are carried up out of the hole. By the guide the chips will rise through the opening K and the thimble L. The worm appears to be, by far, the best guide.

AUGERS, *machinery for making.* The object of the inventor, Mr. Palmer, is to manufacture the "single-twist" auger, usually made of a rod of metal, twisted round a cylinder into a helical curve. The auger which the inventor's machinery is intended to manufacture, is formed of a long rod of metal, (either of a triangular or other proper shape, in its cross-section.) The iron should be rolled in square bars or rods, of the size required, and be cut into pieces of sufficient length, to make the tool or instrument intended. A small piece of steel of proper size for the cutting-lip, and the conical screw, if it is to be added, is next welded upon one end of each one of the pieces, and the end is next turned or bent down at right angles to the remainder, upon an anvil, so as to fit into the cavity of the lower section of the dies, for forming the lip, or the lip and screw cone. About three-fourths of the length of the rod from the steel knob is next heated to the necessary temperature, to be rolled down by the next portion of the machinery. The next portion of the process of manufacturing the auger, consists in forming the cutting-lip, or the cutting-lip and conical screw-blank, upon its end. For this purpose, dies are employed to form the lip without the conic blank. The head of steel being heated, is placed between the dies, and the upper of them caused to descend, with the force necessary to swedge or compress the metal into the shape required. The knob thus formed, is next bent down to the angle re-

quired to be applied to the machine, by which the rod is twisted in the helical curve. The next operation is to give the requisite degree of uniformity to the size and spread of the twist, which is accomplished by hammering in the machine, consisting of a trip-hammer, arranged and operated over a die-anvil or bed-piece, grooved out, so as to receive the twisted helix when laid thereon. By turning the auger around, first in one direction and next in the opposite, successively, so as to cause it to pass back and forth between the hammer and bed-piece or anvil, the twist is spread out in a uniform manner. The lower part of the hammer should be curved to correspond with the circumference of the exterior of the twist of the auger. The twisted portion of the auger is again heated, and rolled between heavy iron plates, for the purpose of straightening the twist; during which operation care should be taken that the cutting lip of the auger does not come in contact with the plates. The auger is next to be finished by filing, and upon grinding and polishing wheels, or by other proper means, in such manner as may be desirable; and when a screw is to be connected with the cutting-lip, it may be cut upon the blank by any contrivance adapted to the purpose.

197.



Various machines are used to hold the auger in the required position whilst boring, of which the most common is that used by house carpenters for keeping the tool perpendicular to the face of the work. The foot of the frame rests upon the timber, and guides hold the auger at right angles to it: motion is conveyed through bevel geers and a crank. For ship carpenter's use, the following cut represents a frame invented by Richard Coffin, of Haverhill.

A is the foot. D is the frame. C is a rod and crank attached to the auger H. B is the cup and head. E is the spring. G G are two rods for the purpose of disconnecting the catches F F from the rod C.

If you wish to bore, pull the spring E by the handle to the left; shove down the left-hand rod G, to disconnect the left-hand catch from the rod C. The right hand catch holds the spring, and throws its power towards the auger H, and so on; the cup B allows its ball to roll in the auger and frame in any position, and the thumb-screw will hold it in that position; the other thumb-screw is to hold the slide which elevates or depresses the auger.

AUGERS, *double and single twist*, of Sandford, Newton and Smith of Meriden, Conn. Constructed with a uniformly decreasing length of twist, with a corresponding gradual tapering of the cavity of the auger, from the shank to the lower or cutting extremity. Any person skilled in the art of making augers can form the graduated double-twist with tongs and hammers, in the ordinary mode of twisting double-twist augers, by exercising due care and attention. A better method is to have the dies in what auger manufacturers call crimp-jaws, so constructed as to conform in size, graduated length of twist, and taper of the cavity, to the proposed auger. The auger having been first twisted by the common method, with the tongs and other tools, to about the shortness of a medium in the proposed twist, is, while hot, put into the crimps, which are then brought suddenly together by the usual process, the auger being at the same time turned partially round, backward and forward. The twist is thus made of a gradually increasing length, with a corresponding gradual enlarging cavity from the lower or cutting end to the other extremity of the twist.

To form single-twist augers with this improvement, that part of the rod which is to form the twist, should, before being twisted, be drawn with a graduated taper from the part which is to form the shank, to that which is to form the lower or cutting end. The auger may then be twisted in the usual way, by having the mould upon which it is formed or twisted, made to conform in size, graduated length of twist, and taper of cavity, to the proposed auger. The mould is a machine well known to all makers of single-twist augers.

The superiority of augers made with this improvement consists, in that the clogging of the chips or core in the twist, while in the process of boring, is effectually prevented; thereby materially diminishing the friction. And also, that the shortness of the twist at the lower end gives a better opportunity to finish the cutting-lips, so that they may bore more smoothly and evenly than when the auger is made in the ordinary way, with a slack or open twist.

What the inventors claim as their improvement and invention, is the making or constructing double or single twist augers, with a gradually increasing length of twist, and the consequent gradual enlargement of cavity from the lower or cutting end to the other extremity of the twist.

AUGER, *double-lipped, convex and concave*. Improvement in the form and construction of concave screw-augers, by N. C. Sandford, Meriden, Conn. This improvement consists as follows: Instead of having the plate, from which the auger is to be twisted, of concave shape throughout, as is usual in forming concave augers, the lower extremity of the plate is of convex shape, or of even thickness, though the former is preferred. In augers of five-eighths diameter it will be sufficient to have about one inch of the lower extremity of convex shape, or of even thickness, as aforesaid, varying in proportion as the diameter of the auger is increased or diminished.

The advantage of this mode of construction consists in, that the workman, when twisting the auger, which is done in the ordinary mode, is better enabled to give to the plate a short twist at the lower extremity, and finish the cutting-lips or edges in the best and most approved method for easy boring, than when the plate is formed in the usual way, of concave shape throughout.

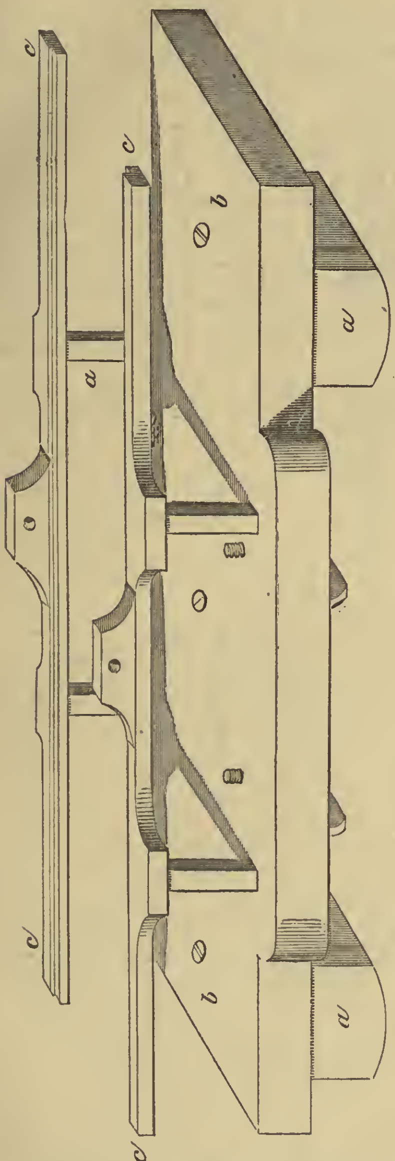
What Mr. Sandford claims as his invention, is the forming of the lower part of the plate of a convex shape, or of even thickness, when this is combined with the upper part of the plate formed of a concave

shape. The whole plate being formed for the purpose of making therefrom a double-lipped, convex, and concave auger.

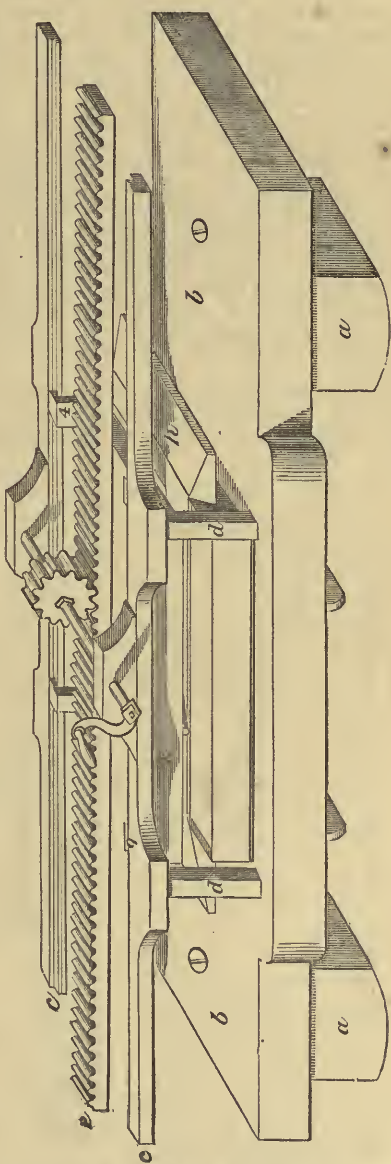
AUGER MACHINE. This new and useful improvement in the mode of equalizing and straightening the twist of double and single twist screw augers, invented by Sandford and Smith, of Meriden, Conn., may be described as follows:

Set firmly in the ground, or otherwise secure to the floor, two posts, marked *a*, Fig. 208, about six feet apart and fifteen inches in diameter, of sufficient length to elevate the machine to a convenient

208.



209.

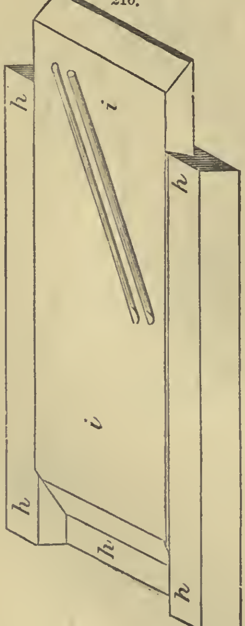


distance from the ground. Upon the upper surface of these posts is placed horizontally, and secured strongly, a piece of timber *b*, say of oak, about twenty inches wide on its upper surface, and four inches thick. This we term the bed of the machine. Two straight cast-iron bars *c*, about two inches thick and two inches wide, of the same length as the bed, and raised about twelve inches therefrom, and then placed about twelve inches apart, parallel to each other and to the bed. Each of these bars is secured to the bed by two vertical posts of iron, D. Fig. 208 shows the machine as thus far constructed. We then take a piece of cast-iron, say two feet long, fourteen inches wide, and one inch thick, with its edges raised about one inch, so as to form a dovetail on its upper surface. This we call the

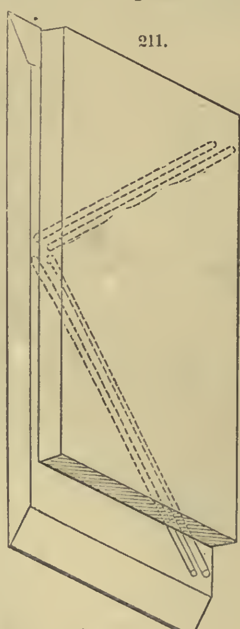
lower stock, and is represented by that portion of Fig. 210 marked h. This stock is placed in the centre of the bed, between the bars; screws passing through the bed and attached to the stock, serve to elevate or depress it at pleasure. Another screw, passing through the centre of the stock and through the bed, enables the operator to confine and hold the stock firmly on the first-named four screws.

Another piece of cast-iron, of similar dimensions, but with the dovetail on its under surface, is then placed under the bars, so that about one inch of each edge of the upper surface of its entire length shall bear upon the under surface of the bars. This we term the upper stock, and is held to the bars by four hooks, marked g, in Fig. 209, attached to the upper surface of the stock, and resting in the upper surface of the bars, so as to admit a sliding movement of this upper stock. This movement is effected by means of a rack e, and pinion; the rack, to be of sufficient strength, should be formed of a cast-iron bar, about two inches square, and of the same length as the bars, with cogs about two inches in length, and is attached lengthwise to the surface of the upper stock. The pinions and shaft should be of corresponding dimensions; and being turned by means of a crank or wrench, give an alternate backward or forward movement to the upper stock. Fig. 209 represents the machine with the upper stock k, and the lower stock h, in their respective places, and the rack e, and pinion attached. There are then inserted into these stocks, metallic plates, or dies, of about one inch thickness, which fit into and are securely held by the dovetails above mentioned. To each of these plates, or dies, are secured, by means of rivets or screws, two wales of cast-steel, running parallel to each other in an angular direction across the plates. Fig. 210 shows one of these plates i, partially inserted in the stock h. When the plates are separated from their respective stocks, the wales upon the plate are designed for the lower stock, and *vice versa;* so that when the plates are inserted in their respective stocks, the wales upon the upper plate run in an opposite direction from those upon the lower plate, forming an angle with each other. The size of the wales will depend upon the size of the auger to be formed; and the angle at which they cross the plate must be governed by the openness or closeness of the proposed twist, so that separate plates, adapted to each size of auger respectively, will be required.

If it is desired to form the auger so as to make the graduated twist, it may be effected by slightly curving and also tapering, as shown in Fig. 212, the wales; increasing or diminishing the curve and taper, in proportion to the degree of graduation contemplated.



210.



211.

212.

The plates are adjusted at the proper distance from each other, required by the size of the auger to be formed, by means of the screws.

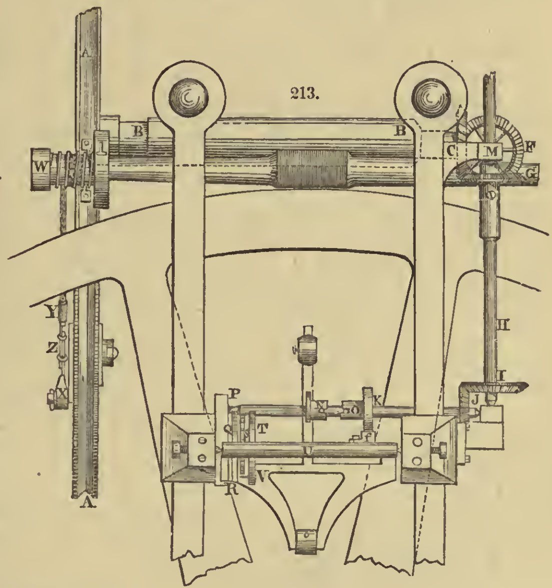
To work the machine the crank is turned backward, so as to move the upper plate directly over the opposite extremity of the wales upon the lower plate, as shown in Fig. 211. The machine is then ready for operation. The auger being twisted by hand in the usual way, (which can be done with great expedition, as particular nicety in this respect is rendered unnecessary by the use of the machine,) is placed while hot in the machine, with the part nearest the shank on the wales, which being adapted to the size of the auger to be operated upon, will fill the cavity of the twist. The upper plate is then moved forward by turning the crank, and rolls the twist part of the auger between the plates, these giving it an exact and uniform size; while, at the same time, the wales operate upon the cavities of the twist, opening or closing them as may be necessary, and by a single forward move-

ment of the machine, produces a perfectly even and regular twist. Thus forming a better article, and at less expense, than can be done by any method now in use.

Messrs. Sandford and Smith, claim the raising upon and securing to the surface of level metallic, or other plates composed of hard substance, wales running either in straight or curved lines, and operated substantially in the manner just specified, for the purpose of forming the twist of double and single twist screw augers.

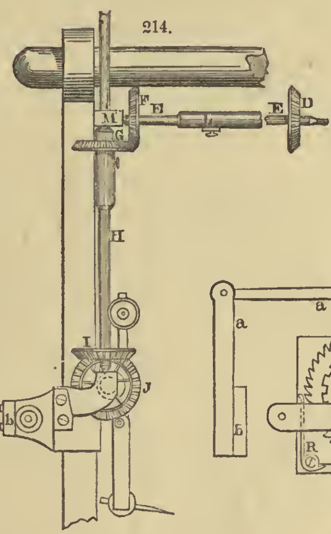
AUTOMATIC DIVIDING MACHINE, *arranged for use in the Coast Survey Office, by* Joseph Saxton, *assistant in the office of weights and measures, Washington, and constructed by William Würdeman, mechanician, coast-survey office.*—The dividing machine, which has been rendered automatic by Mr. Saxton, was imported for use in the coast-survey office, by the late F. R. Hassler, Esq., superintendent. The graduations made by means of it, by different persons, were unsatisfactory. Many causes were assignable for this, and it was considered by the present superintendent, Professor A. D. Bache, desirable that the most obvious of the causes of error should be got rid of, by rendering the machine automatic, before the minor causes of irregularity were sought for. This was done by Mr. Saxton, in the manner described in the following pages. The result has been very successful, not only in its first application, but in permitting the determination and removal of sources of error, previously concealed in the working of the machine. The drawings of the proposed additions upon a scale necessary for working, were made by Mr. Saxton, and the work was executed by Mr. William Würdeman and his assistant mechanicians in the coast-survey office. Accuracy, beauty of finish, ease of reading, economy of time, and labor in dividing, have all been gained by the improvements.

213.

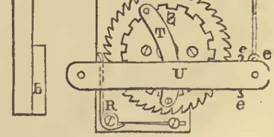


The machinery for rendering the dividing machine automatic, consists of a brass wheel A, about 20 inches in diameter, mounted on the axis B, Fig. 213. One of the arms of the wheel A has a slit extending from near the centre of the rim; in this slit is fixed the crank-pin so that it can be placed at any required distance from the centre. On the edge of the wheel is turned a groove, in which runs a cord for driving the wheel. On the other end of the axis is fixed the wheel C, which is geared into the wheel D, on the lower end of the vertical shaft E, Fig. 214. On the upper end of the same shaft, is another wheel F, geared into the wheel G, on the horizontal shaft H. On the end of the shaft H, is a wheel I, which gears into the wheel J, on the axis K. The wheels C D F G I and J are all bevel wheels, having the same number of teeth, (60) and work into each other at right angles.

214.



215.



The shaft E has on it a sliding-joint L, for altering its length; the shaft H is turned and ground of uniform thickness, so that it may slide accurately through the socket of the wheel G, and also through its bearing at M, in which it turns. The axis K has on it two eccentrics, N and O: N to raise the tracing point, and O to move it horizontally. One-half of the circumference of N is concentric with the axis on which it turns, so as to keep the point up while the crank-wheel moves half a revolution, and is moving the dividing plate. The other is eccentric to the axis about one-tenth of an inch, so as to let the point rest on the circle while it is making the division. The eccentric O has about $\frac{1}{8}$th of its circumference concentric to the axis; the rest is described from a point about $\frac{1}{8}$th of an inch from the centre. N and O must be fixed on the axis with regard to each other, so that N will raise the point before O begins to move it back, and both with regard to the crank-wheel A, so that the point

will be raised before the crank begins to move the dividing plate, and keep it up until it is done moving and O has moved the point back, and then let it down before O begins to let it return. The axis K has also on it, near the end, a small cog P, to shift the ratchet-wheel Q one tooth every revolution of K. The ratchet-wheel has 60 teeth, and is kept in its proper position by the detent spring R. In front of the wheel, and fastened to it by two screws, is a circular plate S, Figs. 213 and 215, with 20 notches in its edge, the deepest one for the longest line, or 5°; the next for 30′; and the shallowest for 15′; and the edge of the plate for the 5′ lines.

The segment T, Figs. 213 and 215, is fixed on the vertical part of the tracing-frame U, and has a pin in the end at V, of such a size that it can drop into the notches in S, as they are brought under it by the revolutions of the ratchet-wheel, and so regulate the length of the division lines. The time of raising the ratchet must be when the stop-pin is raised out of the notch, by the motion of the traces backwards. To give motion to the screw, a stout fusee-chain is used, one-eighth of an inch broad, and one-fourteenth of an inch thick, which answers well; one end is attached to the ratchet-barrel W, round which it is wound five or six turns; the other end is attached to the crank-pin X. Near the lower end of the chain, at Y, is a small tube, containing a strong spiral spring, arranged like the common spring weighing-machine, but having a motion of only about $\frac{1}{8}$th of an inch; the spring must be so strong as not to give by the force required to turn the screw, but only to give a little when the ratchet comes up to the stop, and the crank is just passing the lower centre. Between the spring and the crank-pin is an arrangement for lengthening or shortening the chain, when it is arranged for making a larger or smaller division; for this purpose, two pieces of brass wire, about six inches long, having a screw cut on them their whole length, and each filed away one-half, and two small milled nuts, tapped with the same thread, are run on each; the two wires are laid together, and the nuts screwed up until they embrace both wires, as shown at Z, Fig. 213.

The crank-pin is fixed on a slide, projecting beyond the nut which fastens it, so that it may be extended, if necessary, beyond the circumference of the wheel, or by reversing, it may be brought quite to the centre. When the divisions are to have the long end towards the centre, a jointed lever, as shown at *a*, Fig. 215, is used. It is screwed fast to the cross-bar *b*, Figs. 214 and 215, directly over the eccentric O, and connected to the vertical framo U at *c*, and the stop-pin V is shifted to the other end of T, and the abutting piece *f* on U, is to be removed, when the eccentric O will act against the lever *a*, at *d*, and move the point in an opposite direction. The tracing-frame is made to follow the eccentric, by a weight and cord passing over a pulley and hooked to the vertical part of the tracing frame at *e e*, Fig. 215.

When the adjustment is made for dividing with the long end of the division lines, towards the circumference of the circle, all the wheels connecting the axis K with the axis B should be marked with a dot on the tooth and space in which it works, and a line should be drawn on the shafts E and H, and a corresponding mark on the sockets through which they pass, so that they may always be fastened in the same position. The axis K should have two short pins fastened on it, and notches in the ends of the sockets N and O, to fix them in their proper position when the lines are towards the circumference or centre, as the case may require. The slit in the crank-wheel A, in which the crank-pin is fastened, should also be graduated, showing the distance of the pin from the centre, for each degree, minute, and second that may be required in dividing.

By marking the position of each part of the machine in this way, much time and trouble will be saved in making the necessary changes for different kinds of dividing, whether it be in the number, or the direction in which the long lines are to be extended. The tracing point should be adjusted so as not to be raised more than about the thirtieth of an inch, or it will be liable, in descending, to make a small dot at the commencement of each line, which would injure the appearance. In the drawing, the eccentric N is represented as acting on the tail of the tracing-frame, but it is better to make it act on a steel pin in the side of the tail.

By this arrangement of the crank for turning the dividing-screw, the stops of the ratchet are brought in contact when the crank is passing its centres, and the motion of the screw is so slow, that it is not possible for the stops to strike so hard as to do any injury, and the dividing may be done with great rapidity.

AWLS. See Boring Tools.

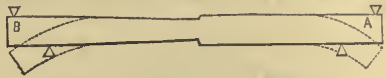
AXLE. A shaft supporting a wheel; the wheel may run on the axle, or be fastened to it, and the axle turn on bearings. For size and form of mill axles or shafts, see Gearing.

ON THE FORM OF RAILWAY AXLES. A very extensive course of experiments has been gone through by Mr. Thorneycroft, approximating as closely as possible to the forces on axles when in use, with a view to ascertain the best form to be given to axles, to enable them to resist fracture or deflection. The railway axle is viewed as having certain relations to a girder in principle. Girders generally have their two ends resting on two points of support, and the load is either located at fixed distances from the props, or dispersed over the whole surface; of the axle the wheels may be considered the props, and the journals the loaded parts. It is found that the inclined surface of the wheel tire given by coneing, ranges from 1 in 12 to 1 in 20, and, as a matter of course, the direct tendency of the wheels under a load is to descend that incline, so that every vertical blow which the wheels may receive is compounded of two forces, viz: the one to crush the wheels in the direction of their vertical plane, and the other to move the lower parts of the wheels together; it will be seen that these two forces have a direct tendency to bend the axle somewhere between the wheels.

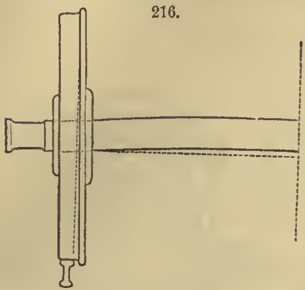
An axle reduced in the middle to $1\frac{3}{4}$ inch diameter, was placed upon two props 4 feet 9 inches apart, and loaded in the middle, the utmost of its deflection without a permanent set, was .232 inches, the load carried 7 tons. An axle reduced to 4 inches in the middle, and then placed upon the props 4 feet 9 inches apart, its utmost deflection without a permanent set was .281 inches, the load carried 9 tons. Another axle, but parallel $4\frac{5}{16}$ inches diameter, was placed upon the props 4 feet 9 inches apart, its utmost deflection without a permanent set, was .343 inches, the load carried 14 tons. Hence by reducing an axle of $4\frac{5}{16}$ inches diameter in the middle to $3\frac{3}{4}$ inches, its limit of elasticity is reduced from .343

inches to .232 inches, and the load, to produce that elasticity, from 14 to 7 tons. Fig.216, shows the position of the wheels to the rails when the bending of the axle has exceeded its elastic limit.

217.

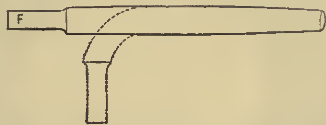


216.



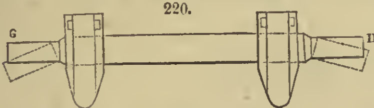
218.

219.



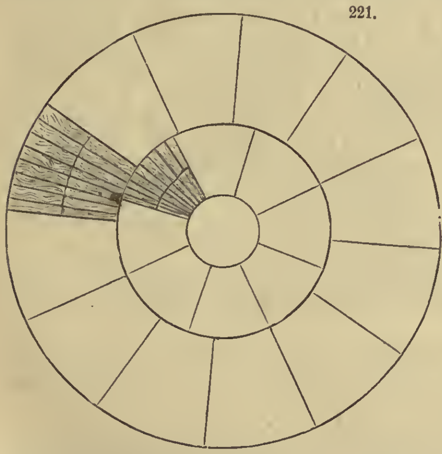
To ascertain what influence the reduction of an axle in the middle would have on its strength to resist sudden impact, compared to an unreduced one, an axle was made as represented by fig.217, which shows the end A, parallel to the centre, 4½ inches diameter, and the end B is drawn down from the back of the wheel towards the centre, where it is 4 inches diameter. The end A was then subjected to impact—the relative position of the prop and ram was the back of the wheel and the neck of the journal, this end received 46 blows of the ram, and bent to an angle of 18°. The end B was then subjected to impact—the prop and the ram in the same relative position, when it bent back to an angle of 22° with only 16 blows of the ram (as shown by the dotted lines in fig.217. The object of the third experiment was to ascertain what influence a shoulder behind the wheel would have on the strength of the axle at that part, compared to one without a shoulder. Figs.218,219, were one axle cut in two, and the end E was turned from the neck of the journal, leaving a shoulder ⅛th inch deep, as a stop to the wheel; the end F was turned from the neck of the journal to the same diameter, but no shoulder left. The end E was subjected to hydraulic pressure, the load being in a direct line with the shoulder, when it broke in two with a load of 60 tons. The end F was subjected in the same way to hydraulic pressure, when it bent into the form shown by the dotted lines, with 84 tons. To ascertain what influence the position of the wheel, in relation to the neck of the journal, would have on the strength of the journal under impact, fig.220, a piece of an axle with a journal taken down at each end was used; the end G was keyed into a cast-iron frame, the face of the frame in a line with the neck of the journal, the journal was then subjected to the impact of a ram, falling 10 feet. when it broke off at the seventh blow. The end H was keyed into the cast-iron frame in the same way, but with the neck of the journal projecting 1½ inch from the face of the frame, the journal was then subjected to the impact of the same ram falling 10 feet, when it broke at the 24th blow.

220.



From these experiments it is obvious that neither shafts nor railway axles ought to be reduced in the middle, but rather, if there is to be a departure from the parallel form, they should be made thickest in the middle, and thus effectually prevent any vibration or bending whatever.

221.



Railway axles are mostly made solid, those drawn under the hammer being better and safer than those that are rolled. Fig.221, represents the section of a fagoted axle, as constructed by the Brunswick Iron works, England; * the segments show the forms of the pile composing the axle. Fig.222, is a section of a hollow axle as constructed at the same works. Fig.223, a plan of the same axle with a portion taken off showing the cavity.

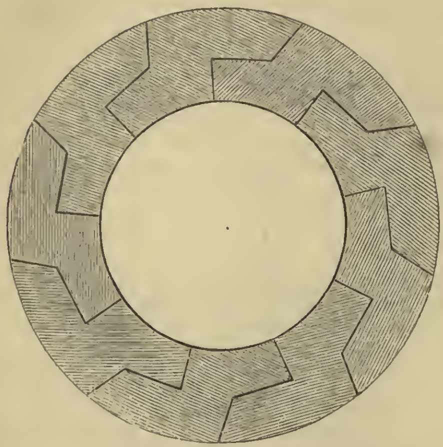
The selection of the tubular form of axle originated from the knowledge that, with a considerably less weight of material in the form of the tube, a much greater strength can be obtained to resist torsion, deflection by pressure or weight, or concussion from blows. The use of hollow axles was tried some years ago, but was not continued, the main objection being that there appeared a great difficulty of insuring, by the particular mode of manufacture adopted at that time, a sufficient uniformity of thickness of the sides of the tube through out, and also of the soundness of material. Since then a mode of manufacturing hollow railway axles has been introduced, which, it is believed, secures the utmost strength with the least possible amount of material, uniformity of structure of the iron, perfect equality of thickness of material, and soundness of manufacture.

The plan adopted is as follows: A number of segmental bars of the best quality of iron are rolled to

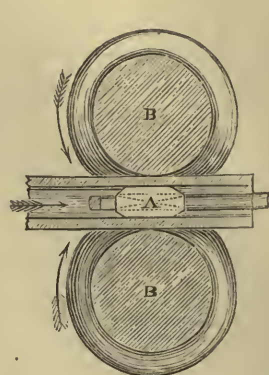
* Geo. W. Billings agent, 66 Broadway, New York.

a section, so as to form, when put together ready for welding, a complete cylinder about 1½ times the diameter of the axle when finished, the bars fitting correctly together, so as to have no interstices, and overlapping in such a manner as to insure a perfect and sound weld when completed.

222.



224.



223.

This cylinder of loose segmental bars is temporarily held together by a screw-clip, and each end being put into the furnace until a welding heat is produced, the bars are then partially welded together, and the clip removed. The whole cylinder is then placed in the furnace and brought to a proper welding heat: it is then passed through a series of rollers, B B, fig.224, which have each a mandril of an egg form A, in the centre of the circular opening, which is attached and supported on the end of a fixed bar, the bar being firmly secured at the opposite end to resist the end pressure of strain during the process of rolling. The mandrils are made of cast-iron, chilled, fitting on like a socket on the end of the bar to a shoulder, and they are secured by a screw-nut, so that they are easily removed when required.

The motion of the rolls is so arranged by a reversing clutch on the shaft, that as soon as the axle cylinder has been drawn clear through, the motion is reversed, and the axle which has been drawn on the mandril-rod, is again drawn back through the same openings in the rolls; it is immediately passed through the next smaller groove of the roll, with a decreased size of mandril, and again reversed back through the same groove in a similar manner, and so on through a series of grooves in quick succession, each decreasing in size, and consequently increasing the compression and strength of the iron of which the axle is formed; and by the last groove it is passed through, it is reduced to the proper diameter. At each time it is changed from one groove to another, the axle cylinder is turned by the workmen a quarter round, so as to equalize the pressure on every part of the surface, to insure uniformity of the compression of the iron, and thoroughly complete a sound welding throughout every part of the axle. The axle, after being welded and drawn down in the rolls to the proper size, is taken at once to a hammer, where it is planished between semicircular swages over its entire surface. A small jet of water plays upon it during this process, which enables the workmen to detect at once, by the inequality of color, any unsoundness in the welding. From the hammer it is taken to the circular saws, where it is cut accurately to the length required, and ready to have the bearing formed upon it. The ends are reheated, and gradually drawn down by a hammer to the proper dimensions and form of the journals, a mandril being inserted in the end of the tube during the process of hammering.

The weight of two axles of the solid description finished is, say 5 cwt., and if replaced with hollow axles of equal strength, the weight may be reduced 1½ cwt. Two different kinds of bearings are used, the parallel bearing with the rounded shoulder, and also the double conical bearing. In either description of bearing the hollow axle is good, although it is believed that the conical bearing for either the solid or hollow axle has less tendency to injure the texture of the iron during the formation of the journal than the parallel shouldered axle.

The experiments on transverse strength by a heavy weight falling on the centre of the axle, and giving the blow on opposite sides alternately, show that the hollow axle is nearly double the strength in that respect of the corresponding solid axle, the amount of bending being only 5 inches instead of 9¾ inches; and the number of blows required to break the hollow axle being 29, whilst the solid axle broke at the fifth blow, shows the hollow axle to be greatly stronger in resistance to fracture. The experiments on strength of journals show that, instead of the journals breaking off square and short at the shoulder, as in the solid axles, the hollow axle journal stands a considerably greater number of blows, and then only splits up longitudinally, instead of breaking off transversely, being a very important advantage in point of safety in working.

BACKING. In masonry, the filling in behind the face of the wall.

BACK-LINKS. The links in a parallel motion which connect the air-pump rod to the beam.

BACKWATER. Water in the race of a mill, and rising above the bottom of the wheel.

BAKING. See BREAD.

BALANCE, as applied to machinery, refers to parts in equipoise, as balance *Docks*, *Gates*, *Valves*, which, See.

BALANCE. A well known modification of the first order of levers, commonly called the beam and scales. See SCALES.

BALLASTING. A term applied to the covering of roads generally, and to the filling-in material, above, below, and between the several stone blocks and sleepers upon railways, &c.; it is laid for the purpose of keeping the road dry, as in the event of water lying upon it, the rails invariably sink, as it causes them to rest unequally. Ballasting is composed of gravel, broken stone, or the like, and is laid about two feet thick on railways, and it is generally from 6 to 12 inches thick on roads.

BALLISTIC PENDULUM. See GUNPOWDER.

BALKS. Long pieces of timber.

BALUSTERS. Small columns or rods capped by a rail.

BAR. A piece of timber or metal placed horizontally, and running across from one part of any framework to another.

BAR, (in navigation.) An accumulation of sand or shingle at the commencement or mouths of rivers, harbors, &c., being formed by the action of the tides.

BARBERY-WOOD. See WOODS, *varieties of.*

BAROMETER. An instrument used for observing the pressure and elasticity, or variations in density of the atmosphere. It is commonly employed for the purpose of determining approaching variations in the weather; and more scientifically for measuring altitudes. There are various modifications of the barometer, as the Diagonal, Horizontal, Marine, Pendant, Reduced, and Wheel Barometer; in all of which the principle of construction is the same—the only difference being in its application.

The essential part of a barometer is a well-formed glass tube, closed at one end, perfectly clear and free from flaws, 33 or 34 inches long, of equal bore, filled with pure mercury, and inverted, the open end being inserted in a cup partly filled with the same metal, so that the mercury in the tube may be supported by atmospheric pressure.

The vacant space between the top of the mercury and the top of the tube is called the Torricellian Vacuum, in honor of the inventor of the instrument.

On pouring mercury into the barometer-tube and inverting it, the air thus confined between the mercury and the inner surface of the tube, will escape into the Torricellian vacuum. In order to get rid of this air, as well as moisture, the tube is first gently warmed, so as to dry it thoroughly. A quantity of pure mercury is then poured in, so as to occupy two or three inches of the sealed end of the tube, which is held over the fire until the mercury boils, taking care to turn the tube round upon its axis, so that the heat may be equally applied. After boiling for a minute or two, the open end is closed by a cork to prevent the introduction of moist air, and the tube is then allowed to cool, in order that the cooled mercury which is next to be poured in may not crack the tube. When a second portion of mercury, about equal to the first, has been poured in, the part of the tube containing this new portion is held over the fire until it boils. It is again removed from the fire, and corked up as before. A third portion of mercury is then introduced, and the heat again applied to that part of the tube containing the last addition of metal; and in this way the tube is at length filled, with the exception of a small portion from which the mercury has been expelled by the heat. This is filled up with mercury, and the finger is now placed over the opened end so as carefully to exclude any air; the tube is then reversed into a cup of pure mercury; as the column sinks, it expels the last portion of mercury which had not been boiled; and as there is neither air nor aqueous vapour above the mercurial column, its length exactly measures the atmospheric pressure. A film of air is always retained on the outside of the tube, and also at its under edges, which film creeps by small portions at a time into the interior, and rises up in innumerable bubbles into the vacuum, the film being constantly renewed by the descent of more air between the outside of the tube and the mercury in the cup, and thus the outer air slowly insinuates itself into the barometer. In this way the most carefully constructed barometers have become deteriorated in the course of years.

This irregular and uncertain deterioration of barometers was remedied by Professor Daniell, by uniting a ring of platinum with the open end of the barometer-tube, so as to bring it into contact with the mercury, thus effectually preventing the ingress of air into the tube.

The same philosopher also invented a new mode of filling barometer-tubes, by pouring the mercury into the tube while both are under the exhausted receiver of a good air-pump. The mercury is poured through a long slender funnel extending to the bottom of the tube, and dipping into a small portion of mercury previously introduced, and boiled. By this means all agitation is confined to the tube of the funnel, and the tube left perfectly free of air. The mercury was afterwards boiled *in vacuo*.

The excellence of the barometer chiefly depends on the absence of all matter except mercury from the tube, and its value may be tested by three indications:—*First*, by the brightness of the mercurial column, and the absence of any flaw, speck or dulness of surface; *secondly*, by the *barometric light*, as it is called, or flashes of electric light in the Torricellian vacuum, produced by the friction of the mercury against the glass, when the column is made to oscillate through an inch or two in the dark; *thirdly*, by a peculiar clicking sound, produced when the mercury is made to strike the top of the tube. If air be present in the tube, it will form a cushion at the top, and prevent, or greatly modify, this click.

The sectional area of the tube is of no consequence, as the atmosphere presses with the same intensity upon the surface of the mercury in the cup, the column suspended in the tube will be of the same height, whatever its internal diameter.

The height of the mercurial column must be measured from the surface of the mercury in the cistern. When the atmospheric pressure increases, and the mercury in the tube rises, a portion of the metal is drawn out of the cistern into the tube, and the level of the mercury in the cistern is depressed so, on the contrary, when the atmospheric pressure diminishes, a quantity of mercury is forced out of the tube into the cistern, and the level of the metal in the latter rises.

In some instruments the scale, accurately divided into inches and parts of inches, is made movable, and terminates in an ivory point, which is brought down to the surface of the mercury. When this point and its reflection appear to be in contact, the height indicated by the scale is correct. In other forms of the barometer, the mercury in the cistern is always maintained at the same level, for which purpose the cistern is formed partly of leather, so that, by means of a screw at the bottom, the surface of the mercury may always be adjusted to the neutral point before taking an observation. The divisions of the scale usually begin at the 27th inch, and are continued to the 31st. But in instruments intended to measure the height of mountains, or for accompanying balloons, the scale begins at the 12th or 15th inch. Each inch is divided into ten parts, and these are subdivided into hundredths by means of a small sliding scale, called a *vernier* or *nonius*.

The words "Change," "Fair," and "Rain" engraved on the plate of the barometer, are calculated to mislead; in winter a fine bright day will succeed a stormy night, the mercury ranging as low as 29 inches, or opposite to 'Rain.' It is not so much the *absolute* height as the actual rising and falling of the mercury, which determines the kind of weather likely to follow.

The barometer ought to be fixed in a truly vertical position, and if possible with a northern aspect, in order that it be subject to as few changes of temperature as possible. It is usual, for the sake of comparison, to reduce the observations to 32°, for which purpose tables for correction for temperature are given in scientific works devoted to the subject of the barometer. The height of the cistern of the barometer above the level of the sea, and, if possible, the difference of the height of the mercury with some standard, should be ascertained, in order that the observations made with it should be comparative with others made in different parts of the country. Before taking an observation, the instrument should be gently tapped, to prevent any adhesion of the mercury to the tube; the gauge should be adjusted to the surface-line of the cistern, and the index of the vernier brought level with the top of the mercury.

Various contrivances have been made for increasing the length of the scale, or for making it more convenient for use. The most popular form is the common wheel-barometer, as it is called. In this instrument, the tube, instead of terminating at the bottom in a cistern, is recurved so as to form an inverted siphon. As a rise of the mercury in the longer or closed limb is equivalent to a fall in the shorter limb, and *vice versa*, a float is placed on the surface of the mercury in the shorter limb, and is connected with a string passing over a pulley, and very nearly balanced by another weight on the other side of the pulley. An index hand attached to the pulley moves over the surface of a dial-plate, graduated so as to indicate the oscillations of the mercurial column. With an increase of atmospheric pressure the mercury in the longer tube rises, and that in the short tube is depressed, together with the float, and this gives a small motion of revolution to the pulley, and also to the attached index hand. A fall in the longer column causes the mercury with its float in the short limb to rise, and consequently moves the index hand in the contrary direction.

The *measurement of heights* was the first useful purpose to which the barometer was proposed to be applied.

Although the atmosphere may extend to the height of 45 miles, yet its *lower half* is so compressed as to occupy only $3\frac{1}{2}$ miles, so greatly do the upper portions expand when relieved from pressure

Hence at the height of	$3\frac{1}{2}$ miles,	7 miles,	$10\frac{1}{2}$ miles,	14 miles,	&c.
the elasticity of the atmosphere is	$\frac{1}{2}$,	$\frac{1}{4}$th,	$\frac{1}{8}$th,	$\frac{1}{16}$th,	&c.

Halley was induced, by certain mathematical considerations, to fix upon the number 62,170 as a constant multiplier, and the rule for the measurement of heights may be stated as follows:—Observe the height of the barometer at the earth's surface, and then at the top of the mountain, or other elevated station; take the logarithms of these numbers, and subtract the smaller from the greater; multiply the difference by 62,170, and the result is the height in English feet. This process gives a very near approximation, especially in temperate climates.

But the progress of science soon rendered it evident that a correction for temperature was necessary in barometrical measurements, and a formula has been contrived to meet most of the difficulties of the question. The following rule will be found of easy application:—Multiply the difference of the logarithms of the two heights by the barometer, by 63,946; the result is the elevation in English feet. Then, in order to correct for temperature, take the mean of the temperature at the two elevations; if that be 89·68° Fahr., no correction is necessary; if above that quantity, add $\frac{1}{450}$th to the whole height found for each degree above 69·68°; if below, subtract the same quantity. For example: Humboldt found that at the level of the sea, near the foot of Chimborazo, the barometer stood at exactly 30 inches, while at the summit of the mountain it was only 14·85. The logarithm of 30 is 1·4771213, and the logarithm of 14·85 is 1·1717237; then subtracting

$$\begin{array}{r} 1{\cdot}4771213 \\ 1{\cdot}1717237 \\ \hline 0{\cdot}3053976 \end{array}$$

Multiply this by 63,946, which produces 19,539 for the elevation in feet. If the mean temperature of the two stations were 69·68°, no correction is necessary for temperature. This is a tolerably close ap

proximation: the most careful calculation has given 19,332 for the real height, and this was probably estimated for a lower temperature.

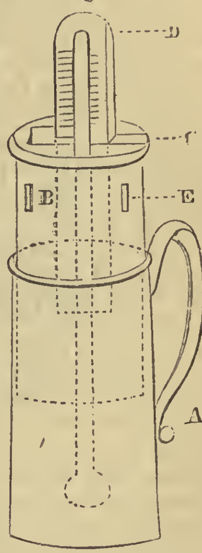
A method has been given by Leslie for measuring heights without the use of logarithms. His rule is as follows:—Note the exact barometric pressure at the base and the summit of the elevation, and then make the following proportion:—As the sum of the two pressures is to their difference, so is the constant number 52,000 feet to the answer required in feet. Suppose for example the two pressures were 29·48 and 26·36; then

As 29·48 + 26·36 : 29·48 — 26·36 : : 52,000 feet : 2,905·4 feet, the answer required.

This rule has been found applicable to the mean temperature of England for all heights under 5,000 feet.

Another method of obtaining approximate differences of altitude, is by a comparison of the *temperatures* of boiling water (which vary with the pressure of the atmosphere). The apparatus is exceedingly simple, and the instrument not so liable to injury as the mercurial barometer, being much more portable, and easily replaced. A. Common tin pot 9 inches high, by 2 in diameter. B. A sliding tube of tin, moved up and down in the pot; the head of the tube is closed, but has a slit in it. C. to admit of a thermometer passing through a collar of cork, which shuts up the slit when the thermometer is placed.

Fig. 1



D. Thermometer with so much of the scale as may be desirable.

E. Holes for the escape of steam.

The boiling point for the level of the sea should be correctly marked by a number of careful observations, and the difference, if any, must be noted as an index error.

These thermometers are very useful in ascertaining heights where strict accuracy is not required, and they have the advantage over mercurial barometers in being portable. In moderate elevations, the difference of *one degree* in the temperature at which water boils, indicates a change of level of *about* 500 *feet*, corresponding to a difference of 0·6 of an inch in a mercurial barometer. See ANEROID.

BAR-WOOD. See WOODS, *varieties of.*

BARREL, (of a drum-wheel.) The cylindrical body or axle round which the rope is rolled.

BARREL, (of a pump.) The cylinder, or hollow part of the pump, in which the piston works.

BARROW. See WHEEL-BARROW.

BARYTES, found in tolerable abundance in Wales, and some parts of England, and also in the State of Connecticut. The salts of barytes employed in the arts and manufactures, are confined to the carbonate and sulphate. The use to which the native carbonate has been applied is the preparation of the various salts of barytes, which are made by saturating the respective acids with the powdered native carbonate.

An artificial carbonate is used in Birmingham in the manufacture of plate and flint glass, as a cheap substitute for part of the alkali. It is also used in the manufacture of porcelain, jasper, &c.

Sulphate of Barytes is employed as a pigment and also for the purpose of adulteration. It is known as "permanent white," and is made by precipitating the sulphate from a soluble salt of barytes, by means of sulphuric acid, which when washed and dried forms a beautiful white powder, that is not acted upon by sulphuretted hydrogen gas. It is to this that it owes its superiority over white lead as a water-colour. Oils destroy its whiteness, and render it nearly transparent; so that it is only useful as a water-colour.

The sulphate of barytes used in adulterating white lead is made by levigating the whitest varieties of the native sulphate, and afterwards bleaching it by boiling with dilute sulphuric or muriatic acid, for the purpose of dissolving out any iron which it may contain. When washed and dried it forms a dense white powder. Some of the native sulphate is sufficiently pure as not to require the bleaching process. That which is white and soft, possessing little or no crystalline structure, is preferred by the manufacturer, being easily reduced to powder. The presence of barytes in white lead can easily be detected by dissolving out all the carbonate of lead, by dilute acetic acid. The sulphate of barytes being unacted upon, can then be washed, and the quantity ascertained by weighing.

BASE LINES, (in surveying.) The main lines of a survey, upon which the correctness of the whole depends; it is therefore necessary to proceed with the utmost care in the laying out of the several base lines of a survey.

BASE LINE. (In perspective.) The intersection of the plane of the picture with the ground plane.

BASKET. A kind of vessel made of osier, wicker, rushes, straw, whalebone, &c. The weaving of baskets is entirely hand work, but simple machines are used in the splitting of the materials. For strong, heavy baskets, strips of ash are considered the most serviceable.

BASE. A rest or support; particularly applied to the bottom of columns, pedestals and edifices.

BASES. In chemistry, a term applied to all the metals, alkalis, earths, and other bodies, which unite with acids, or with gases. Thus in sulphate of copper, the copper is said to be the base of the salt, from the supposition that the non-acid principle is that which gives diversity or distinctness of character to compounds. The term is now retained from its convenience, rather than the truth of the above opinion.

BAT. The name given to a half or other portion of a brick.

BATTENS. Strips of board or plank, from $1\frac{1}{2}$ to 6 inches wide, nailed over the joints of other boards; often ornamented with a bead or corniced to give architectural effect on the cheaper class of houses. Batten doors are such as are made of two thicknesses of boards nailed together; generally the boards are nailed crossways of each other, but often diagonally.

BATTER. The face of a retaining, or other wall, when built in a leaning position, the top part falling back within the line of base; walls of this description are sometimes termed *tallus walls*. The usual batter is from 1 to 3 inches horizontal for each foot in vertical height. See MASONRY.

BATTERY. Two or more pieces of artillery, united for the purpose of dispersing troops, or destroying that which covers and protects them. It is also used to signify the equipment of a certain number of pieces of ordnance.

BAY. In architecture, the space between the beams or arches. A part of a window between the mullions is often called a bay or day.

BAY-TREE. See WOODS, *varieties of.*

BEAM, in building, usually a horizontal piece of timber or metal. For the proper form of simple beams to resist the required strains, see STRENGTH OF MATERIALS—for the relation of the parts of a trussed beam, see BRIDGE. The term working or walking beam is applied to the balance lever, transferring the power from the piston of common draught engines to the crank. See ENGINE.

BEARING. That part of a shaft or spindle which is in contact with the supports. See GEERING.

BEARING. The distance that a beam or rafter is suspended in the clear between supports.

BED. A term used in masonry to describe the direction in which the natural strata in stones lie; it is also applied to the top and bottom surface of stones when worked for building.

BED-MOULDINGS. A collective term for all the mouldings beneath the corona or principal projecting member of a cornice.

BEECH. See WOODS, *varieties of.*

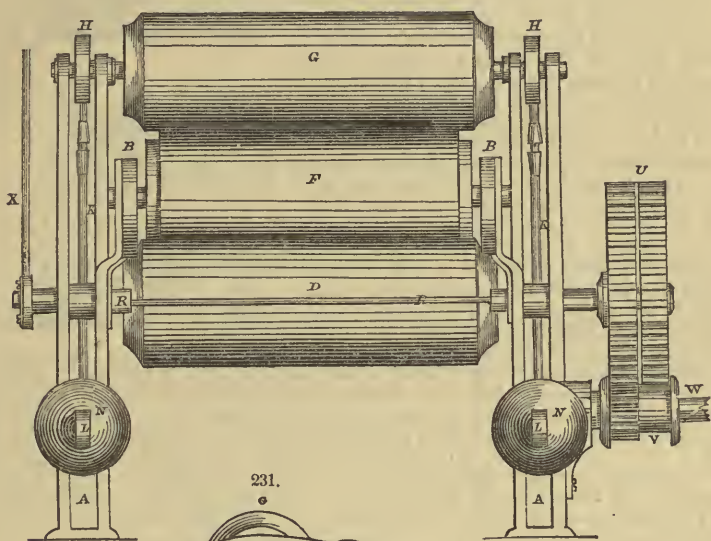
BEEF-WOOD. See WOODS, *varieties of.*

BEETLE. A heavy wooden mallet or rammer.

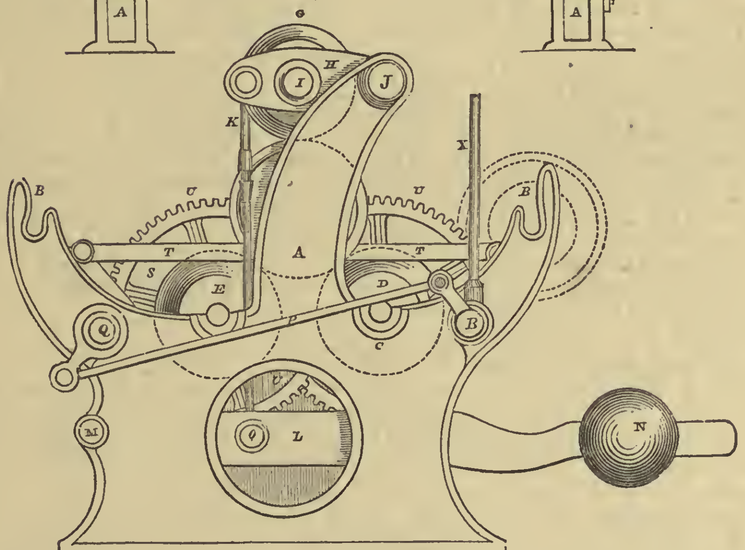
BEETLING MACHINE. A machine used in bleacheries to give to cotton fabrics a soft, glossy appearance. The usual form consists of a cylinder, on which, as the cloth is rolled, it is beaten by stampers similar in their construction to those used in gold crushing; see METALLURGY. An invention has been made to give the same finish by rolls as in a calender, of which the following is the description. The accompanying engravings represent at Fig. 230 a front elevation, and at Fig. 231 an end elevation of the above-mentioned machine, with the same letters of reference applying to similar parts. A A are cast-iron standard frames, having side-claw projecting bearings B B, Fig. 231, with two central horn-shaped ones A^1, carrying the pressure-lever links; C C are bush-bearings for the journals of the beetling rollers D and E, which rotate horizontally with each other in opposite directions; F F is the roller upon which the cotton fabrics, about to undergo the beetling process, are wound; G G is the pressure-roller, mounted in the lever-link motion-head H H, upon the central horn-standard *j*, in a manner subsequently explained; I is the shaft upon which the pressure-roller revolves; K K two connecting-rods on each side of the machine, attached in vertical positions at the top to the links H H, and at their lower ends to the weighted levers L L; M is the centre stud, upon which the levers L L radiate; N N are two spherical-shaped balls or weights, for giving pressure to the roller G, through the medium of the levers L L, assisted by their own gravity; O is the bearing on which the connecting-rods K K move; P is an intermediate crank motion-rod, coupling the two way link-shafts V R, and giving motion horizontally to the longitudinal rest-bars T T, through the quarter-way links S S, in gear with the same; U U are two spur-wheels, mounted upon the beetling roller-shafts D and E, in gear with a pinion V, on the driving-shaft; W X is a long hand-lever, the object of which is to raise the different rollers from their beds by it in the manner hereafter explained. Having thus far described the various arrangements and parts of which this invention consists, it is necessary to explain its mode of working, and the numerous advantages that may result from its application to the various purposes for which it is intended. Steam, or other motive power, is in the usual manner first applied to the driving-shaft W, which is mounted in a bracket bearing against the standard-framing, as represented in the engraving; whilst the other end is similarly mounted against a wall or other convenient place, and when driven by the action of steam, it causes the pinion V, on the end, which takes into the spur-wheels U U, to propel the same, and thereby give the required motion to the machine or apparatus during the process of beetling. It must be observed, that the cotton fabrics about to be mangled or beetled, are first wound upon the roller F; to accomplish which, the roller has to be removed or taken out of its place, which is performed in the manner hereafter explained. Having completed the operation of winding the cotton on the rollers, it is then passed between the beetling-rollers D and E, which are furnished with peripheries, such as are seen in the two smaller engravings annexed; these are embossed, or checkered in different patterns corresponding to the rollers employed. The fabrics are then taken from the rollers and replaced by others, during the working of the machine, and the operations effected. The pressure to which the fabrics are exposed by the constant rotation of the rollers between which they pass, is produced and carried into effect as follows:—The roller G G, with its moveable link-bearings on each side, centred on the horn-shaped standards, are caused, through the medium of the side connecting-rods K K, to receive the entire weight of the levers L L, in addition to the weights H H on the ends, and consequently offer a sustaining pressure to the fabrics during the process of beetling. On the other hand, when it becomes necessary to supply the apparatus with plain cotton fabrics, and remove those already beetled, the levers L L, which are represented as having holes at one end for the employment of any suitable or convenient tackle, are to be by such means raised, the action of which will have the effect of raising also the head-links and pressure-roller, and thus, by removing the weight, enable the roller beneath to be lifted out of its seat, and placed in one of the end claw-bearings B B, as represented by the dotted lines. The mode of effecting this part of the operations will

be readily comprehended by reference to the engraving, Fig. 231, where T T shows a bar of iron horizontally placed on each side, beneath the journals of the roller F, forming a rail or table upon which they are to be moved. When a downward motion of the lever handle is given by the operator, it causes the coupling-rod P, through the medium links P R, in connection with others on the same shaft, in gear with the rest-bar T T, to move upwards horizontally, similar to the action of a parallel rule, and raise the rollers F or B out of, or into their respective places, by enabling the rollers to be rolled along them, when disengaged from their bearings or seats, and carefully lowered into their places, in readiness for the next operation. From these observations it will be seen that, first, the levers L L are to be raised in the manner which will cause the roller G G to be also raised, through the medium of

230.



231.

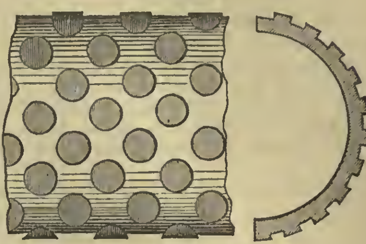


the connecting-rods K K, when the pressure will be removed from the lower rollers, and which will enable them to be raised to the required height, so as to transfer them from one seat or bearing to another, and thus allow the fabrics to be changed by removing those already having undergone the process, and supplying the other roller with plain ones. The patentee, although he describes and sets forth the employment of the side-levers, yet does not confine himself exclusively, as other and equally effectual means may be applied with the same advantages, such as steam pressure, liquids, or otherwise; and in many cases the weight of the rollers themselves might be found sufficient to give the required pressure without the intervention of additional pressure.

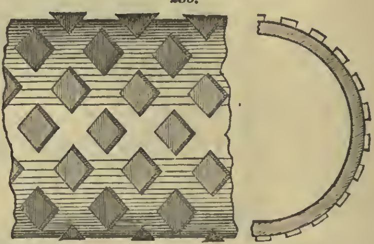
The next object to which the patentee directs attention, is to the improved mode of constructing roller-mangles, which consists of very nearly the same arrangement of rollers, the only apparent difference being, the introduction of a flexible lever or spring, firmly fixed to the standards upon which

the pressure-roller is mounted, being brought to act upon the same to any degree of force, by the application of a hand-wheel and screw-spindle, supported in bearings, suitably arranged. To the end of the screw-spindle two fixed studs are attached, between which the lower end of the flexible lever or spring is introduced, so that when the spindle is screwed to or from the centre of such standard, carrying the roller, the pressure is applied by reason of the standard moving from a centre with the roller under an elastic pressure thus given by the forward or backward application of the screw hand-wheel spindle. The patentee states that cast-iron rollers may be employed for dry articles, but for damp ones, bell-metal would be found better adapted. One of the advantages derived from this system of mangling is the small space the machine occupies, together with the accommodation which it offers by being placed within a piece of furniture having drawers for the purpose of disposing of the various articles when so mangled, and thus forming a very useful piece of furniture, and which may, if necessary, be rendered highly ornamental in place of the present incommodious machine now in use. The same principle also extends to a portable description of mangle, which the patentee states may be temporarily set up on a table or dresser, and made to answer all the purposes for which it is intended, motion being given to it by hand-levers in the usual manner, but employing, as a means of giving pressure, a lever, as in the first-mentioned instance; but with this difference, that the connecting-rod K, in the beetling apparatus, has in this instance a rack and pinion as a means of adjusting it, so as to obtain the requisite pressure. The patentee, after describing the peculiar forms given to the several rollers comprising a series of different patterns, and the best means of constructing them and forming the corrugations or indentations upon them, would wish it to be distinctly understood, that he claims as new and of his invention:—First, the employment of rollers having indented, grooved, checkered, or undulated surfaces or peripheries, for producing by pressure corresponding marks or impressions therewith upon cotton or other fabrics. Secondly, for the general arrangement of parts constituting the action and construction of the said improved machinery. Thirdly, for the employment of water or other fluids within the aforesaid rollers, to act independently of other pressure apparatus, such as the long levers in Figs. 230 and 231, of the annexed engravings; also for the application of steam to such purposes, causing, in the usual manner by its expansion within a cylinder, a pressure to be exerted upon the rollers, and at the same time that such application should be available for the purposes of taking off and removing the pressure when required, the same means employed for the one shall be found effectual in performing the other. Fourthly, and lastly, for the use of the numerous patterns as applied to cylinders employed in the process of beetling, or to other like machines or apparatus, either for mangling, or otherwise, as hereinbefore fully detailed. See CALENDERS.

232.



233.



BELLS. The bell of the Montreal Cathedral is the largest in America. Its proportions are as follows:—diameter at mouth, 8 ft. 7 in., at shoulder, 4 ft. 8 in. Height to shoulder, 5 ft. 11 in. The thickest part, or sound bow, is 8 inches. Weight $13\frac{1}{2}$ tons. See CASTINGS AND FOUNDINGS.

BELL-CRANK. A bent lever or arc, used chiefly in the hanging of bells, to allow the wire to accommodate itself to the alteration of motion requisite in turning corners.

BELL-METAL. See METALS AND ALLOYS.

BELT, in building, a string-course and blocking-course; a course of stones projecting from a wall, either moulded, plain, fluted or enriched.

BELTING. A belt is a band or strap, passing from one pulley over another, serving to convey motion between shafts. Belting is usually employed at speeds varying from 300 to 5,000 feet per minute. The size of the belt will depend on the power to be transmitted. A certain degree of tension, varying with the width of belt and size of pulley, and, to a considerable degree, with the tractive nature of the surface of the pulley, as well as the amount of resistance, is required to prevent slipping. This force or tightness may be equal throughout its parts, while the machinery is at rest, but when in active operation, it becomes far otherwise. It is evident that the only force tending to induce motion in the driven pulley is the difference in tension between the two parts of the belt. A portion of the belt extends from opposite sides of the pulley, in nearly parallel directions, and each portion tends by its pull to turn the pulley in opposite directions. If the driven shaft is performing any work, there must necessarily be a difference in the tension of the parts, and this, however rapidly the belt may be moving, so that every portion is alternately exposed to a greater and a lesser strain. It is also equally plain, that other things being equal, this difference in strain is directly proportioned to the amount of work or power which is transmitted. This strain is then determined by dividing the power to be transmitted by the velocity; thus, if a belt moving at a velocity of 1500 feet per minute, be required to transmit 5 horse power; that is, $33000 \times 5 = 165000$ lbs. ft.; then $\frac{165000}{1500} = 110$ lbs., the strain on the belt to convey the power. In addition to this strain, it must be remarked, that the belt is stretched on the pulleys, so that it does not slip while conveying the power. The strain given above may be considered approxi-

mately as the difference of tension between the two sides. Morin gives the following Table to deter mine the strain on each side of the belt.

Portion of the circumference embraced by the belt.	VALUE OF K.			
	New belts on wooden drums.	Ordinary belts		Wet belts on iron pulleys.
		On wooden drums.	On iron pulleys.	
0.20	1.87	1.80	1.42	1.61
0.30	2.57	2.43	1.69	2.05
0.40	3.51	3.26	2.02	2.60
0.50	4.81	4.38	2.41	3.30
0.60	6.59	5.88	2.87	4.19
0.70	9.00	7.90	3.43	5.32
0.80	12.34	10.62	4.09	6.75
0.90	16.90	14.27	4.87	8.57
1.00	23.14	19.16	5.81	10.89

Application of the table.—Find in the table the value of K according to the given circumstances; from this number subtract unit or one, and divide the strain on the belt to convey the power by this remainder, and the quotient will be the minimum tension or that on the *slack* side. Add to this quotient 10 per cent. for friction due to shafting, or other causes. The tension on the leading or *tight* belt will be the above product added to the strain, as given by the power required to be conveyed.

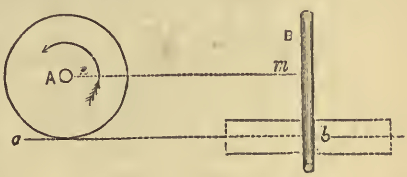
Applying this to the example above of a strain on the belt of 110 lbs. with the ordinary belt embracing $\frac{1}{2}$ or 0.50 of the circumference, the value of K in the table is 2.41; subtract 1, = 1.41; 110 divided by 1.41 = 78 lbs.;

78 + 10 per cent. or 78 + 7.8 = 85.8, the tension on the slack belt.

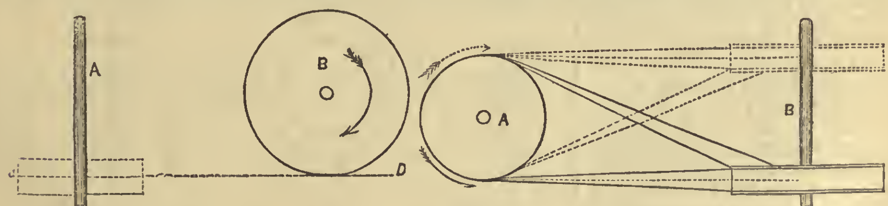
85.8 + 110 = 195.8, the tension on the tight belt.

Good belting of an ordinary thickness of $\frac{3}{16}$ of an inch should sustain a strain of 50 lbs. per inch of width without risk, and without serious wear for a considerable time. Therefore, in the example above, the belt moving at a velocity of 1500 feet per minute, required to transmit a power of five horses should be $\frac{195.8}{50}$, or very nearly 4 inches in width.

When the belt is shifted, whilst in motion, to a new position on a drum or pulley, or from fast to loose pulley, or *vice versa*, the lateral pressure must be applied on the *advancing* side of the belt, on the side on which the belt is approaching the pulley, and not on the side on which it is running off. It is only necessary that a belt, to maintain its position, should have its advancing side in the plane of rotation of that section of the pulley on which it is required to remain, without regard to the retiring side. On this principle, motion may be conveyed by belts to shafts oblique to each other. Let A and B (fig. 261) be two shafts at right angles to each other, A vertical, B horizontal, so that the line run perpendicular to the direction of one axis is also perpendicular to the other, and let it be required to connect them by pulleys and a belt, that their direction of motion may be as shown by the arrows, their velocities will be as 3 of A to 2 of B. On A describe the circumference of the pulley proposed on that shaft; to this circumference draw a tangent $a\,b$ parallel to $m\,n$, this line will be the projection of the edge of the belt as it leaves A, and the centre of



the belt as it approaches B; consequently, lay off the pulley b on each side of this line, and of a diameter proportional to the velocity required. To fix the position of the pulley on A, let fig. 262 be an



other view taken at right angles to fig. 261, and let the axis B have the direction of motion indicated by the arrow, then the circle of the pulley being described, and a tangent $a'\,b'$ drawn to it perpendicular to the axis B as before determined, the position of the pulley on the shaft A is established.

The position of the two pulleys are thus fixed in such a way, that the belt is always delivered by the pulley it is receding from, into the plane of rotation of the pulley towards which it is approaching. If

the motion be reversed, the belt will run off; thus (fig. 263), if the motion of the shaft A is reversed, the pulley B must be placed in the position shown by the dotted lines.

It is not an essential condition that the shafts should be at right angles to each other to have motion transferred by a belt. They may be placed at any angle to each other, provided the shafts lie in parallel planes, so that the perpendicular drawn to one axis is perpendicular to the other. If otherwise, recourse must be had to guide-pulleys, which should be considerably convex on their face.

It is to be observed that the faces of pulleys are generally made more or less convex, as the tendency of a belt in motion is to mount the highest part of the pulley; by a slight rounding of the face, therefore, the belt preserves its proper position.

BENCH, or BERM. A ledge on the face of a cutting.

BENCH MARKS, (in surveying.) Fixed points left on the line of survey, for reference at any future time, consisting of cuts in trees, pegs driven in the ground, and the like.

BENDING OF TIMBER. See Woods, *varieties of.*

BENZOLE. An oil prepared from coal tar, extremely volatile: if a stream of air be passed through a reservoir of Benzole, it will imbibe enough of the vapor to become an inflammable and luminous gas. On this principle many arrangements have been patented for illumination of buildings by benzole, but as yet the manufacture of benzole is too expensive.

BETON. See Mortar.

BEVEL, any angle except one of 90 degrees. The term bevel is also applied to an instrument for drawing angles, in general use among workmen. In construction, it somewhat resembles the common square, with this difference, that the blade is movable about a centre in the stock, so that it can be set at various angles.

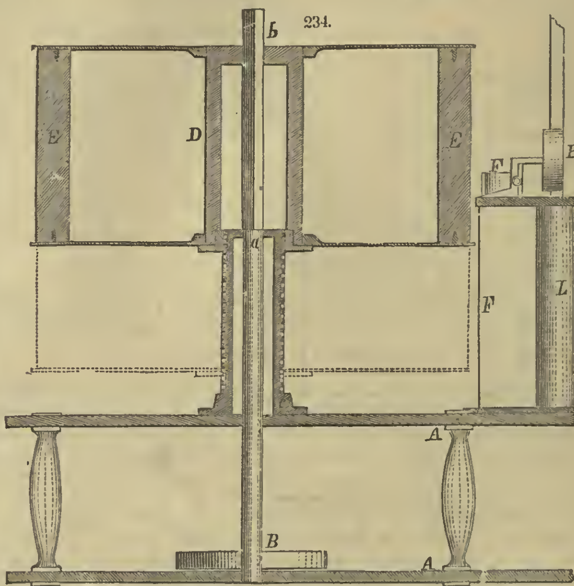
BEVEL WHEEL. See Geering.

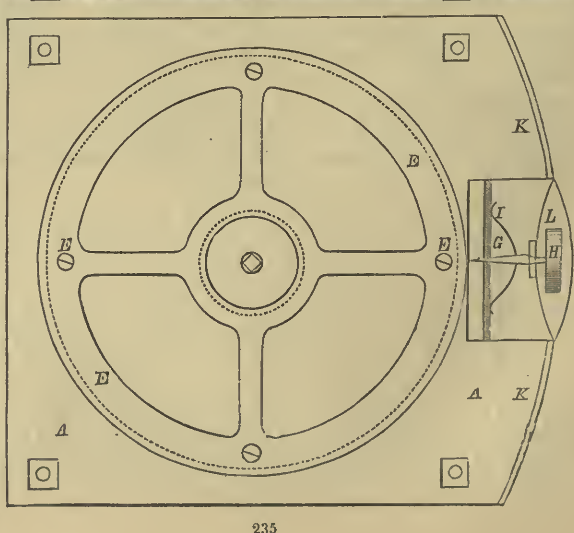
BINNACLE, a box near the helm, containing the compass.

BIRAM'S TELL-TALE. *Description.*—Fig. 234 is a side elevation in section, and Fig. 235, a plan of the apparatus, (on a scale a little less than half size.)

A A is the frame, supposed to contain the works of a portable timepiece, of which B is the fusee; C is a hollow screw, fixed upon the frame A, through which the axle of the fusee is prolonged, being supported by, and turning in a circular opening at *a*, above which the axle is square, the diagonal of the square being equal to the diameter at *a*; D is a hollow tube, having a female screw fitted into the bottom, to turn easily upon the male-screw C; the top of the tube D has a square opening to fit easily upon the square end of the axle of the fusee; which axle should project about half an inch beyond the tube D, when in the position shown in the figure, to receive the key or handle used in winding up the timepiece; E is the barrel or cylinder, round which the registering paper is placed, which should be made to fit upon the tube D, sufficiently tight to retain its position wherever placed, but capable of being easily turned round upon the tube, or slightly elevated or depressed, for the purpose of adjusting it to the index F, to show the time of the day, and also to adjust the registering lines with the pricker G. F, the index showing the time, is a fine wire, placed vertically as near as possible to the cylinder, the ends being secured in a frame attached to A. The top of the frame also carries the pricker G, placed exactly over the wire F, which is acted upon, and makes an

234.





235

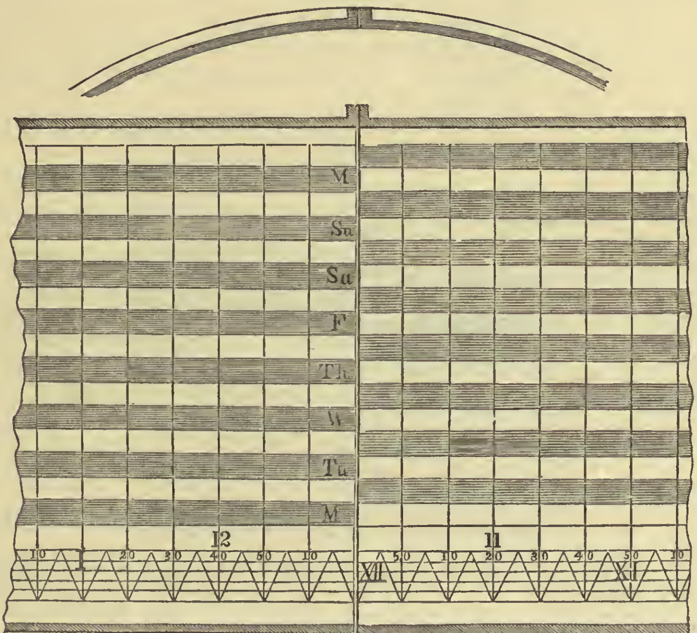
impression upon the registering paper, when a finger is pressed upon the stud H; I shows a slight spring, intended to return the pricker and stud to their position when the finger is removed; L is a piece of glass in front of the timepiece, the horizontal section of which is that of a double convex lens, but the sides vertically are parallel with each other; this magnifies the parallel and diagonal lines upon the paper which show the minutes, *horizontally* only, showing the time more distinctly to the fraction of a minute; K K are two pieces of plane glass, on each side of L, for the purpose of throwing more light upon the barrel.

Fig. 236 shows a portion of the registering paper, of the full size, with the shaded lines upon it indicating the days of the week; this paper is of exactly the circumference of the cylinder, and is put upon a strip of leather, gutta percha, or other flexible material, also of the length and width of the barrel, to each end of which is riveted a strip of brass, having a projection on each side to catch into a notch in the projecting flanges of the barrel. When the registering paper is changed, the barrel may be taken off from the tube D, and the leather and paper from the cylinder; and then a new paper put on, the ends of the paper being turned underneath the leather, and retained by any adhesive application, such as that made use of in postage stamps.

The registering paper is divided vertically by twelve equidistant parallel lines, representing the hours, and again subdivided between each of the above lines by other finer lines into ten minutes. On the lower edge of the paper are five parallel lines crossed by two diagonal lines between each of the above subdivision or ten-minute lines, by which each subdivision is again divided into minutes, the time of the day being shown by the point when the index wire F intersects these small parallel and diagonal lines. The shaded lines representing the days of the week are not drawn parallel with the edge of the paper, but in such a manner that when the paper is fixed round the barrel the shaded lines at one end of the paper fit opposite the intervals at the other end, these shaded lines and intervals being each exactly equal in width to the pitch of the screw C.

Now, suppose the timepiece newly wound up, and a new registering paper placed upon the barrel at midnight on Sunday: (of course this untimely hour is not necessary, as the operation may be done at any time of the day.) The barrel will then have been removed from the position shown by the dotted lines in Fig. 234, to the shaded part above in the same figure, and the pricker G would then be oppo-

236.



site the commencement of the underside of the line M, (Fig. 236,) and every part of the underside of that line would by 12 at noon have passed under the point of the pricker; when the barrel having made one revolution would also have descended one thread of the screw, and during the next revolution the upper side of the line M, representing the afternoon hours of Monday, would have passed under the pricker, and so on through the week; the lower side of the line representing each day passing under the pricker during the forenoon, and the upper side on the afternoon of such day. It is therefore obvious, that any impression made upon the paper by the pricker, would show the day and the exact time of day when such impression was made, and when the paper was removed from the barrel the punctures remaining upon it would be an enduring testimony, to be consulted and checked at leisure, of the operations recorded upon it during the week.

The uses to which this tell-tale might be applied are various. If as a watchman's clock, it may be used by several people who are required to be at a certain spot at certain or uncertain intervals. When a person presses upon the stud, he should be required to make a memorandum of the time by the clock

these memoranda he would give up to the inspector at the end of the week, who would compare whether the punctures upon the paper corresponded with the return; and if not, the writer would of course be detected making a false statement. In an establishment where there are a number of individuals, and it is desirable to ascertain the time of their attendance, they might be required to write their names, and the time of their arriving, in a book, at the same time pressing the tell-tale; when, although several might arrive and sign so near together that the punctures upon the paper might run one into another, yet the time between the first and last would be distinct, and if the names were written in succession, it would be evident that they had been written during the time between the first and last puncture. Again: any individual leaving an establishment during the day, might be required to write his name in the same way, with the time of his leaving and returning, at each time pressing upon the tell-tale, which would be a great check against a person absenting himself improperly, or being absent too long. It might also readily be applied to registering the performance of a steam-engine, or other machinery, by so connecting it with the machinery that the pricker should puncture the paper after a certain number of strokes of the engine, or otherwise.

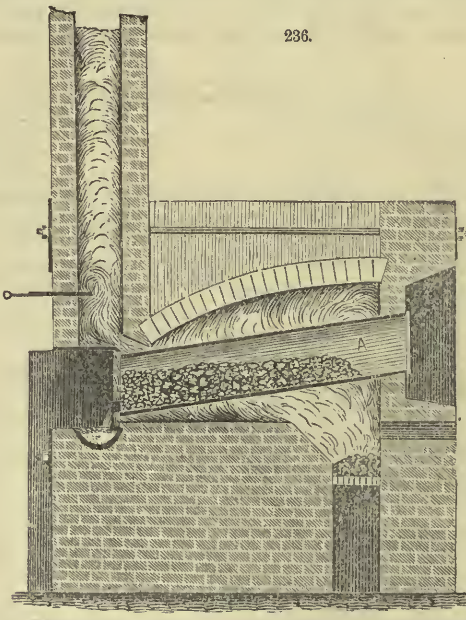
The tell-tale, as in the engravings, is shown attached to a portable timepiece, regulated by a balance escapement; but it is applicable also to a common eight-day clock, with slight modifications.

BIRCH. See Woods, *varieties of.*

BISMUTH, is a rare metal, but its distinguished qualities are that it is very fusible, and causes other metals to become so. It melts when pure at 480°; it may be distilled in a close vessel, and then crystallizes in laminae. It is very brittle, like antimony, and of a brilliant lustre; its color is white, tending to flesh-color. Its specific gravity is 9·83, which may be increased to 9·88 by hammering. It expands in the act of cooling, which renders it peculiarly suitable for castings.

The operation of smelting bismuth is extremely simple; the metal having but a weak affinity for other substances is obtained by simply heating its ore in a modern liquation furnace, Fig. 236. A, is a

236.



cast-iron retort, at the highest part of which the crude ore is charged. B shows a cast-iron bowl into which the metal flows. About half a cwt. of broken ore is charged in each retort, of which there are four in a furnace side by side. This quantity nearly half fills a retort, so that the upper part of it is empty. The lower end of it is closed with a clay plate, or slab, provided with an aperture for the discharge of the melted metal. The pipes, when properly heated, soon cause the metal to flow into the dish B, which contains some charcoal-dust. By applying a brisk fire and some stirring to the ore, all the metal contained in it is obtained within half an hour. The residuum of the ore is now scraped out of the retort into a trough with water, and the pipes are filled afresh. About a ton of ore is smelted in a day of eight hours. The metal is remelted, cast into iron moulds in the form of ingots, and is now ready for the market. See Metals and Alloys.

BLAST-FURNACES. See Iron.

BLASTING. The operation of detaching and separating blocks of stone or earth from their natural or quarry beds, which was usually performed in former times by the following process:—Long wooden wedges were driven, in a very dry state, into holes prepared for them, and previously well heated; a quantity of cold water was then poured over the wedges, which, upon becoming thoroughly saturated, swelled and caused a fracture of the rocks. The same effects are now generally produced by the ex-

ploding force of gunpowder, which was first used for that purpose about the year 1620. A hole is first driven into the stone by a jumper, or chisel, which is held in a proper direction by one man while another strikes it with a hammer, the former turning his instrument at every blow, to form a round hole; sunk to various depths, from 1 to 3 feet, according to circumstances. If water appears in the hole, some stiff clay is crammed in, by which it is absorbed, and the fissures through which it entered filled up. When the hole is of some considerable size, and of great depth, a long runner succeeds the jumper, 6 or 8 feet long, and chisel-pointed at both ends, which is lifted up and dropped into the hole, and being heavy, perforates the rock. For deep holes a second longer runner succeeds the first. When sufficiently deep, the hole is charged with powder, and a small taper rod or needle of copper is inserted, so as to reach the bottom of the hole; the remaining space is *tamped* or filled up with broken bricks and clay; the needle is now withdrawn, and the vent thus formed filled with fine powder, which is ignited by a match.

Since the introduction of the safety-fuse, the copper needle is dispensed with, as well as the tamping bar, by the use of which premature explosions were frequent. The safety-fuse is made by machinery. String is coiled so as to form a cylinder, which receives the powder specially manufactured for the purpose, and by a continuous operation the fuse is formed in coils of any length. In practice, the charge of powder is placed in the hole and the required length of fuse carried down to it; the hole is then filled slowly with dry sand and tamped with a pointed stick. The fuse is left projecting sufficiently above the hole to be readily lighted, and of length enough to enable the workmen to withdraw before the explosion.

In blasting operations of magnitude, the steam drill is effectively employed. See Drill.

When it is desired to move large masses of rock, as in excavating ledges, it is usual to open a seam, as it is termed; this is effected by drilling a very deep hole, and charging it with a quantity of powder only sufficient to separate the mass to be moved. The seam thus made is then partly filled by pouring in powder, and tamping it with dry sand. The charge is then ignited by means of a safety-fuse in the usual manner.

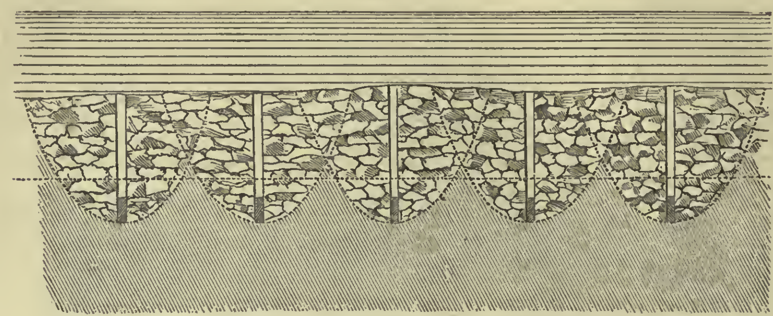
The galvanic battery has been successfully applied to Blasting, both on land and under water. It is well known that a piece of platinum or iron wire when made to connect two copper wires leading from two poles of the battery, instantly becomes red-hot, and capable of igniting gunpowder, or even of igniting a spirit lamp. For dry blasting two insulated wires connected at the bottom with a piece of platinum wire are inserted into the charge, and after the usual tamping, the powder is exploded by establishing a galvanic current through the wire by means of a battery. For submarine blasting, more precautions are necessary to insure the insulation of the wires and the keeping of the powder dry. The charge of powder is contained in a canister, in the top of which is fixed a cork coated with sealing-wax, through which descend, water-tight, two vertical copper wires, reaching into the middle of the charge. These are separate during their whole course except at the bottom, where they are connected by a fine platinum wire; and at the top they rise a little way above the cork, and are curled round into two distinct loops. After the charge is introduced, the top is cemented on the canister with putty; two copper wires, wound with cotton and coated with varnish, are then connected with the wires in the canister, one to each loop, and of sufficient length to reach from the point of explosion to the battery, which is at a sufficient distance to insure safety, either in a boat or upon land. A double chain of communication then exists, properly insulated, from the boat to the charge of powder, which has been fixed in the required position by a diving bell or other means. It is then only necessary to bring one wire into connection with each pole of the galvanic battery, which by the passage of the galvanic fluid heats the platinum, and ignites the powder in the canister. A battery of six cells is sufficiently powerful when using a length of 100 yards of wire.

The galvanic battery was employed in the operations at Round-Down Cliff, near Dover, Eng., in 1843, when a mass of chalk estimated at 291,666 cubic yards was displaced by a single explosion of 18,000 lbs. of gunpowder, ignited by the galvanic current. The wires used were each 1,000 feet in length, and it was ascertained by experiment that the electric fluid will fire powder at a distance of 2,300 feet of wire.

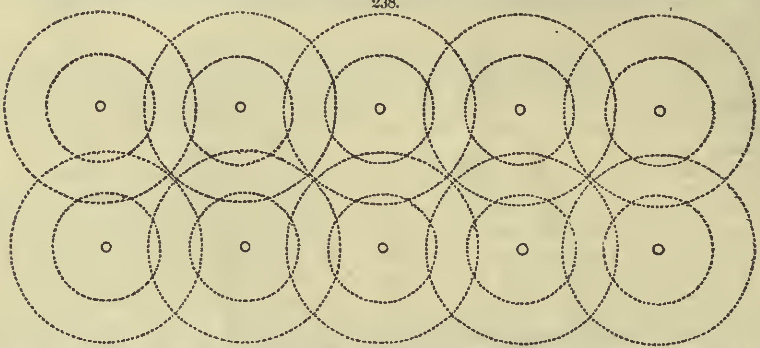
Blasting under water. The method of blasting rock under water, by the aid of the diving bell, as practised in Ireland, is as follows:—Three men are employed in the bell: one holds the jumper or boring iron, the other two strike alternately quick, smart strokes with hammers. When the hole is bored of the requisite depth, a tin cartridge filled with gunpowder, about two inches in diameter and a foot in length, is inserted and sand placed above it. To the top of the cartridge a tin pipe is soldered, having a brass screw at the upper end. The diving bell is then raised up slowly, and additional tin pipes with brass screws are attached, till the pipes are about 2 feet above the surface of the water. In the old practice the tube was filled with powder in a train, and fired; but in many instances the heat melted the solder of the pipe, and the water entering extinguished the fire. The improved method is to leave the tube empty. The man who is to fire the charge is placed in a boat close to the tube, and to the top of the tube a piece of cord is attached, which he holds in his left hand. Having in the boat a small portable furnace with small bits of iron red hot in it, he takes one of the bits of iron with a pair of nippers and drops it down the tube, which instantly ignites the charge and blows up the rock. A small part of the tube is destroyed next the cartridge, but the greater part, which is held by the cord, is reserved for future service. The workmen in the boat experience no shock by the explosion; but those who stand upon the shore or upon any part of the rocks, connected with those blasted, feel a very strong concussion. A certain depth of water above the charge—at least 12 feet—is necessary for safety. The workmen are generally down in the diving bell 5 hours in the day without coming up; and in the summer one set of men are down 10 hours one day, and 5 the next, and so on alternately. Figs. 237, 238, are sections and plans of means adopted by blasting to improve the navigation of the river Severn. Pipes $3\frac{1}{2}$ to 4 inches in diameter, $\frac{3}{16}$ an inch thick, and 9 feet long, were driven at

intervals of 6 feet from each other, through the gravel into the marl. These formed curbs for the boring of the holes into tho marl.

237.



238.



The holes were bored two feet below the proposed bottom of the dredging, as it was expected that each shot would dislocate, or break into small pieces, a mass of marl of a conical or parabolic form, of which the bore-hole would be the centre, and its bottom the apex, so that four adjoining shots would leave between them a pyramidical piece of marl, where the powder would have produced little or no effect. By carrying the shot-holes lower than the bottom of the intended dredging, the apex only of this pyramid was left to be removed, and in practice this was found to form but a small impediment, Figs. 237, 238.

The cartridges, or charges, were formed of strong duck or canvas bags, somewhat tapered at the bottom; these were filled with the required charge of powder, varying from 2 lb. to 4 lb., according to the depth of the marl; the weights of powder used for depths of 4 feet, 4 feet six inches, and 5 feet, were respectively about 2 lb., 3 lb., and 4 lb. The end of a coil of Bickford's patent fuse was inserted to the centre of the powder, and the neck of the bag was carefully gathered up round the fuse, and well tied with small twine. If the cartridge was small, it was then dipped into melted pitch, which had about one-fourth of tallow melted with it, or otherwise the melted pitch was ladled over it, till it was uniformly coated; in this state, the cartridges were hung to drain and stiffen. When hard, they were well rubbed over with tallow, and lastly powdered over with dry whiting. The tallow, whilst it ensured the stopping of any little cracks in the pitch, facilitated the passage of the cartridge down the hole; the whiting also prevented the pitch from adhering to any thing.

The charge was carefully pushed down into the hole by a wooden ramrod of suitable diameter, with the end rounded; the same instrument was used for ramming down the tamping. The material found to answer best for this purpose, was the small fragments of hard marl, separated by the action of the weather from the lofty escarpment at each of these shoals; this was gradually filled into the holes, and rammed solidly, till the bore was full up to the surface; the timber-dogs which held the pipes were then removed, the pipes were loosened from the marl, ropes were attached to the pipes and to the raft, or to some loose pieces of timber, and the shots were fired.

Mr. Maillefert bases his method of blasting beneath water without drilling, on the great resistance which the water offers to the passage of bodies through it, and which is as the squares of the velocity and the mass of water to be displaced; hence by placing a charge of gunpowder on or against the surface of the rock to be blasted, at a proper depth under water, and by firing off that charge, the considerable volume of gas which is almost instantaneously produced by such an explosion, would, in forcing its way through the water, meet with a resistance which would make it act in all directions, though in a different degree, somewhat like powder confined in a mine, and that the proportion of the concussion which would thus be directed against the rock, would be sufficient to disintegrate even the hardest and most tenacious kinds.

This conclusion proved perfectly correct in all cases where a proper proportion existed between the depth of water above the charge, the quantity and quality of the powder exploded, and the character of the rock.

The mode of procedure in carrying out this method of blasting is as follows:

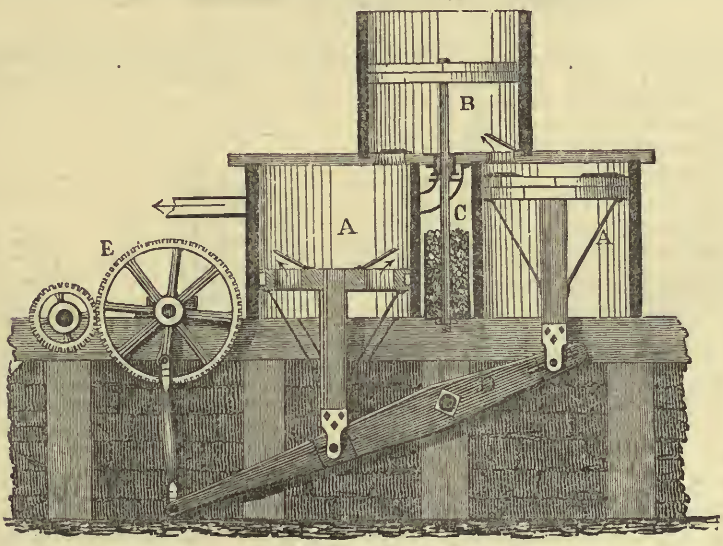
Having inserted an insulated conductor into a canister, made of tin or other suitable material, it is filled with gunpowder, and closed up so as to prevent access of the water. The cylinder is then lowered on the rock, from a boat or float, and by means of a rope or chain. Sliding along the guide-rod, it is placed exactly *on* the spot to be blasted, after which the guide-rod is withdrawn, the boat or float moved away far enough not to be injured by the agitation of the water consequent upon the explosion, which is effected by connecting the conductor with a galvanic battery, also placed at a suitable distance.

The results obtained in Hell-Gate, where nearly sixteen hundred cubic yards of the hardest rock (Gneiss) have been broken down and removed under very difficult circumstances, as an experiment, in less than seven and a half months, are sufficient to indicate what is to be expected from this method of blasting.

BLAST. The air introduced into a furnace.

BLAST MACHINES. In most metallurgical operations, the fire is urged to the proper degree of heat by forcing air into the fuel. This is done by machines which are driven by power. The pressure of the blast thus generated, and the velocity with which it enters the fuel, is greater or less according to the kind of fuel, and the effect which it is intended to produce. The most common blast machines are smith's bellows: these, however, are of limited use in smelting metals. Cylinder machines are constructed with a double and single stroke; wooden ones are generally of the latter, and the iron of the first description. In addition, there are machines with one, two, and three cylinders. One of the chief aims in constructing a blast machine must be to produce a uniform pressure. This is difficult, even with a regulator attached. Most of our blast machines do not furnish that uniformity which is required. Fig. 254 is a vertical section of a wooden blast machine; A, A, are two simple working cylinders, in each of the pistons of which there are two valves. On the top of these cylinders there are valves which lead to the regulator B, in which a piston moves that is connected by an iron piston-rod with the weight C. A balance beam D, sets both pistons A A in motion, and is itself moved by a crank pin and connecting-rod from the wheel E, which, again, is moved by a water-wheel or a steam-engine

254.

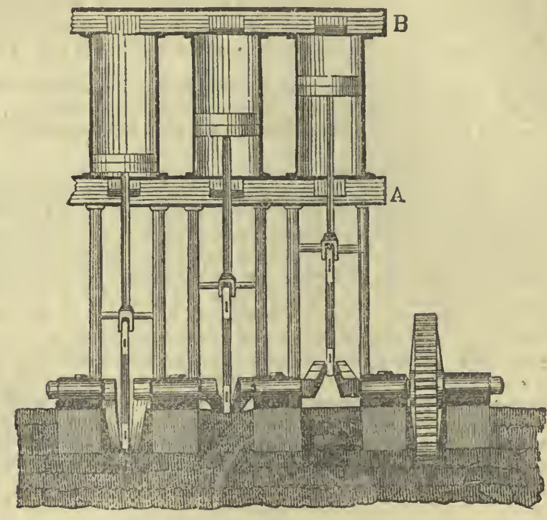


The whole machine is fastened to substantial timbers, which rest upon a good foundation of hewn stones. These cylinders and the regulator, are from 3½ to 5 feet in diameter, and not often of more than 3 feet stroke. The cylinders are constructed of segments of circles cut out of 1½ inch plank of dry ash wood, and well nailed and glued together. The fibre of the wood runs then parallel with the circumference. This form secures great solidity, prevents warping, and affords so much strength, when the thickness of the sides is at least three inches, that no iron hoops, or binders of any kind, are required. When the interior surfaces of the cylinders are well covered by a coating of fine plumbago, there is not much friction. Fat, grease, or oil of any kind, should not be put within a blast cylinder. Black-lead and glue, formed to a thin paste, is the best lubrication in this case. From 15 to 16 strokes per minute may be made with this machine. The packing of the pistons may be either of metal, wood or leather, although the latter is generally chosen. The valves are constructed of dry, light wood, and a close fit is secured by a piece of leather or of vulcanized rubber, which at the same time serves the purpose of hinges. In wooden cylinders the pressure cannot well be increased above ¾ of a pound to the square inch.

To obviate the use of a regulator, machines have been constructed with three blowing cylinders, the strokes being made to lap on to each other, as in fig. 255. Two hollow cast-iron beams, A, A, support the cylinders, and one serves in the mean time as the conductor of the blast, in the other the sucking

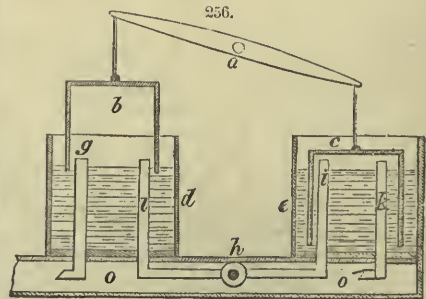
valves are located. At the top is a round pipe, B, running the length of the machine in which the blast is gathered from the upper parts of the cylinders. The upper and the lower pipes are connected by an upright pipe, and from this the blast is conducted to the desired spot at the furnaces.

255.



Another species of blowing-machine is the water-bellows. The nature of these machines will be readily understood by the help of the following diagram. The side figure is a vertical section of the machine. *a* is the fulcrum of the lever or beam, with two inverted vessels, *b* and *c*, suspended from its extremities; these vessels are open underneath, but air-tight above. *d* and *e* are two larger vessels, filled with water to the same level, in which the vessels *b* and *c* rise and fall alternately. *g h i* is a tube or pipe, which passes through the vessels *d* and *e*, and reaches above the surface of the water; at the extremities are two valves, which respectively open outwards into the inverted vessels, with a pipe at *h* open to the atmosphere. *k* and *l* are pipes passing through the bottom of *d* and *e*, and extending a little above the surface of the water; they are open at top, and have valves at bottom opening into the trunk *o*, to which the pipe is fitted which conducts the blast to the furnace. An alternating motion being imparted to the beam by a steam-engine or other first mover, the air passes up the tubes *g h i*, and fills each inverted vessel as they are successively drawn up out of the water; the descent of the inverted vessel closes the valves at *g* and *i*, and opens those at the bottom of the tubes *k* and *l*, through which the air is driven forward by the trunk *o*, and thus by the reciprocation of the beam, a continual blast is maintained through the trunk *o* and the tuyere of the furnace.

256.



A blast machine should be carefully constructed, in order to obtain the best results from it: iron ones are in all cases preferable. The piston is generally made similar to that of a steam engine. The form and position of the valves is one of the most important points connected with a blast machine. Air being elastic, expands when the pressure upon it is released: the compressed air ought to be driven out altogether at each stroke. We may locate the valves horizontally in the cylinder heads, even when the cylinders are vertical, as has been shown in fig. 254, but the weight of the valve is an objection to this. The vertical valve has a decided advantage. In whatever form the valve may be applied, waste room ought to be avoided. Valves should be as light as possible: the wooden valve lined with leather or vulcanized rubber, is for these reasons preferable to one of metal. In order to diminish the bad effects arising from the weight of valves, their number may be increased; this affords more space for the passage of air without increase of weight.

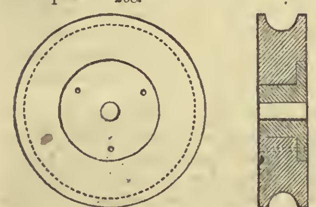
The size of a blowing cylinder depends upon the volume of air which is wanted. The stroke of the piston is generally limited by parts of the machinery depending on the locality and on the moving power; the number of strokes is also subject to considerations of economy and locality. A speed of 3 feet per second is considered an average velocity: multiply the velocity by the surface of the piston in feet, to obtain the quantity of air of the blast per second; but as blast is lost by leakage and waste room, multiply that result by $\frac{3}{4}$ for iron cylinders, and by $\frac{2}{3}$ for wooden ones. The quantity of air necessary in the consumption of a certain quantity of fuel, must be so calculated as to be sufficient to ox-

ldize it to the highest degree. It requires 100 pounds of air to convert 8·1 pounds of carbon into carbonic acid, in case all the oxygen is consumed. But this is not often accomplished; therefore 6 pounds may be assumed in reverberatories, which, in many instances, such as in reheating and roasting furnaces, is reduced to 5 and even 4 pounds of coal to 100 pounds of air. It has been ascertained at blast furnaces, that, when the quantity of fuel used during 12 hours in pounds is divided by 5, it shows the number of cubic feet of air required in one minute. Thus, when a blast furnace is to consume twenty charges of charcoal, of 15 bushels each, during 12 hours, and the charcoal weighs 20 pounds per bushel, the quantity of air which must be furnished to the furnace in each minute, of atmospheric density, is $\frac{15 \times 20 \times 20}{5} = 1200$ cubic feet.

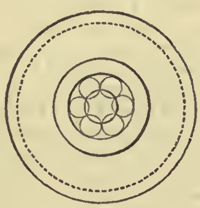
Regulators. Piston blowers do not form a blast of uniform density; but as this is, in most cases, of the utmost importance, particularly in blast furnaces, regulators are attached to these machines. At present sheet iron right cylinders, of from 4 to 8 ft. in diameter, and from 15 ft. to 40 ft. in length, are generally adopted as the most suitable and best forms. The thickness of the sheet iron is not often more than $\frac{1}{8}$ of an inch, frequently less; the heads are formed of cast-iron, or of sheet-iron and stiffened by wood and iron screws. This chamber, or regulator, is provided with a safety-valve, to insure it against bursting from excessive pressure. The blast is introduced at one end, and tapped at the same or the opposite end. The equalization of the blast is produced by the elasticity of the air. It is easily understood, that in a large chamber the pulsations of the blast machine are not so strong as in a small one, but the size must be limited for reasons of economy. As a general rule, it is established that the capacity of this regulator should be from 10 to 18 times that of one of the blast cylinders; but harm ensues if it is larger. For charcoal furnaces it should have a capacity at least 20 or 25 times that of the cylinder; it may be smaller for anthracite and coke furnaces.

BLOCKS, in the Navy and Marine Architecture, a species of pulley very extensively used for moving heavy weights, by means of ropes or chains passing over the pulleys; also occasionally in architectural and other works. A block consists of one or more pulleys, called sheaves, which are generally formed of lignumvitæ, or some hard wood inserted between cheek pieces, forming what is called the shell of the block, and turning upon a pin passing through the shell and the centres of the sheaves. Blocks are suspended by straps, either of rope or iron; the latter are called iron-strapped blocks, and have frequently a swivel-hook. A combination of two blocks, one of which is attached to the load to be raised, is called a tackle, and the power is to be estimated by the space through which the fall (which is that part of the rope to which the power is applied) passes, compared with the space through which the load is raised, deducting for friction, which is great, owing to the rigidity of the ropes, and the small diameter of the sheaves; these, for nautical purposes, are necessarily limited by considerations as to weight and space.

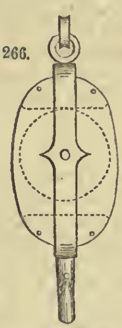
268.



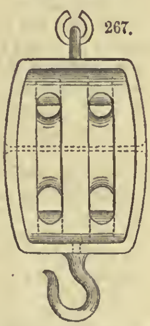
270.



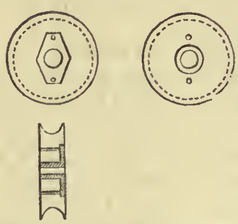
266.



267.



269.



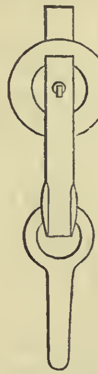
The shells are almost invariably of wood, in the smaller blocks being made of a single piece of wood, with a channel morticed for the reception of the sheave. Formerly almost all blocks were made in this manner, and beautiful and effective machines were made at the Woolwich Dock, by Mr. Bennet, for forming the different parts of a block, but in this country the shells are now made in pieces, and bolted or riveted together at the top and bottom. Each block is furnished with a strap or band of rope or iron, encircling it and terminating in an eye or hook. A block having a fixed position is called a *standing* block, whilst one which is attached to the weight and hoisted with it, is called a running block. A *Snatch* block consists of a single sheave with a notch cut through one side of the shell to allow the rope to be lifted in or out without inserting it end first. Figs. *266, 267, is a form of block in common use for shipping in this country. Its construction is easily understood from the figure. The block is double, or with two sheaves, and the shell consists of three large pieces with four pieces inserted between them at the top and bottom of the block. The whole is firmly bound with an iron strap. Figs. 268, 269, represent the construction of sheaves, with iron bushings, the collars and rivets being counter sunk. Fig. 270 is an elevation of a sheave showing an arrangement of friction pulleys or rolls, to admit of an easier motion.

Figs. 271, 272, represent a front and side elevation of a single block complete, constructed according to Waterman and Russell's Patent.† Figs. 273, 274, represent a like view of a double block of the same Patent with the shells removed.

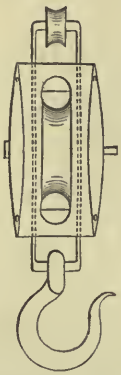
*Jas. Carroll, Burling Slip. † Burr & Co., South st., N. Y.

The peculiarity of these blocks consists in the iron straps being closely adjusted to each side of the sheave, so as barely to have its discs free of lateral friction, and then being made to combine in a solid iron bar, at just sufficient distance from the periphery of the sheave to leave the rope space to run without chafing, while the combined bar or straps extend sufficiently without the block to form the hooks at each extremity. These blocks are in many respects to be preferred to the old-fashioned blocks, whose iron straps are a mere hoop around the wood of the block, leaving all the space of the wood between

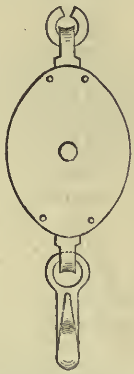
273.



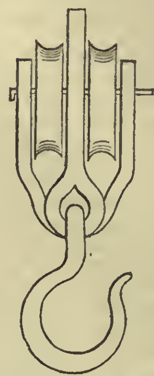
272.



271.



274.



this hoop and the sheave for the pin to spring or bend. Thus a much larger pin is required, which of course will produce more friction, and besides, it cannot be hardened to inflexibility or be made of hardened steel, lest it should break; from the leverage which the weight on the sheave exerts on the support of the pins, the iron at the *outside* of the blocks. If the pin should bend, the friction it produces would not only be increased by cutting the corners at the discs where it passes through the sheave, but the sheave is exceedingly liable to be canted to the right or left, and to suffer in consequence a lateral friction, from contact with the wood of the block. But the patent iron-strapped blocks admit of no such leverage. The straps being close by the sides of the sheave, preclude the bending of the pin in the least, and give only the advantage of dead weight to the power that could be exerted to break it. Indeed, this weight must be sufficient to cut the pin square off by dead force before it will give way, and this without the advantage of any bend or twist whatever. The pins of these blocks are of hardened steel. At their introduction, these blocks were tested at the Navy Yard, Washington, and were found superior to their own blocks; they are now much used in every service.

There is a species of blocks termed "*Dead-eyes*," which are used for tightening or setting up, as it is called, the standing rigging of ships. It consists merely of a circular block of wood, with a groove on its circumference, round which the lower end of the shroud, or an iron strap, is fastened: three holes passing through the face, (ranged in a triangle,) to receive the laniard or smaller rope, which forms a species of tackle for tightening the shrouds. There are no sheaves in the dead-eye, but the edges of the holes are rounded off to prevent cutting the lanyard; but this very imperfectly answers the purpose; as from the roughness of the grain of the wood, which is usually elm, and from the stiffness of the rope, the laniard renders with difficulty; and from the great strain to which it is subjected, it is frequently broken. A very simple and effectual improvement has been made in this respect, by inserting a half-sheave of lignumvitæ into each of the holes which causes the laniard to render with greater facility, and the shroud to be set up in half the usual time.

BLOWING MACHINES. See Blast.

BLOW-OFF COCKS AND PIPES. See Engines.

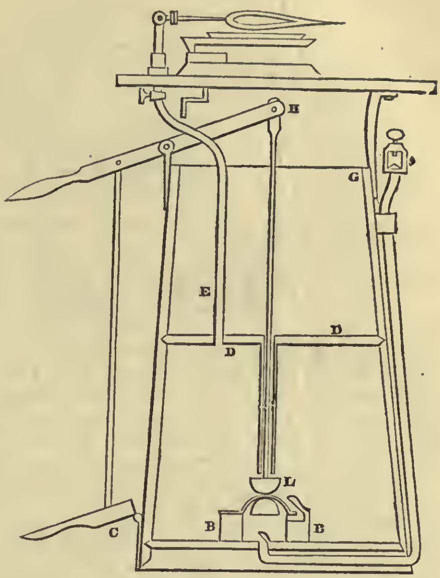
BLOW-PIPE. An instrument for exciting intense combustion upon a small scale; it is extensively used in many branches of the arts, and also in philosophical experiments upon metallic substances. In its simplest form it is merely a conical brass tube, curved at the small end, in which is a very minute aperture; and a stream of air being urged through it by the mouth against the flame of a lamp or candle, a heat equal to that of the most violent furnaces may be produced. The body intended to be operated upon should not exceed the size of a peppercorn, and should be supported upon a piece of well-burned, close-grained charcoal, unless it be of such nature as to sink into the pores of the charcoal, or to have its properties affected by its inflammable quality. Such bodies may be placed in a small spoon made of pure gold, silver, or platinum. Many advantages may be derived from the use of this simple and valuable instrument. It is portable; the most expensive materials, and the minutest specimens of bodies, may be used in the experiments; and the whole process is under the eye of the observer. In the blow-pipes used by enamellers, glass-blowers, and others, the current of air is maintained by a small pair of double bellows.

Early in the present century, Dr. Hare, of Philadelphia, made a most important improvement in the blow-pipe, by substituting for the flame of a lamp that arising from a mingled current of oxygen and hydrogen, of which we shall treat presently.

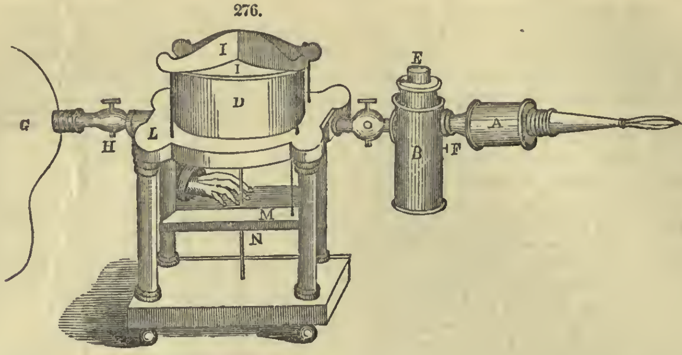
The Hydrostatic Blow-pipe consists of a cask, divided by a horizontal diaphragm into two parts D D. From the upper apartment, a pipe of about 3 inches diameter (its axis coincident with that of the cask) descends, until within about 6 inches of the bottom. On this is fastened by screws, a hollow cylinder of wood B B, externally 12 inches in diameter, and internally 8 inches. Around the rim of this cylinder a piece of leather is nailed, so as to be air-tight. On one side a small groove

is made in the upper surface of the block, so that a lateral passage may be left when nailed on each side of the groove. This lateral passage communicates with a hole bored vertically into the wood by a centre-bit; and a small strip of leather being extended so as to cover this hole, is made, with the addition of some disks of metal, to constitute a valve opening upwards. In the bottom of the cask there is another valve opening upwards. A piston-rod, passing perpendicularly through the pipe from the handle H, is fastened near its lower extremity to a hemispherical mass of lead L. The portion of the rod beyond this proceeds through the centre of the leather which covers the cavity of the wooden cylinder; also through another mass of lead like the first, which, being forced up by a screw and nut, subjects the leather between it and the upper leaden hemisphere to a pressure sufficient to render the juncture air-tight. From the partition, an eduction-pipe E is carried under the table, where it is fastened by means of a screw to a cock which carries a blow-pipe, so attached by a small swivel-joint as to be adjusted in any required direction. A suction-pipe passes from the opening covered by the lower valve, under the bottom of the cask, and rises vertically close to it on the outside, terminating in a union-joint for the attachment of any flexible tube which may be necessary. The apparatus being thus arranged, and the cask supplied with water until the partition is covered to about the depth of 2 inches, if the piston be lifted, the leather will be bulged up, and will remove in some degree the atmospheric pressure from the cavity beneath it; consequently the air must enter through the lower cavity to restore the equilibrium. When the piston is depressed, the leather being bulged in an opposite direction, the cavity beneath it is diminished, and the air being thus compressed, forces its way through the lateral valve into the lower compartment of the cask, which compartment being previously full of water, a portion of the fluid is pressed up through the pipe into the upper apartment. The same result ensues each time that the stroke is repeated, so that the lower compartment soon becomes filled with air, which is retained by the cock until its discharge by the blow-pipe is necessary. Dr. Hare, in his oxy-hydrogen blow-pipe, did not mix the gases in his gas reservoir, but supported the flame of the hydrogen by a current of oxygen issuing from different jets. Subsequently, it was found that the heat produced was materially affected by the *proportions* in which the gases were mixed, and that the greatest intensity of heat was obtained by two volumes of hydrogen united with one of oxygen; and various attempts were made to mix and *burn* the gases in their due proportion, but with little success, until the important improvement effected in the instrument by Dr. Clarke, Professor at Cambridge. This improvement consisted in first mixing the gases in a bladder, in the exact proportions to form water, and afterwards condensing them in a strong iron chest, by means of a condensing syringe. To an opening at the end of this chest he attached a great number of layers of fine wire gauze, through which the mixed gases were driven by their elastic force into a small tube, at the end of which they were inflamed. By this arrangement he obtained a much greater heat than had been effected by Dr. Hare's invention, and was enabled to make a great number of experiments highly interesting to science. Unfortunately, however, for the general adoption of his plan, it was soon found that his instrument was unsafe to use; *that the wire gauze would not prevent the explosion of the gases;* that in several cases, when used by the most experienced and cautious operators, the instruments were burst. The explosions were tremendous, and resembled the bursting of a bomb, the fragments of the iron chest being scattered with great force in all directions. After trying various plans to render the invention safe, the Doctor, as a protection, had the iron chest placed behind a brick wall at the back of the operator, the gases being conveyed through a tube passing through the wall. In this state the instrument remained, until Mr. Goldsworthy Gurney applied himself to its improvement, and after numerous experiments, which are highly interesting, and are fully detailed in his published lectures, he succeeded in producing an instrument unattended with the slightest danger in its use, and admirably adapted both for scientific investigation, and for various operations in the arts. The annexed engraving is a representation of the instrument. A is the safety-chamber; B a water-trough, through which the gas is made to pass from the gasometer D by the cock C, through a tube which reaches to the bottom of the water-trough; E is a cock fitted into the neck of the same, from which it is thrown out should an explosion take place on the surface of the water. F is a gage, to indicate the necessary height of the column of water in the trough. G is a transferring bladder, which is made to screw and unscrew to and from the stop-cock H, for the purpose of supplying the gasometer with gases, which may be charged and recharged at pleasure, by an assistant, during its action, so as to keep up the most intense flame for any length of time. A valve is placed between the gasometer and the transferring bladder, which prevents the return of the gas. I I is a light wooden or stiff pasteboard cap, which combines sufficient strength with great lightness, so that in case an explosion of the gasometer should happen, it is merely thrown a short height into the air, by the force breaking the strings which connect the cap to the press-board. To these strings are attached

275.



276.



small wires which pass through the table of the instrument, as at L, into the press-board below, where they are secured; this press-board is kept in a horizontal position by the stand, so that when the requisite pressure is given to it, the cap I I is brought to bear equally on the gasometer D. The gasometer bladder (or silk bag) is tied to a piece of bladder, which screws into a long tube laid into and across the table, which permits it to be unscrewed at pleasure from the body of the instrument, and immersed in water when it requires softening, affording also the means of fixing on another bladder, if any accident should render it necessary. The stop-cock of the charging bladder G is fixed to one end of the tube just described, and the stop-cock of the water-trough on the other end. To operate with this instrument, pressure by the hand is applied to the press-board, which draws down the cap I I on the gasometer D, and forces the gas which it contains through the stop-cock C, and through the water-tube and safety-chamber A, to the jet at the end, where it is burned. When the pressure on the press-board is too slight, or when the hand is taken off, the flame returns into the safety-chamber, and is extinguished. When it is required to suspend the operation, the hand need only be taken off the pressing-board; the water in the trough acts as a self-acting valve in preventing the escape of gas from the instrument, and saves the necessity of turning the stop-cock. A silk tube is attached to the end of the tube before described, in the water-trough, which prevents the splashing of the water, sometimes occasioned by unskilful management. We omitted to state that the safety-chamber A is filled with numerous disks of very fine wire gauze closely packed, and should the flame be driven in, which will sometimes happen, it will not enter the bag or reservoir D, but will explode above the surface of the water in the chamber B, merely driving out the cork. An improvement has, however, been since introduced in the construction of the safety-chamber, by Mr. Wilkinson, by which the retrograde motion of the flame appears to be effectually prevented, and a much larger jet may be employed than heretofore with perfect safety. This improvement consists in filling the chamber A with alternate layers of wire gauze and of asbestos, previously beaten with a mallet, and pulled out to resemble floss silk. Mr. Wilkinson received from the Society of Arts a silver medal for his communication on the subject, and we understand that Mr. Hemming has recently made some further improvements in the construction of the instrument. We must here advert to the wonderful effects produced by the oxy-hydrogen blow-pipe, which almost instantaneously reduces the hardest and most refractory substances. Gun-flints are instantly fused by it, and formed into a transparent glass; china melts into a perfect crystal. All kinds of porcelain are readily fused, previously assuming a beautiful crystallized appearance. Rock crystal is quickly melted, giving out a beautiful light. Emerald, sapphire, topaz, and all the other precious stones, melt before it into transparent glassy substances. Barytes, strontian, lime, and alumina, exhibit very striking and beautiful phenomena. Magnesia fuses into hard granular particles, which will scratch glass. The metals, even platina, are *all* quickly fused by it; and all descriptions of stones, slates, and minerals, are melted, sublimed, or volatilized, by its all-subduing power.

BLOW-PIPE. Dr. Hare's Hydro-oxygen; *On certain improvements in the Construction and Supply of the Hydro-oxygen Blow-pipe, by which Rhodium, Iridium, or the Osmiuret of Iridium, also Platinum in the large way, have been fused.* By Robert Hare, M. D., Professor of Chemistry in the University of Pennsylvania.

While a pupil of my predecessor, Dr. Woodhouse, in the year 1801, having observed that a jet of hydrogen when inflamed in atmospheric air, of which only one-fifth is oxygen, was productive of a heat of pre-eminent intensity, I was led to infer that in combining with pure oxygen, the gas in question ought to produce a temperature at least five times as great. This led to the contrivance of two modes of producing a jet consisting of a mixture of hydrogen with oxygen. Agreeably to one mode, the gaseous currents, meeting like the branches of a river, were made analogously to form a common stream. This object was accomplished by means of perforations drilled in a conical frustrum of pure silver, so as to converge until met by another shorter perforation, commencing at the opposite surface, and so extended as to join them at the point of their meeting. The other mode was that of causing one tube to be within another, so as to be concentric, the outer tube being a little the longer of the two; the latter being employed for hydrogen, the former for oxygen.

In the year 1814, this last-mentioned mode was improved, so as to have the means of securing, by adjusting screws, the concentricity of the tubes, and varying the distance of the orifice of efflux of the inner tube from that of the other.

The constructions employed in 1801, were described and published in a pamphlet, and afterwards

republished in Tillock's Philosophical Magazine, vol. xiv., and in Annals de Chymie, vol. xiv. At the same time an account was given of the fusion of pure lime and magnesia, and of the fusion of platinum. Subsequently, in a paper published in the Transactions of the American Philosophical Society, it was mentioned that I had volatilized platinum.

About the year 1811, Professor Silliman, in a memoir read before the Connecticut Academy of Sciences, gave an account of a series of experiments, in which the experiments which I had performed were repeated, and many additional fusions made. I had adverted to the intensity of the light produced during the exposure of lime to the flame. Alluding to the heat and light, my words were, "the eyes could not sustain the one, nor the most refractory substances resist the other." The intensity of the light was still more insisted upon by Silliman.

My experiments were also repeated by Mr. Rubens Peale, during many successive years, at the Philadelphia Museum, for the amusement of visiters.

About the year 1813–14, it was ascertained, at the laboratory of Dr. Parrish, that a bladder being supplied with a mixture of hydrogen and oxygen, in due proportion, and punctured by a pin, while subjected to compression, on igniting the resulting jet, the gas within the bladder did not explode. Of course, a burning jet of flame thus created was found competent to produce, while it lasted, the same effect as when otherwise generated by the same gaseous mixture.

Soon after this result was obtained, Sir Humphrey Davy discovered, that if a lamp flame be completely surrounded by a gauze of fine wire, it may be introduced into an inflammable gaseous mixture without causing it to explode. This was ascribed to the refrigerating influence of the metal, keeping the gaseous mixture below the temperature requisite for inflammation. Hence it was inferred, that if a mixture of hydrogen and oxygen, while condensed within a suitable receiver, was allowed to escape through a capillary metallic tube, so as to form a jet, this might be made to burn without communicating ignition to the portion remaining in the receiver.

By means of an apparatus contrived agreeably to this idea, Dr. Clark, of Cambridge, England, repeated the experiments, made many years before by Silliman and myself, without any other reference to ours, than such as was of a nature to do injustice. An exposition of the invalidity of Dr. Clark's pretensions to originality was made in Silliman's Journal for 1820, vol. ii., and in Tillock's Philosophical Magazine for 1821, vol. lvii.

The light produced by the hydro-oxygen flame with lime having been observed by Lieutenant Drummond, of the British Navy, was ingeniously proposed by him as the means of illumination in lighthouses, and has been, in consequence, subsequently used as a substitute for the solar rays, in an instrument known as the hydro-oxygen microscope, which is a modification of that which has been called the solar microscope. The name of Drummond light has consequently been given to a mode of illumination, which I originally produced as above stated.

The instrument which was used by Professor Silliman and by Rubens Peale, was that above described as having two perforations meeting in one. In this form it was, I believe, employed by Dr. Hope, of Edinburgh, and Dr. Thompson, of Glasgow, who both treated it as my contrivance, anteriorly to the publication of Dr. Clark's memoir.

The other form, consisting of two concentric pipes, was modified by a Mr. Mangham, with the view of producing a lime light for the microscope above alluded to. When I saw Mr. Mangham at the Adelaide gallery in 1836, he treated this instrument as mine, in another form. I was surprised afterwards to learn that he had obtained a premium for this modification from the British Society for the Encouragement of Arts, without any allusion to the original inventor.

After my return from Europe in 1836, I was very much in want of a piece of platinum of a certain weight, while many more scraps than were adequate to form such a piece were in my possession. This induced new efforts to extend the power of my blow-pipe; and after many experiments, I succeeded so as to fuse twenty-eight ounces of platinum into one mass.

Although small lumps of platinum had been fused by many operators, with the hydro-oxygen blow-pipe, as well as myself, it had not, up to the year 1837, been found sufficiently competent to enable artists to resort to this process. I am informed by Mr. Saxton, that some efforts which were made while he was in London were so little successful, that the project was abandoned. There was an impression that the metal was rendered less malleable when fused upon charcoal, as in the experiments alluded to. This is contradicted by my experiments, agreeably to which fused platinum is as malleable as the best specimens obtained by the Wollaston process, and is less liable to flake. The celebrated Dr. Ure, on seeing the platinum in the forms of wire, of leaf, and plate, said that there was no one in Europe who could fuse platinum in such masses. He also alleged that it had been found so difficult to weld platinum, that no resort was had to that process. In this I concur, having had the welding tried by a skilful smith, both with a forge heat, and with a heat given by the hydro-oxygen blow-pipe. An incorporation of two ingots was effected on their being hammered together, when heated nearly to fusion; but on hammering the resulting mass cold, a separation took place along the joint by which the ingots were united.

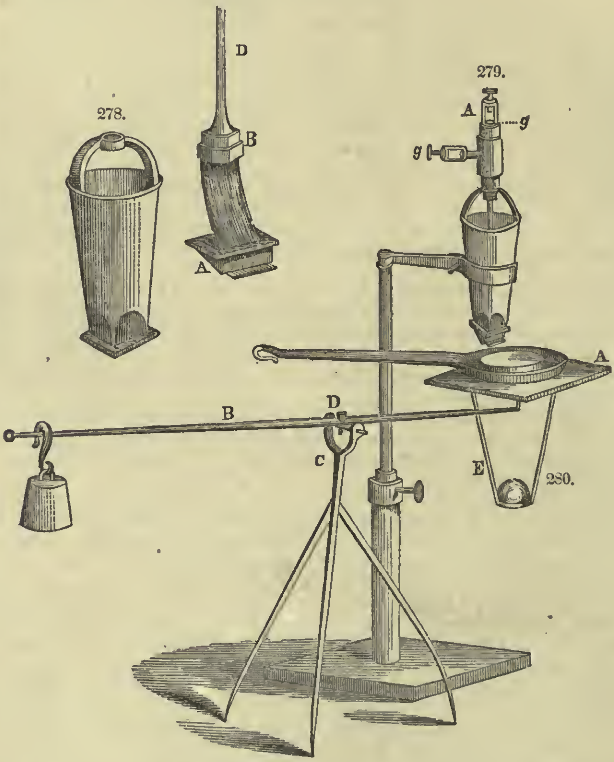
The difficulty seems to arise from the rapidity with which the platinum becomes refrigerated. It seems to have a less capacity for heat than iron, and, not burning in the air as iron does, has not the benefit of the heat acquired by iron from its own combustion with atmospheric oxygen.

Latterly, by means of the instrument and process which it is my object here to describe, I have been enabled to obtain malleable platinum from the ore directly, by the continued application of the flame. From some specimens of platinum I have procured as much as ninety per cent. of malleable metal. The malleability is not inferior to that of the best specimens obtained, by reducing it to the state of sponge, through the agency of aqua regia and sal ammoniac. There is, however, a greater liability to tarnish, arising, probably, from the presence of a minute portion of palladium.

Of the fusion of iridium and rhodium, I have already given an account in the Bulletin of the Society, which was subsequently embodied in an article prepared for Silliman's Journal for October last, 1846.

It remains now to give an account of the apparatus employed in the fusion of platina on a large scale.

Fig. 277 represents the association of fifteen jet-pipes of platina with one large pipe, D B, at their upper ends, so that their bores communicate, by means of an appropriate brass casting, with that of the large pipe, the joints secured by hard solder. Their lower extremities are made to protrude about half an inch from a box A, of cast brass, their junctures, with the appropriate perforations severally made for them, being secured by silver solder. They come out obliquely in a line along one corner of the box, an interval of about a quarter of an inch alternating with each orifice. By means of flanges, the brass box is secured to a conical frustum of copper, Fig. 278, so as to form the bottom thereof, while the pipe, extending above the copper case, is screwed to a hollow cylinder of brass, A, Fig. 279, provided with two nozzles and gallows screws *g g* for the attachment of appropriate hollow knobs, to which pipes are soldered, proceeding from the reservoirs of oxygen and hydrogen. Cocks are interposed by which to regulate the emission of the gases in due proportion.



In connecting the pipes conveying the gases with the brass cylinder, A, Fig. 279, care should be taken to attach that conveying oxygen to the upper nozzle, while the other, conveying hydrogen, should be attached to the lower nozzle; since, by these means, their great difference in density tends to promote admixture, which, evidently, it must be advantageous to effect.

The object of surrounding the jet-pipes with water, by means of the copper box,* is to secure them against being heated to such a degree as to cause the flame to retrocede and burn within them, so as finally to explode within the cylinder, A, *g g*, Fig. 279. It is preferable to add ice or snow to the water, in order to prevent undue heat.

Fig. 280 represents a moveable platform, A, of cast-iron, wholly supported upon the point of the iron lever D B, which is curved towards the extremity under the platform, so as to point upwards, and to enter a small central conical cavity made for its reception. The lever is supported by a universal joint upon the fulcrum C, so that by means of the sliding-weight at one end, the platform and its appurtenances are counterpoised at the other. The platform is kept in a horizontal position by the cannon-ball, supported in a sort of iron stirrup terminating in a ring, in which the ball is placed. Upon the platform is situated an iron pan with a handle, holding the brick, on a cavity in which, as already

* Since the engraving was made, I have preferred to use water-tight boxes, with gallows screws and nozzles, situated one near the bottom on one side, the other on the opposite side near the top. By means of the lower nozzle, a pipe is attached, communicating with a head of cold water, the other being so situated as to carry the water into a waste pipe, or large tub; a circulation may be kept up during the whole time that the operation is going on.

As a support, a brick of kaolin is used, having an oblong elipsoidal depression on the upper face for the reception of the metal to be fused.

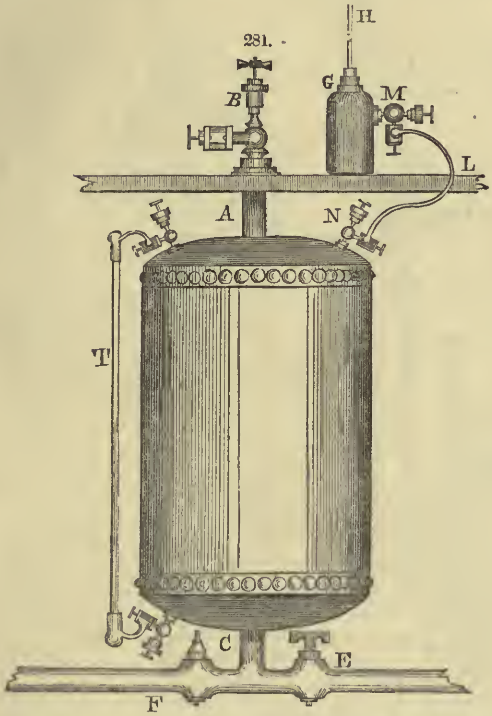
mentioned, the metal is supported. The apparatus being duly prepared, and connected with the supply pipes, the hydrogen is first allowed to escape, and then the oxygen, until the ignition has attained apparently a maximum. The accomplishment of this object may, of course, require the adjustment of either cock several times, especially where there is any decline in the pressure either of the one or the other gas in its appropriate reservoir.

By means of the handles of the lever and of the pan, the operator is enabled to bring the metal into the position most favorable for the influence of the heat, while his hands and face are sufficiently remote to render the process supportable. In fusing any quantity, not being more than four ounces, the platform may be dispensed with, the handle of the pan being held in one hand of the operator, while by the other the cocks may be adjusted.

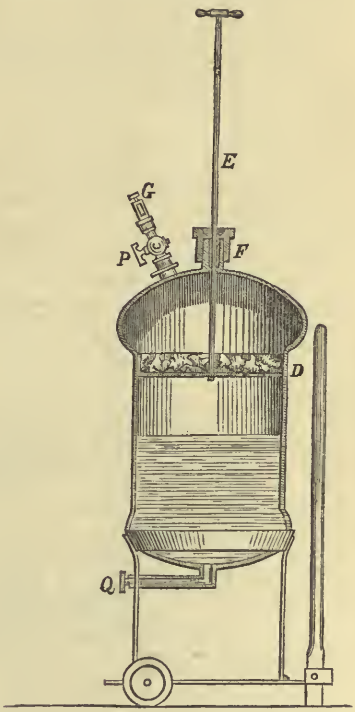
When the blow-pipe of fifteen jets, or any larger, may be employed, and the platform is necessarily resorted to, the cocks must be adjusted by an assistant.

Fig. 281 represents a cask made of boiler-iron, three-sixteenths of an inch thick, so as to resist an enormous pressure. The joints are secured by riveting, as in constructing high-pressure boilers.

281.



282.



This cask communicates with the hydrant-pipes, so called, by which our city is supplied with water, of which the pressure varies from a half to more than two atmospheres, say from seven to thirty pounds per square inch, according to the number and bore of the cocks from which the water may be flowing at the time, for the consumption of the community. Hence, experiments, while using this head, are best made towards bedtime, or between that time and sunrise. The vessel is filled with water by opening a cock F on one side of the pipe C, and allowing the air to escape through the valve-cocks B. Being thus supplied, the cock F closed, and a communication with a bell-glass, into which oxygen is proceeding from a generating apparatus, being made by means of a flexible leaden tube, on opening the valve-cock B and the cock E the water will run out, and be replaced by gas from the bell. This process being continued till the iron cask is sufficiently supplied with gas, the cock E must be shut. Whenever the gas is wanted for the supply of the blow-pipe, it is only necessary to establish a communication between the valve-cock B and the upper gallows-screw, Fig. 279, of the cylinder A, and to open the cock F so as to admit the water to press upon the gas, the efflux being regulated by B, or preferably by a cock of the ordinary construction, one of which kind should be interposed at a convenient position between the valve-cock B and cylinder A.

T represents a glass tube, which, by due communication with the interior, shows the height of the water, and consequently the quantity of gas in the vessel.

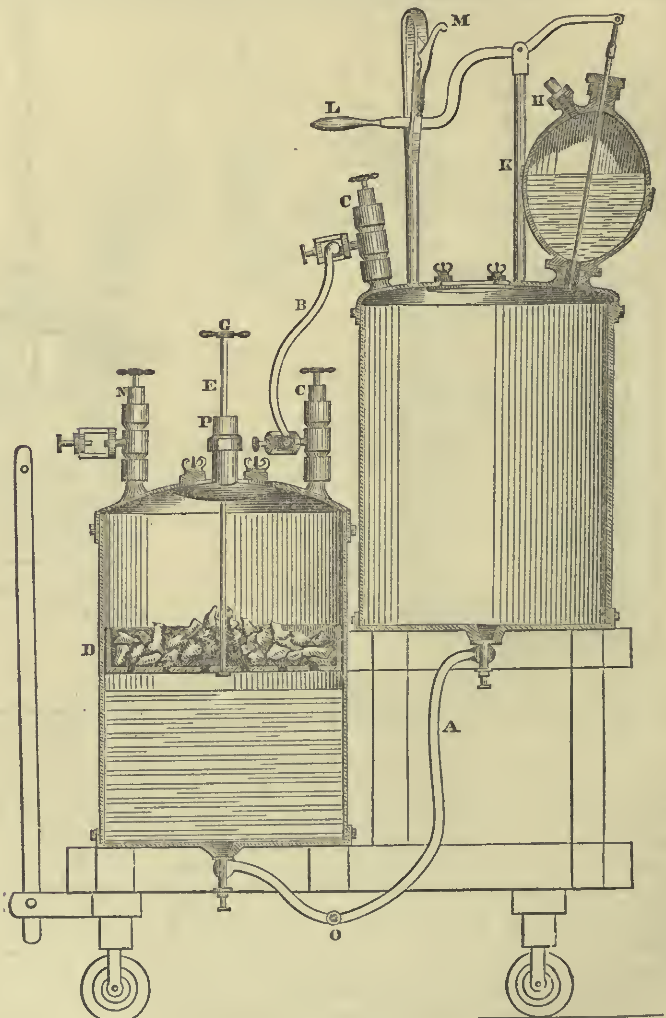
G H represents a gaging apparatus, consisting of a cast-iron flask, of about a half a pint in content, and a glass tube of about a quarter of an inch in bore, which should be at least five feet in height. The tube is secured air-tight into the neck of the flask, so as to reach nearly to the bottom within. The flask is nearly full of mercury. Under these circumstances, when a communication is made, by a leaden pipe between the cavity of the flask and that of the reservoir, an equilibrium of pressure resulting, the extent of the pressure is indicated by the rise of the mercury in the tube.

In order to generate hydrogen for the supply of a reservoir like that represented by the preceding figure, I have employed the vessel represented by Fig. 282. This vessel, by means of a suitable aperture, susceptible of being closed by a screw-plug, is half filled with diluted sulphuric acid. Being furnished with a tray of sheet copper D, punctured like a coal-sieve, and supported by a copper sliding-rod E, strips of zinc are introduced in quantity equal to the capacity of the tray. The sliding-rod passes through a stuffing-box F, at top of the reservoir, so that the operator may, by lowering or raising the tray, regulate or suspend the reaction between the zinc and its solvent, accordingly as the supply of hydrogen is to be produced, suspended, increased, or diminished.

The communication with the reservoir is opened and regulated by means of the cock P, furnished with a gallows-screw G for the attachment of a leaden pipe, as above described, in the process for supplying the reservoir with oxygen.

Another apparatus for producing a supply of hydrogen, is represented in Fig. 000. It consists of two

283.



similar vessels of boiler-iron, each capable of holding forty gallons. They are lined internally with copper, being situated upon a wooden frame, so that the bottom of one is two-thirds as high as the top of the other. The upper portion of these vessels communicate by a leaden pipe B, of about half an inch bore, furnished with a cock, while the lower portions communicate by another leaden pipe of a bore of 1½ inches.

The upper vessel is surmounted by a globular copper vessel, of about twelve inches in diameter which, from its construction, renders it possible to introduce an additional supply of concentrated acid while the apparatus is in operation, without reducing the pressure within the reservoir, by permitting the excess above the pressure of the atmosphere to escape. This object is accomplished as follows:—

The valve at the end of the rod, attached to the lever L, being kept shut by the catch M, the screw-plug H removed, the acid is introduced through the aperture thus opened. In the next place, the plug being replaced, and the valve depressed by means of the lever and rod, so as no longer to close the opening, which it had occupied, the acid descends from the chamber into the cavity of the vessel beneath it. The valve is of course restored to its previous position as soon as the acid has effected its descent.

The lowermost vessel is furnished with a perforated copper tray, supported by a copper sliding-rod, in a way quite analogous to that already described in the case of the copper reservoir. It is also supplied with zinc and its solvent in like manner, being made half full of the diluted sulphuric acid. Of course, on contact being produced between the zinc and its solvent, the generation of hydrogen will take place. So long as the communication between the upper portions of the two vessels is open, the gas will extend itself into both, occupying the whole of the upper vessel, and that half of the lower one which is unoccupied by the liquid. But if, in this way, the pressure reaches to two atmospheres, as indicated by the gage, on shutting the communication through the pipe B, the pressure in the inferior vessel will augment, that in the superior vessel remaining as before, but the liquid will consequently begin to pass out of the inferior vessel through the pipe A, and thus may lessen the contact between the acid and zinc, and finally suspend it altogether. Meanwhile the gas in the upper vessel being condensed to nearly half its previous bulk, the pressure will be nearly four atmospheres. It will, in fact, always be nearly double that which existed before the pipe B was closed.

In order that nearly the whole of the acid shall be expelled from the inferior vessel, the tray must be depressed till it touches the bottom of that vessel.

The pressure being four atmospheres at commencement, as soon as, by means of a pipe attached to the valve-cock N, an escape of gas is allowed, the acid is forced again upon the zinc, and thus prevents a decline of pressure to any extent sufficiently to interfere with the process.

The gases may be used from a receiver in which they exist, in due proportion, safely by the following means. Two safety-tubes are to be made, not by Hemming's process exactly, but as follows:—A copper tube, silver soldered, of which the metal is about the eighth of an inch in thickness, is stuffed with the finest copper wire, great care being taken to have the filaments straight and parallel. The tube is then to be subjected to the wire-drawing apparatus, so as to compress the tube on its contents until the draught becomes so hard, as that it cannot be pushed farther without annealing. The stuffed tube thus made is to be cut into segments, in lengths about equal to the diameter, by a fine saw. The surfaces of the sections are to be filed gently with a smooth file. By these means, they appear to the naked eye like the superfices of a solid metallic cylinder. Brass caps being fitted on these sections, they are to be interposed by soldering, at the distance of a foot or more, into the pipe for supplying the jet. Under these circumstances, the posterior section, becoming hot, may allow the frame to retrocede; but the anterior section being beyond the reach of any possible combustion, and remaining cold, will not allow of the retrocession; and as soon as the flame passes the first section, the operator, being warned, will of course close the cock, and subject the posterior section to refrigeration before proceeding again.

But this plan of operating may be rendered still more secure by interposing a mercury bottle, or other suitable iron vessel, half full of oil of turpentine, between the reservoir and safety-tubes, as in the arrangement of a Woulfe's bottle. A leaden pipe proceeding from the reservoir is, by a gallows-screw, attached to an iron tube which descends into the bottle, so as that its orifice may be near the bottom. The leaden pipe communicating through the safety-tubes with the jet-pipe, is attached to the neck of the bottle. Thus the gaseous mixture has to bubble through the oil of turpentine in order to proceed through the safety-tubes to the jet-pipe. If, while this process is going on, the flame should, by retrocession, reach the cavity of the bottle, exploding in contact with the turpentine, a compound is formed, which is, *per se*, inexplosive from the excess of carbonaceous matter. Meanwhile the shock, acting on the surface of the oil, drives it into the bore of the iron tube, and thus, both by its chemical and mechanical influence, renders it utterly impossible that the flame should reach the cavity of the reservoir.

BOBBINET MACHINERY, is the name of machines which are intended for manufacturing a peculiar net-like texture, whose constructure is inferred from that of the pillow-made or bone-lace, and which, in its most simple intertwisting, is known by the name of *plain bobbinet* and *quillings*. The simple intertwisting of the plain bobbinet has been altered in various manners, and thus have been produced new kinds of texture, partly very different in appearance from that of the plain bobbinet; and in recent time furnishing very fine fancy articles, much in demand. They are termed *figured bobbinet* in the following description, which treats chiefly of the most common and most recent systems of bobbinet machines.

The machines for manufacturing quillings, and which are known by the term *stripe-machines*, work quillings or edgings from ½ to 4 and 6 inches in breadth, and of considerable length. A great many edgings, connected with and by the side of each other, thus forming one broad piece, are worked simultaneously, and are subsequently separated. As the quillings are, as it were, to be edged at both borders, for the sake of fastness and durability, this edging and intertwisting of the several quillings require particular contrivances in the machines, which thus, according to the different systems applied to them, are more or less complicated.

Those for manufacturing the figured bobbinet are in general narrow; that is to say, there can be worked only pieces of inconsiderable breadth by them.

This is owing partly to the circumstance, that older machines, originally intended for manufacturing pieces six or eight quarters of a yard wide, have been arranged for figured bobbinet, to make them still fit for use in any way; and partly to the fact that the making of figured bobbinet is by far more difficult than that of plain bobbinet, and that it requires the most eager attention and skilfulness of the operative. To the latter it would be almost impossible to overlook broad pieces of this kind, or the work would go on so slowly that such an arrangement could be of no great avail.

Alphabetical Survey and Explanation of the Letters in the Figs. 284 *to* 394.

A, right side-frame, Figs. 285 and 286.
A_1, left side-frame, Figs. 284, 286, and 287.
B, fore front-frame, Figs. 284, 303, 317.
B_1, back front-frame, Figs. 284, 303, 317.
C, joist joining the uppermost parts of the side-frames, Fig. 286.
C_1, pillars screwed on C, and bearing the sockets of the lace-beam A, Fig. 286.
D, rounded iron bars across which the texture passes on its way to the lace-beam, Fig. 286.
D_1, D_2, cross-beams at the right and left sides of the frame, Figs. 284 and 285.
E, front pusher-bar, Figs. 284, 288, and 289.
E_1, back pusher-bar, Figs. 284, 288, and 289.
F, a kind of reed composed of perforated brasses for the warp-threads, Figs. 284 and 286.
F_1, steel springs of the hold-fast contrivance, Fig. 357.
G, warp-beam, Fig. 284.
G_1, G_2, lever-arms of the point-bars, Figs. 284, 285, 288, and 289.
H, lever bearing the weight-stone R, Figs. 284, 286, and 287.
H_1, lever moving the front point-bar, Fig. 287.
H_2, lever moving the back point-bar, Figs. 287, 288, and 289.
I, cradle-arms, Figs. 284, 285, and 286.
I_1, cradle-pieces, Figs. 284, 285, and 286.
K, front bolt-bar, Figs. 286, 288, 289, 300, and 303.
K_1, back bolt-bar, Figs. 287, 288, 289, and 303.
L, front comb, Figs. 284, 288, and 289.
L_1, back comb, Figs. 284, 288, and 289.
M, front point-bar, Figs. 284, 285, 288, 289.
N, back point-bar, Figs. 284, 285, 288, and 289.
N_1, crowbar of the front point-bar, Figs. 286 and 287.
N_2, crowbar of the back point-bar, Figs. 288 and 289.
O, socket-frame in the midst of the machine. P, socket-frame at the side of the machine. Both are fastened to B and B^1, and bear the sockets of the lockers, Figs. 315 and 317.
P_1, forked bars for both point-bars, Figs. 287, 288, and 289.
Q, weight-stone for the tension of the warp, Figs. 284, 285, 286, and 287.
Q_1, lifting-thumb acting on the forked bar P_1, Figs. 288 and 289.
R, grooved disks for the cords or strings S, Fig. 286.
R_1, large rowels, Fig. 284.
R_2, shell-wheel of the front point-bar, Fig. 286.
R_3, shell-wheel of the back point-bar, Figs. 286, 288, and 289.
S, cords or strings for the tension of the warp, Figs. 284, 285, 286, and 287.
S_1, support of the front point-bar, Fig. 287.
S_2, support of the back point-bar, Figs. 287, 288, and 289.
T, T_1, shafts to which the lever-arms G_1 and G_2 are fastened, Figs. 284, 288, and 289.
U, large heart-shaped disk to bring about the swinging movement of the pusher-bars, Figs. 284, 288, 289, and 290.
U_1, similar disk in Figs. 358 and 359.
V, great spur-wheel with 48 cogs at the principal axis W, Figs. 285 and 286.
W, principal axis of the machine, Figs. 284, 286, 288, and 289.
W^1, driving axis of the machinery for the thong-disk Y, Figs. 284, 285, and 287.
X, dented wheel at the axis W_1, with 36 cogs, Fig. 285.
Y, thong-disk at the axis W_1, Fig. 286.
Y_1, thong of the disk Y, Fig. 286.
Z, the lace-beam, Fig. 284.

a, front guide-bar, Figs. 284, 331, 332, 303, 317, &c.
a_1, adjusting screw for the lateral movement of the front guide-bar, Figs. 331, 332, and 333.
a_2, adjusting screw for the lateral movement of the back guide-bar, Fig. 333.
b, back guide-bar, Figs. 284, 303, 315, 317, and 333.
b_1, b_2, curved stays through which the adjusting screws *a* and a_2 pass, Figs. 331 and 333.
b_3, common pivot of the levers H and H_2, and of the crowbar N and N_2, Figs. 287, 288, and 289.
c, front series of guides, Fig. 284.
c_1, projecting bolt, through which the supporting screws *d* and d_2 pass, Figs. 331 and 333.
c_2, c_3, adjusting screws of the levers H_1 and H_2, Fig. 287.
d, back series of guides, Fig. 284.
d_1, d_2, supporting screws of the guide-bars, Figs. 331, 333.
e, middle stay of the bolt-bars, Figs. 300, 301, 302.
f, warp-threads, Figs. 284, 335, 336, and 360.

f_1, steel springs for pushing back the guide-bars, Figs. 285, 295.
f_2, pivots on which the point-bars turn, Figs. 285, 288, 289.
g, socket-irons of the warp-beam, Fig. 284.
g_1, g_2, lever-bars for the lockers, Figs. 285, 288, and 289.
h, lever-arm at the midst of the axis w, Figs. 358 and 359.
h_1, h_2, lever-arms at the ends of the axis w, Figs. 358, 359, and 284, 285, 288, 289.
i, pivot of the lever-bars g_1 and g_2, Figs. 284, 285, 288, 289.
k, k_1, weft-threads, Fig. 360.
k_2, curved arms, to which the pivots f_2 of the point-bars are fixed, Figs. 285, 288, 289.
l, front carriage-line, Figs. 284, 288, 289.
l_1, back carriage-line, Figs. 284, 288, 289.
l_2, sockets of the shafts T and T_1, Figs. 285, 286.
l_3, sockets of the shafts w in Figs. 358, 359.
m, m_1, drawer-bars of the lever-arms h_1 and h_2, Figs. 358, 359, and 284, 285, 286, 288.
m_2, adjusting screw for the lateral movement of the front comb, Figs. 286, 300, 301.
m_3, adjusting screw for fixing the back comb, Figs. 286, 288, 300, 301.
n, point-pieces, Figs. 284, 286, 288, 289.
n_1, n_2, split sockets of the guide-bars, Figs. 304, 305 a, in the midst of D_1 and D_2, and of the machine.
n_3, spiral-spring of the point-bars, Fig. 285.
o, comb-shifting disk at the shaft t, Fig. 286.
o_1, ratchet-wheel of the front guide-bar, Fig. 286, left side.
o_2, ratchet-wheel of the back guide-bar, Figs. 285, 286.
o_3, comb-shifting disk at the shaft t, right side, Fig. 286.
p, locker-bar, Figs. 284, 288, 289, 309.
p_1, bolts or rails to which the adjusting screws m_2 and m_3 are fixed, Figs. 300, 301, 286.
p_2, socket-pieces at D_1 and D_2, Figs. 284, 285, 286.
q, locker, Figs. 284, 288, 289, 309.
q_1, supporting arms or stays of the bolt-bars, Figs. 284, 285, 287, 300, 301, 302, 303
q_2, screws for supporting the bolt-bars, Fig. 317.
r, sliding roller of the large heart-shaped disk U, Figs. 284, 288, 289
$(r,)$ sliding roller of the large heart-shaped disk U_1, in Figs. 358 and 359.
r_1, roller of the locker-disk v_1, Fig. 286.
r_2, roller of the locker-disk v_2, Fig. 286.
r_3, rowels at the bar D, Fig. 286.
r_4, sliding roller of the shell-wheels R_2 and R_3, Figs. 288 and 289.
s, arms by which the point-bars are connected with the supporting bars S_1 and S_2, Figs. 287, 288, 289
s_1, s_2, dented wheels at the axis W, Fig. 286.
t, shafts to which are fixed all ratchet-wheels and disks, Figs. 285, 286, 288, 289.
t_1, t_2, dented wheels at the axis t, Fig. 286.
u, pivot on which the pushing levers x_1 and x_2 move, Fig. 285.
u_1, angular lever of the front guide-bars, Fig. 295.
u_2, angular lever of the back guide-bars, Fig. 295.
u_3, pushing lever of the front comb, to the right, Fig. 286.
u_4, pushing lever of the front comb, to the left, Fig. 286.
v, motive power or quarter-wheel of the lockers, Figs. 284, 311, 312.
v_1, locker-disk for the back locker, at the axis W, Fig. 286.
v_2, locker-disk for the front locker, at the same axis, Figs. 284, 286, 288, 289.
w, shafts to which the lever-arms h, h_1 and h_2, are fixed, Figs. 386, 289, 358 and 359.
w_1, shafts to which the cradle-arms I, and cradle-pieces I_1 are fixed, Figs. 284, 285, 286, 287.
w_2, dented wheel of the lace-beam, Fig. 285.
x, socket of the shaft w, Fig. 284.
x_1, pushing lever of the front guide-bar, Figs. 286 and 295.
x_2, pushing lever of the back guide-bar, Figs. 286 and 295.
x_3, x_4, angular levers for pushing the bolt-bars, Figs. 285 and 287.
y, bolt or rail, through which the common peg of the angular levers u_1 and u_2 are put, Fig. 295.
y_1, adjusting screw of the point-bar, on which the upper fork of the bar S_1 is acting, Figs. 288, 289
y_2, adjusting screws of the point-bar, which strike against the side-frame A and A_1, Fig. 285.
z, a trigger, Fig. 286.
z_1, z_2, dented bars for the lockers, Figs. 284, 287, 311, 312, 314.

α, foot-screws of the bolt-bars, Figs. 284, 285, 286, 287, 300, 303.
β, notch in which the middle stays e are running, Fig. 317.
ϑ, δ, iron pegs at the lower fork of the bar S_1, Figs. 288 and 289.

Machines for manufacturing broad plain Bobbinet.

The latest and most approved construction of these machines is according to the *double-locker* system. Machines of this system can be arranged for any breadth of the piece, and are working for weeks, and even months, with great precision and quickness, without any interruption which might be produced by irregularity in the mechanism. Being commonly of considerable breadth, the motive power must be very strong; therefore it is driven either by water or steam.

In the following, we give a description of a machine for webs 8 quarters wide, constructed according to the *double-locker* system, and illustrated by Figs. 284 to 375, in the most careful manner. The illustrations are given with all particulars required, which may enable the mechanic to draw upon a large scale from them.

The machine for manufacturing plain bobbinet, though being the most simple of all bobbinet machines, belongs, however, by its construction to the most complicated ones. Its web is represented by Fig. 360 on a large scale. One and the same thread is marked along its way by the same letter. The threads f are extended up and down, or proceed downwards in serpentine lines, while the two other sets of threads k and k_1 proceed from the right to the left, and from the left to the right in slanting directions. By this, the twisting and interlacing of the threads is produced. The perpendicular threads in the figure, which are parallel to the border, may be regarded as the warp, and the two sets of slanting threads as the weft, in comparing bobbinet with a common web. The straight warp-threads receive their twist from the tension of the weft-threads, twisted obliquely round them alternately to the right and left.

This seemingly simple union of the threads requires, however, a very complicated mechanism, which must be understood before the operation of the machines can be comprehended, and their result examined more closely.

At the chief frame A A, B B, C, are shown all parts of the machine. (See Figs. 284 to 287.) Fig. 284 shows the machine near its centre in transverse section; Fig. 285 gives an end view of the right side of the machine, before which the operative has his ordinary place. Fig. 286 gives a front view of the fore side, and Fig. 287 an end view of the left side.

Two and two opposite sides of the frame are completely equal to each other, viz: A and A_1, B and B_1; all four are united by screw-bolts. The joist C, Figs. 284 and 286, binds the upper ends of A, A^1 together.

The warp of the web consists, as has already been mentioned, of parallel running warp-threads, which are coiled round the warp-beam. In proportion to the proceeding of the fabrication, the warp is unwound, while at the same time the finished lace is wound upon the lace-beam. The lace-beam is placed above the warp-beam, as may be seen by Z and G in Fig. 284, where they are shown in transverse section.

The ends of the *warp-beam* (represented in Fig. 284, in transverse section, and with the warp wound upon it) are provided with strong rollers or disks; and its pivots run in iron sockets, which are fastened to B_1, and in the figure marked by g. The disks R are grooved to receive the cord S, one end of which is fastened at B, while the other end runs vertically downwards, and is fastened to the lever H.

This lever turns on a pivot at the post B_1, and its fore end bears the weight Q. This contrivance serves to keep the warp in due tension while being wound off the warp-beam. This unwinding takes place in four rows of warp-threads, (see Fig. 284,) for which purpose the single threads pass the eyes of a kind of *reed* F. Figs. 284, 286, and 350, 351, consisting of single pieces of latten-plate, called *brasses*, and placed one by one into the grooves of two long staves, bound together at the ends and in the midst. The brasses are regularly perforated in four rows. The reed is oblique, and close above the warp-beam loosely fastened, (see Figs. 284 and 351,) that it (if required) may be lifted a little, and not slip down. The warp-threads are marked with f. Fig. 350 gives the view of a brass; Fig. 350 a transverse section of a row of eyes; and Fig. 351.

The fourfold divided warp passes vertically upwards between two parallel guide-bars, and unites close above them into two series of warp-threads, two and two series of the warp being drawn into two series of guides. The guide-bars (see Figs. 284, 286, 330, 331, 332, 333, 334, 335, 336, 337) are placed along the whole machine and supported at both ends and in the centre, that they may retain their parallel situation and their relative position. They are in all figures marked with a and b—a marking the front and b the back guide-bar. Both guide-bars are liable to lateral movement, by which a lateral shifting of the warp is effected. The series of guides c and d consist, like the reed F, of single pieces put together lengthwise. The number of the pieces, which are to be of entirely equal breadth, depends upon the number of the warp-threads, or of the breadth of the texture.

Every single piece, consisting of a mixture of lead and zinc, is provided with an equal number of guides, being made of iron or steel wire, and cast together with the pieces in uniform distance from each other. Fig. 334 gives a front view of a single lead-piece in its position when screwed to the guide-bar; Fig. 335 a side view of it; Fig. 336 represents a single guide; and Fig. 337 an ear. Guides are almost exclusively used, as by them the drawing in of the warp-threads is considerably facilitated.

The two series of guides c and d divide the warp into two opposite equal parts, of which the texture is to be made. At the point where the texture begins both unite in one warp and are placed in one plane. Each half extends over the whole breadth of the texture, the threads of each series having double the distance between themselves, apparent in the texture.

This arrangement is of the greatest importance. The lace-weaving is facilitated by it, and at the same time some parts can be made stronger, which is of great avail regarding durability and quickness of operation. Moreover, the inconvenience of entangling and tearing the threads is removed.

The texture begins near M N, where the interlacing and twisting of the warp and weft threads is accomplished.

Fig. 360 shows the formation of the regular holes or meshes, completed by the round *points* of the *point-bars* M and N, after the intertwisting of the warp and weft threads having been accomplished

below. The formation of the meshes is effected round the points of the point-bars, and simultaneously across the whole breadth of the warp in horizontal lines. For the formation of one row of meshes only one point-bar is required. Both alternate in this operation, so that one point-bar holds the finished row of meshes, while the other takes up the next following, and thus they relieve each other continually.

In proportion to the proceeding of the formation of the rows of meshes, the texture is wound upon the lace-beam. Figs. 284, 285, 286, 287, 288, 289, 321, 322, 328, and 329, will illustrate what is said here.

The point-bars are marked with M and N,—the front bar with M, and the back point-bar with N. Both are provided with points which are adapted to each other.

The points are cast in lead-pieces which are fixed to the point-bars by screws, (see Figs. 321, 322 and 328, 329;) the last-mentioned figure shows a point-piece N separately. Every point-piece must have exactly the same breadth as the lead-pieces of the series of guides *c* and *d*, whose number is equal to that of the point-pieces. The number of points in each point-piece is likewise equal to that of the guides in each lead-piece. By Fig. 328, it will be perceived that between the single points there is room enough not only for the opposite points, but also for the intertwisting threads.

Z represents the *lace-beam*, running parallel with the warp-beam, and being of equal length, and of equal or smaller diameter. It turns on pivots, whose sockets are placed in similar manner to those of the warp-beam. See Fig. 286.

The successive turning of the lace-beam is effected by a regulator, moved by the machinery.

The finished lace passes on its way from the point-bars to the lace-beam across the rounded iron bar D, Figs. 284, 286, 352, 353, and 354, which serves to support the texture. At both ends of it are rowels r_3 (355) turning on small pivots. The pricks of these rowels enter the meshes close by the borders of the texture, thus preventing its running together. The larger rowels R_1, close above the smaller ones, are intended for the same purpose.

The lace is, by its winding upon the lace-beam, on account of its tension, somewhat less broad than it is when lying on the point-bars.

The union of the warp and weft takes place below M N, and is effected by two rows of weft-threads, each of which is wound round a small *bobbin*, that passes between two and two warp-threads. Thus there are two rows of bobbins which are moved round the warps; and in this way the intertwisting is effected. The bobbin-rows stand parallel with the breadth of the warp, and either both rows before or behind it; or one row before and one behind it.

That the bobbins may occupy these respective positions, they are pushed from one side to the other on *carriages* and *bolts*. Each bobbin has its separate carriage and bolt; and two and two bobbins are with their carriages behind each other, on one bolt. The whole series of bolts is called a *comb*.

The bobbins, carriages, and bolts, are of a peculiar shape, as may be seen by Figs. 284, 286, 288, 289 ·96, 297, 298, 306, 307, 308, 326, 338, 339.

Fig. 296, gives the side view of a carriage with inserted bobbin.

Fig. 297, section of a bobbin.

Fig. 298, carriage viewed from the other side, and without the bobbin.

Fig. 299, section.

Figs. 306, 307_a, and 308_b, show a bolt.

Fig. 306, gives a side view of the bolt, when placed in the machine.

Fig. 307_a, represents its lower edge turned towards the warp.

Fig. 308_b, gives a section of the bolt at its opposite end.

The single bolts are, like the points and guides, cast in lead-pieces, each of which contains as many bolts as there are points and guides in one lead-piece. The breadth of the comb-pieces is exactly equal to that of the other lead-pieces.

Figs. 338, (view from behind,) 339, (front view,) and 326, (side view,) represent a comb-piece.

The small interstices between the single bolts receive the carriages, which thus, with their grooves, are placed upon the bolts. See Figs. 298, 299, 306, 326, 338, and 339.

The bolt-pieces are by the side of each other screwed on a bar, and thus form together the comb.

One of such combs is placed before, and one behind the warp, and the distance between both is not greater than required for the easy passage of the double row of warp-threads.

The bolts of both combs are exactly opposite each other, that the carriages may be pushed from one comb to the other without obstruction.

The bolts are circular, to keep the bobbin-threads at an equal tension, while the carriages are pushed to and fro.

The width of the carriages, compared with the inconsiderable distance by which their bolts stand off, on both sides of the warp, permits this pushing from one comb to the other without any difficulty. Both combs have their correct mutual position with reference to the centre of the circular line.

In the figures, the front comb is marked with L, and the back comb with L_1; the bars on which the combs are screwed, and which are called bolt-bars, are marked with K and K_1, and the carriage-lines with l and l_1. The carriage-line l, which is always nearest to the operative, is called the front, and l_1 the back line. For this reason they use to say front and back carriage-thread series, or briefly front and back carriage-threads, instead of bobbin-thread series, etc.

The unwinding of the threads and turning motion of the bobbins, is to be seen by Figs. 296, 297, 298, and 299.

The swinging movement of the carriages on their circular bolts is not a continual one, but is made in short regular intervals. The pauses occur as soon as the carriage-lines, coming from the one or the other side, have passed the warp-threads and stand completely on their bolts. Meanwhile the shifting of the warp-threads (not being hindered now by the carriages) to the right or to the left takes place. As soon as the carriages pass the warp-threads, the regular twisting and crossing is accomplished, and at the same time the mesh of net completed.

The swinging movement of the carriages is effected in the following manner. See Figs. 284, 288, and 289.

E and E_1 are two bars, parallel to the carriage-lines, but somewhat longer, and their oblique side turned towards them.

Both bars are, with their ends, placed so that they cannot shift their places. Figs. 284, 288, and 289 show the different positions which they occupy. They are close above the comb, seize the carriages, and push them from one comb to the other, as soon as put in a swinging motion.

This motion is in consequence of their moveable sockets being put in the rifts of the cradle-pieces I_1, which are moved backwards and forwards like a pendulum. See Figs. 284, 285, 286, 287, 340 to 344.

By Figs. 284 and 289, it may be seen that these *pusher-bars* never can pass the centre, but stop at some distance from the warp before they make their retrograde motion. Thus the pushing of the carriages beyond the midst, cannot be effected by them; this must be done by the drawer-bars, or the blades of the locker, (here called *double-locker.*) These are marked with q, and the locker-bar on which they are screwed, with p. Fig. 294 gives a transverse section of the double locker-blades. The locker-bars p are placed at both sides of the warps below the comb, towards the bolts of the carriages. The locker-blades may be cast either each separately, or, more properly, both together, and then fastened to the locker-bar by screws. Their material is brass, but the bars are made of wrought-iron. The length of the combined locker-blades is somewhat exceeding that of the comb, and they therefore can seize a whole carriage-line at the pointed ends of the carriages projecting from beneath the comb. See Figs. 284, 288, 289, 296, and 298. By a slight angular movement of the blades, the carriages, pushed to them by the pusher-bars, are seized at their feet, and drawn across the midst of the machine through the warp-threads. The movements of the pusher-bars and lockers are thus supporting each other, and by this, the swinging of the carriages is completely effected. The lockers serve at the same time to keep back the carriage-lines during the above-mentioned pauses, thus prevent them getting into the centre, and bringing the warp-threads out of order during their shifting. The periodic angular movement of the locker is effected by motive power, dented bars and eccentric disks acting upon the axis of the locker-bars. Figs. 284, 288, and 289 will more distinctly explain the operations of the single locker-blades.

In Fig. 284, both carriage-lines stand on the back comb. The front blade of the back locker holds the hind-feet of the front carriage-line, and thus retains also the back carriage line. The front locker is completely turned over, so that its blades by no means hinder the carriages from sliding on the front comb. In Fig. 285, the front blade of the front locker has already drawn over the front carriage-line, and keeps it on the comb. The back carriage-line is on the back comb, and is retained there by a blade of the back locker.

In Fig. 286, both carriage-lines are on the front comb, and the back line, together with the front carriage-line, is retained by the back locker-blade. The figures also show the counter-movement of both lockers, the necessity of the removal and height of the locker-blades, etc. This highly ingenious contrivance is invented by Mr. Morley.

The chief parts of the machine, their movements and functions in general, are now known, and it will hereafter not be difficult more to follow the movements, operations, and connection. But first, a stand-point must be afforded, from which the whole progress of the machine can be overlooked. For this purpose, it will be suitable to commence with the moment when a row of meshes is completed and seized by the point-bars, and at the same time to notice the particulars concerning the rotation of the shafts, wheels, and disks.

The great dented wheel V (with 48 cogs) at the principal axis W, makes *three* rotations during the two movement-periods, in which two rows of meshes are completed. It is the same with the two dented wheels s_1 and s_2.

The large heart-shaped disk U, and the two small locker-disks v_1 and v_2 make likewise *three* rotations in this time. Each rotation of these disks brings about four interrupted movements of the pushing and locker bars. Every such movement causes a carriage-line to cross a comb. Consequently, for completing one row of meshes, six movements of carriage-lines are required.

The dented wheels t_1 and t_2, (of the axis t,) which are turned by s_1 and s_2, have thrice as many cogs as the latter dented wheels, and, for this reason, they make only one rotation, while the principal axis W makes three. It is the same with the shafts t, and the pushing-wheels and lifting-thumbs connected with them.

The notches and elevations of the pushing or notched wheels, occupy nearly one-twelfth of the periphery, if taken together.

In Figs. 345, 346, 347, and 348, their mutual position with reference to their notches and elevations is shown, as they must be put on the shafts. This position corresponds to the moment which is represented in the figure of the machines, in Figs. 284, 285, 286, and 287. The disks move in the direction of the arrows.

The pushing-points of the levers are in a vertical plane going through the axis of the shafts t. Equally marked points of the periphery of the pushing or ratchet wheels are during the movement entering this vertical plane, and acting upon their levers simultaneously.

The ratchet wheels in Figs. 345 and 346, are, during a total rotation of the axis, (or during the completion of two rows of meshes,) pushing the front comb twice to the right and twice to the left; the notched wheel o_1, Fig. 347, pushes in the same time the front guide-bar, and with it the front half of the warp, thrice to the right and to the left, and the notched wheel o_2, Fig. 348, does the same with the back guide-bar and the back half of the warp.

The shell-wheel R_2 of the front point-bar (represented in Fig. 287, but omitted in Figs. 288 and 289) has a position entirely opposed to that of R_3, so that the indenture of the shell-wheel R_2 stands deepest while that of R_3 stands highest. (See Fig. 289.)

The points 9, 10, and 11, of the lifting-thumb Q_1, (see Figs. 288 and 289,) are, with reference to the

simultaneous pushing of the ratchet-wheels, corresponding about the points 20, 22, and 12; that is to say, as soon as the points 9, 10, and 11 are active, the points 20, 22, and 12 follow this movement in succession. On the other hand, the edge of the indenture in the shell-wheel R_2 corresponds respectively with 10 and about 16, its centre with 11 and 18, and its opposite edge with 19. The corresponding points of R_3 are respectively 10, and about 22, then 11, 12, and 13.

The relative position of all parts being thus correctly stated, we shall follow the various movements from the moment when a row of meshes has just been completed, and the points are falling or catching in the meshes.

Fig. 289 shows the positions of most of the chief parts in this movement; and there we see that follows:—

The back point-bar is about to fall off. Both carriage-lines are on the front comb. The front half of the warp assumes its usual position, (that is to say, its most frequent position.) Point 12 on o_1 is under the point of the lever x_1, (see Fig. 286.)

The back half of the warp has just now shifted from the left to the right, the lever x_2 being fallen off from 12 on o_2.

The movement ensues. The back point-bar N lifts the row of meshes. The back carriage-line l_1 goes up to the back comb.

After the shafts t and W have made respectively one-twelfth and a quarter of rotation, a pause ensues.

The point-bars have lifted up their rows of meshes almost entirely.

The back carriage-line is on the back comb. All carriages have made a comb-movement.

The front half of the warp retains its usual position, (see above;) the point 13 on o_1 is advanced until beneath the point of the lever.

The back half of the warp has shifted from the right to the left, (the pushing-lever x_2 has risen above the prominence at 13 on o_2.) and assumes its usual position, (see above.)

The first movement is accomplished; and the different parts are in the position of Fig. 288.

The second movement begins. The point-bars are at rest.

The front carriage-line goes up to the back comb, where the back carriage-line moves higher up.

The shafts t and W make, respectively, one-twelfth and a quarter of rotation, and a pause ensues.

Both carriage-lines are on the back comb.

The front comb is pushed from the right to the left, the points 14 of o and o_3, being advanced to beneath the points of the levers.

The front half of the warp has shifted from the right to the left.

The back half of the warp retains its usual position.

The point-bars are at rest.

The second movement is accomplished.

The positions of the different parts represented in the figures, (with the exception of Figs. 288 and 89,) are corresponding to this moment.

The third movement begins.

The front carriage-line l returns to the front comb.

The front point-bar begins to leave its row of meshes. This curve from 9 to 10 of the lifting-thumb acts upon the pin of the fork.

The shafts t make again one-twelfth of their rotation, and the pause ensues.

The front carriage-line is on the front comb, and has moved from the left to the right. The back carriage-line is on the back comb.

The front half of the warp has shifted from the left to the right, and is in its usual position, as is the back half also.

The front point-bar is lifted almost entirely out of the meshes.

The third movement is accomplished.

The fourth movement begins.

The back carriage-line goes up to the front comb.

The front point-bar is lifted out.

The shafts t make their fourth twelfth of the rotation, and the pause ensues.

Both carriage-lines are on the front comb, and move from the right to the left.

The front and back parts of the warp are in their usual position.

The front point-bar is about to lower.

The fourth movement is accomplished.

The fifth movement begins.

The back carriage-line returns to the back comb.

The point-bar lowers. The fifth twelfth of the rotation of the shafts t is made, and the pause ensues.

The back carriage-line is on the back comb.

The front carriage-line is on the front comb, and has moved from the left to the right.

The front half of the warp is in its usual position, and the back half has shifted from the left to the right.

The fifth movement is accomplished.

The sixth movement begins.

The front carriage-line goes up to the back comb.

The front point-bar is lowering, and six-twelfths or one-half of rotation of the shafts t ensues. Both carriage-lines are on the back comb. The interchange or traversing of the carriages is accomplished The carriages have advanced to the right by one station.

The front half of the warp is in its usual position.

The back half of the warp has shifted from the right to the left.

The front point-bar has lowered. It is now exactly in the same position as the back point-bar was in the beginning of the first movement, (see Fig. 289,) and is nearly about to fall off.

The sixth movement is accomplished, and therewith a row of meshes completed.

These six movements constitute the first period of operations.

The next, or second period, comprises almost the same movements, with the exception of the comb-shiftings, as will be perceived by the following explanation:—

The seventh movement begins.

The front carriage-line goes up to the front comb.

The front point-bar falls off, and lifts the seized row of meshes.

The shafts *t* make the seventh twelfth of their rotation.

The front carriage-line is on the front comb, and the back one on the back comb.

The front half of the warp has shifted from the right to the left; the back half is in its usual position.

The front point-bar is lifted almost entirely.

The seventh movement is accomplished.

The eighth movement begins.

The back carriage-line comes up to the front comb.

The front point-bar is lifted.

The shafts *t* make the eighth twelfth of their rotation.

Both carriages are on the front comb.

The front half of the warp having shifted from the left to the right, assumes its usual position.

The back half of the warp retains its usual position.

Both point-bars are at rest.

The eighth movement is accomplished.

The ninth movement begins.

The back carriage-line goes up to the back comb.

The back point-bar begins to leave the meshes, and nine-twelfths of rotation of the shafts *t* are made.

The back carriage-line is on the back comb, and the front line on the front comb.

The front half of the warp is in its usual position.

The back half of the warp shifts from the left to the right.

The back point-bar has nearly left the meshes.

The ninth movement is accomplished.

The tenth movement begins.

The front carriage-line goes up to the back comb.

The back point-bar is entirely taken out.

The tenth twelfth of rotation of the shafts *t* ensues.

Both carriage-lines are on the back comb.

The front half of the warp shifts from the right to the left, and the back half shifts from the left to the right.

The back point-bar is about to lower.

The tenth movement is accomplished.

The eleventh movement begins.

The front carriage-line returns to the front comb.

The back point-bar lowers, and the eleventh twelfth of rotation of the shafts *t* ensues.

The front carriage-line is on the front comb, and the back line on the back comb.

The front half of the warp shifts from the left to the right, and the back half retains its usual position.

The back point-bar is near its deepest standing.

The eleventh movement is accomplished.

The twelfth movement begins.

The back carriage-line goes up to the front comb.

The back point-bar attains its deepest standing. The last twelfth or a total rotation of the shafts *t* is accomplished.

Both carriage-lines are on the front comb.

The front half of the warp is in its usual position, and the back half shifts from the left to the right.

The back point-bar is in its deepest standing, and about to fall off.

The twelfth movement is accomplished. A fresh row of meshes is completed, and is forthwith taken up by the back point-bar.

With the twelfth movement the second period of operations is accomplished, and all is in the position of Fig. 289. Hereupon the same circulation of movements and functions of the different parts begins, and so on.

The following table will serve to render the just-described periods of movements still more conspicuous. The superscriptions of the columns will prove to be sufficient to explain the signification of the letters; and it may only be remarked, that A signifies the front carriage-line, and B the back carriage-line. Each column contains two lines, filled either with points or letters, thus indicating the mutual position of the concerning threads and carriages after every lateral movement. The asterisks (*) in the column superscribed "Front comb," serve to direct the attention on the shifting of the comb.

TABLE *of the Periods of Movements.*

First Period of Movements

Movements.	Front comb.	Front half of the warp.	Back half of the warp.	Back comb.	Movement of the point-bar.
End of the 12th or beginning of the 1st..................	• • A B	• *a*	• *b*	• • • •	The back point-bar is about to fall off.
End of the 1st or beginning of the 2d..................	• • • A	• *a*	*b* •	• • B •	The back point-bar has taken up the row of meshes.
End of the 2d or beginning of the 3d..................	* * • •	*a* •	*b* •	• • A B	Both point-bars at rest.
End of the 3d or beginning of the 4th..................	• • * *A	• *a*	*b* •	• • B •	The front point-bar is lifted out of the meshes.
End of the 4th or beginning of the 5th..................	*A *B • •	• *a*	*b* •	• • • •	The front point-bar is about to lower.
End of the 5th or beginning of the 6th..................	• • * *A	• *a*	• *b*	• • B •	The front point-bar is lowering deeper.
End of the 6th or beginning of the 7th..................	• • • •	• *a*	*b* •	• • A B	The front point-bar has lowered deepest and is about to fall off.
Second Period of Movements.					
End of the 7th or beginning of the 8th..................	• • • A	*a* •	*b* •	• • B •	The front point-bar has lifted the row of meshes.
End of the 8th or beginning of the 9th..................	• • A B	• *a*	*b* •	• • • •	Both point-bars at rest.
End of the 9th or beginning of the 10th..................	• • • A	• *a*	• *b*	• • B •	The back point-bar is lifted out of the meshes.
End of the 10th or beginning of the 11th..................	• • • •	*a* •	*b* •	• • A B	The back point-bar is about to lower.
End of the 11th or beginning of the 12th..................	• • • A	• *a*	*b* •	• • B •	The back point-bar lowers deeper.
End of the 12th or beginning of the 1st..................	• • A B	• *a*	• *b*	• • • •	The back point-bar is about to fall off.

A comparison of this detailed statement, with the illustration given in Fig. 360, will afford a still clearer view of the intertwisting and crossing of the warp and weft or carriage-threads.

In Fig. 360 the warp-threads are marked with *f*. They proceed downwards in serpentine lines, and receive their contorsion from the tension of the weft-threads twisted obliquely round them alternately to the right and the left hand. Before this union, and beneath the point-bars, the warp-threads are tentered vertically. So that the front half of the warp may be better distinguished from the back half, the threads of the former are hatched.

The front carriage-threads are marked with k, and the back threads with k_1. The figure shows the texture on a very large scale. The web consists of nine warp and nine weft threads. Five threads belong to the back half of the warp, and four threads to the front half.

Each (horizontally directed) row of meshes contains four holes or meshes.

The hatched circles within the meshes represent the points of the two point-bars, and are marked with M and N.

Description of an eight-quarters stripe machine.—Machines of this kind furnish bobbinet stripes or quillings, forming one broad piece during the fabrication, but which afterwards are separated from each other.

As these quillings or edgings, for the sake of beauty and solidity, must be, as it were, without a seam, this manufacturing requires a particular contrivance in the bobbinet machines.

The above-described double-locker machine may easily be arranged for manufacturing quillings; and the most practical and suitable contrivances for this purpose are those invented by Mr. Croft.

In Fig. 369 are represented two stripes of equal breadth, and united in such manner as they appear in the whole piece on the lace-beam. The borders or selvages are hatched and marked with f_3 and f_4.

The connecting thread, running in zigzag from one mesh to the other, is marked with k_3, and the other warp and carriage threads respectively with f and kk_1.

Each stripe being a plain narrow lace in itself, and the carriage-threads proceeding in their slanting directions, separately in the one and in the other, of course a contrivance is required in order that the carriages may turn back at the two inner selvages as well as at the two outer ones. This and all other required arrangements are illustrated by Figs. 361 to 394.

Fig. 378 represents a double-locker stripe machine in transverse section, in which latter Figs. 385, 386, 387, 388, and 389, are also given. The most essential parts of the machine are to be seen in Fig. 378.

Beginning from below, there will be perceived two warp-beams, G and G_3. Round the larger one is wound the warp for the plain texture, and round the other are twisted the commonly somewhat stronger selvages f_3 and f_4. In case the latter should be of equal thickness as the other warp-threads, one beam would be sufficient.

The warp-threads are to be drawn through the kind of reed F, and thence through the series of guides c and d, which are fastened to the guide-bars a and b.

The selvage-threads are only laid over the wooden framing-staves of the reed F, (see Fig. 378,) and then (on account of their peculiar lateral movement) drawn through particular iron or brass ears, (one of which is represented by Figs. 391 and 392,) called selvage-guides, which are fastened to the guide-bars a_3 and b_4. The selvage guide-bars are provided with similar sockets, supports, adjusting screws, levers, and springs, as a and b.

The warp is not divided into two equal parts as in the machine described above, but is drawn through the front and back guides c and d unequally divided, and this in such a manner, that in the front warp-half one, and in back half two, warp-threads are omitted at every border of the stripe. The corresponding guides, in the series of guides, are broken off as superfluous.

The selvage-threads, on the other hand, are equally divided, drawn through the series of guides c_4 and d_3, yet those marked with f_3 (see Fig. 369) exclusively through the front, and those marked with f_4 through the back series.

Between the combs L and L_1 all warp and selvage threads are drawn up in two rows, and led to the points n of the point-bars M and N, beneath which the texture is formed, after which it proceeds to the lace-beam.

The comb and the lockers, and locker-bars p and q, are set up in the usual manner.

The carriages are likewise put in with two lines, odd carriage, etc., as has been described above. Yet in the back line, right opposite to the selvage-threads, there are also the turn-again and whipping carriages, briefly called *whipper-carriages*, with the thick and strong connecting threads k_3, (see Fig. 309.) The whipper-carriages make upon the whole the same movements as the other carriages, with the only difference that they do not shift their places, but are running to and fro in the same bolts. During the shifting, they remain in the back comb, while the other carriages change their places in each stripe-section.

Before their peculiar movement, (illustrated by the figures from 378 to 382,) during the shifting, can be explained, some parts and contrivances connected with it must be viewed.

Close beneath the locker-bars p are parallel with them the so-called *picker-bars*, to which the *pickers* p_3 are fastened by screws. The picker-bars have exactly such sockets and supports as the locker-bars At the one end is fixed a short arm e_1, moved by the drawer-bar e^2, by which the picker-bar, with the pickers, can be put in a slight angular movement.

The pickers, made of stiff hammered iron or brass, Figs. 392 and 393, are performing here the functions of the locker blades in the above-described machine, as they, like them, seize the heels or catches of the carriages and push the latter onward, or respectively set them in their places. They, moreover, serve to regulate the movements of the whipper-carriages, and are to be advanced as far as possible towards the midst, yet in such manner that they may not impede the series of guides in their lateral movements.

To retain the whipper-carriages on the back bolt-bar, the back pusher-bar E_1 must be placed by a particular contrivance, which is illustrated by Figs. 378 and 381, and especially by Figs. 385 and 389.

The pusher-bar E_1, made of strong iron or spring steel plates, is at its long outsides strengthened by a rib of wrought-iron and provided with a pivot, by means of which the bar is placed in the sockets of the cradle-pieces I_1 in Figs. 284, 285, 286, etc. The bar has narrow but deep notches, intended to receive the whipper-carriages while the other carriages are shifting their places; but as soon as this shifting is accomplished, the whipper-carriages are let out, and the notches are closed by the covers d_4, which are fixed to the guide-bar g_3, and represented in Figs. 388 and 389. The covers are made of thin iron plate. The guide-bar g_3 is, by means of iron pieces e_3, fixed to the above-mentioned rib in such manner that it is easily to be moved sidewise, and keeps the covers close upon the notches. The bar is constantly attracted or drawn by a small but sufficiently strong spiral spring, fixed with its end to the pusher-bar E_1. The iron pieces e_3, and the slits of the guide-bar g_3, are squared thus, that the covers are exactly upon the notches as long as the spring is acting. Fig. 385 represents this movement.

The uncovering of the notches is effected by a lateral movement of the guide-bar g_3 to the right, and this movement is brought on by the action of a lever on the pivot or tenon a_4 at the bar.

Figs. 390 (giving a side view) and 391 (horizontal section close above the comb) serve to illustrate this movement. K is the front bolt, which, in the moment of the shifting, moves from the right to the left with the comb L. At its lower edge is applied the trigger h_3 which grasps the short one of the two arms of the lever F_3. The turning takes place on the pivot s_3 fixed at a suitable place in the frame. The long lever-arm, bent exactly in conformity with the curve of the comb, and placed in such manner that it is tight beneath the bar E_1, lies close to the left side of the tenon a_4.

Thus as soon as the bolt-bar K is moving to the left, the long arm of the lever F_3, moving to the right, presses against the tenon a_4, overcomes the power of the spiral spring, pushes the guide-bar g_3 to the right, and opens the notches of the pusher-bar.

The notches must be kept open until the shifting is accomplished. But the bolt-bar turning again from the left to the right, after the first quarter of the shifting movement, and, consequently, the long arm of the lever F_3 making the inverse movement, the covers would close the notches again and bring about confusion, if there had not been made a contrivance for preventing it. The chief instrument of this contrivance is the parrying-ledge h_4, screwed on the back bolt-bar. Its position relative to the lever F_3 and the tenon a_4 is shown by the Figs. 390 and 391. The tenon a_4 leans against the parrying-ledge as soon as it is pressed by the lever F_3, and does not give way until the shifting is accomplished. The positions of the tenon a_4, marked with dotted points in Figs. 390 and 391, will sufficiently illustrate this statement.

We shall now take a view of the peculiar movements of the whipper-carriages in the moment of the shifting.

Fig. 378 represents the concurring parts in the movement when the shifting of the front comb begins. Both carriage-lines are on the back comb.

In the next movement the comb makes its lateral movement; the lever F_3 acts upon a_4, and the notches of the pusher-bar E_1 are opened. Simultaneously the back pickers are, by the angular movement of the picker-bars, moved upwards. They now seize the shifted carriages at their heels or catches and push them onward, see Fig. 379, while the other carriages remain at their places, and the whipper-carriages (marked with k_3) pass into the notches of the pusher-bar E_1.

Now the movement of the pusher-bar and locker begins; E_1 pushing onward those carriages, which are not retained by the pickers, and the back locker lowering. As soon as the outer locker-blade is within the back heels of the retained carriages, the pickers move downwards, the just-mentioned carriages are seized by the outer blade of the back locker, and the carriage-movement ensues in the usual manner. The front locker draws the carriages, pushed to it by the pusher-bar E_1, up to the front comb, where, opposite to each whipper-carriage, one common carriage is lacking, (which may appear a matter of course by the above given statement,) and is instead of this in the back line of it. The back carriage-line on the back comb is complete, and has behind itself the line of the whipper-carriages which had been retained in the notches of the pusher-bar E_1. (See Fig. 380.)

The comb moves back; the carriage-movement ensues; the back pusher-bar causes all carriages, without any exception, to move onward; the back locker falls off and the front locker seizes the carriages presented to it and draws them up to the front comb. But just before the front locker seizes the heels of the carriages, the back pickers move upwards again, and consequently retain the whipper-carriages on the back comb. Meanwhile the other carriages have been drawn up to the front comb, where now two lines are, of which the inner one is complete, while in the outer one as many carriages are lacking as there are whipper-carriages on the opposite side. The position of the concurring parts in this movement is represented by Fig. 381.

The back pickers are thus, in this period of movements, performing the function of the back locker, which (as is shown by Fig. 381) has completely turned round, and cannot, for this reason, retain the whipper-carriages.

As soon as now the front comb has moved again from the right to the left, the front pickers spring up, and, seizing the (not in pairs) standing carriages on the front comb at their heels, press them upwards until their back heels or catches are beyond the outer blade of the front locker. (See Fig. 382.) The back pickers remain in their position represented by Fig. 381. Then the usual carriage-movement begins, and before the front comb moves from the left to the right, the front as well as the back pickers fall off. The comb-shifting ensues, and now both carriage-lines on the front and on the back comb are complete. The interchange or traversing of the carriages throughout the whole width of each texture-stripe has occurred, and the movement of the carriages of the complete lines continues in the usual manner until the shifting takes place anew.

This shifting, i. e., the interchange or traversing of the carriages in the texture-stripes, is indeed not easily to be understood; however, the following statement will prove adapted to render the matter pretty clear.

The common carriages are marked with *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, *k*, and the whipper-carriages with k_3; their number is in conformity to the pattern in Fig. 369. The position of the carriages and combs is, according to Fig. 378, the following:

First Position after the first shifting of the front comb. — *Commencement.*	. a b c d k_3 a b c d k_3	back comb.
	. k h g f e k h g f e	
	. . . .	
	. . . .	
	. . . .	
	• • • • • • • • • •	
	• • • • • • • • • • . . .	front comb.

The big points represent the concurring places for the carriages. As soon as the carriages are on the front comb, their position is the following:

First Position. — *End.*	. • • • • k_3 • • • • k_3 . .	back comb.
	a b c d e a b c d e	
	. . . .	
	. . . .	
	. . . .	
	• k h g f • k h g f . .	front comb.
	• • • • • • • • • •	

After the comb's lateral movement to the right, the carriages stand thus:

		·	·	·	·	k_3	·	·	·	·	k_3	. . .	back comb.
		a	b	c	d	e	a	b	c	d	e	. . .	
Second Position.		.	.	.	.	.	.	.	.	.	.		
—		.	.	.	.	.	.	.	.	.	.		
Beginning.		.	.	.	.	.	.	.	.	.	.		
		·	k	h	g	f	·	k	h	g	f	. . .	front comb.
		·	·	·	·	·	·	·	·	·	·		

This position corresponds to Fig. 380; yet as soon as the back carriage-lines have passed the front comb, the position is the following:

		·	·	·	·	·	·	·	·	·	·	.	back comb.
		·	·	·	·	k_3	·	·	·	·	k_3	. .	
Second Position.		.	.	.	.	.	.	.	.	.	.		
—		.	.	.	.	.	.	.	.	.	.		
End.		.	.	.	.	.	.	.	.	.	.		
		a	b	c	d	e	a	b	c	d	e		
		·	k	h	g	f	·	k	h	g	f	. . .	front comb.

The comb moves to the left, and now the carriages stand thus:

		·	·	·	·	·	·	·	·	·	·	. . . .	back comb.
		·	·	·	·	k_3	·	·	·	·	k_3	. . .	
Third Position.		.	.	.	.	.	.	.	.	.	.		
—		.	.	.	.	.	.	.	.	.	.		
Beginning.		.	.	.	.	.	.	.	.	.	.		
	a	b	c	d	e	a	b	c	d	e			
	·	k	h	g	f	·	k	h	g	f		. . .	front comb.

This position corresponds to Fig. 381. The carriages move up to the back comb, and their position is now the following:

		·	·	·	·	·	·	·	·	·	·	. . .	back comb
		b	c	d	e	k_3	b	c	d	e	k_3	. . .	
Third Position.		.	.	.	.	.	.	.	.	.	.		
—		.	.	.	.	.	.	.	.	.	.		
End.		.	.	.	.	.	.	.	.	.	.		
	a	k	h	g	f	a	k	h	g	f		. . .	front comb.
	·	·	·	·	·	·	·	·	·	·			

The comb moves back, and the shifting of the carriages is now accomplished; for the position is thus:

	·	·	·	·	·	·	·	·	·	·	. . .	back comb.
	b	c	d	e	k_3	b	c	d	e	k_3	. . .	
	.	.	.	.	.	.	.	.	.	.		
Fourth Position.	.	.	.	.	.	.	.	.	.	.		
	.	.	.	.	.	.	.	.	.	.		
	a	k	h	g	f	a	k	h	g	f	. . .	front comb.
	·	·	·	·	·	·	·	·	·	·		

&c., &c., &c.

This statement shows at the same time clearly, that all carriages, as for instance, *e* in the first position, or as after the shifting *f* in the fourth position, which are with the whipper-carriages in one and the same bolt, are doing the business of whipper-carriages.

At the ends of the carriage-lines no whipper-carriages nor pickers are required, because the hold-fast contrivance, applied here, together with the notches of the lockers, supply the action of the pickers.

The above explained interchange or traversing of the carriages is rendered necessary by the mentioned order of the warp-threads, and that the stripes of the texture may be provided with seams.

In manufacturing plain broad pieces, the front half of the warp containing one thread less than the back half, there must be in a pattern like that of Fig. 369, four front and five back warp-threads in each stripe. Further, the borders or selvages of plain broad pieces being made of the end threads of the back warp-threads, consequently the seam-threads of the stripes must likewise be contained in the back half of the warp. But as here, on account of the connecting thread, (running in zigzag,) the left seam-thread of a stripe must alternately pass over two bolts, these threads are to be drawn through particular guides adapted for this movement.

The lateral movements of the guide-bars are in the usual manner prepared by ratchet-wheels, levers and angular pieces, or swing-bars. But for effecting the just-mentioned movement for the particular guiding of the seam-threads, the stripe-machine must be provided with two ratchet-wheels more, which are fastened at the axis t, to the right of the machine. Besides these, there are required two other ratchet-wheels for the movement of the pickers, which are fastened at the same axis within the dented wheels t_1 and t_2. (See Fig. 286.) Sometimes the last-named wheels are arranged for this purpose in the manner illustrated by s_4 in Fig. 390.

The figures from 370 to 377 represent all ratchet-wheels of the double-locker stripe-machine. The directions of the arrows indicate those of the movements. The various acting points in the twelve different movements of the concurring parts are marked with ciphers. Equal marked points are simultaneously acting. Point 1 corresponds to the acting point indicated by Fig. 378.

Fig. 370 represents the right ratchet-wheel for the lateral movement of the comb; Fig. 371 the left one of this description; Fig. 372 the front ratchet-wheel for the warp-threads, and Fig. 374 the back ratchet-wheel for the same purpose. (These four wheels, already known by the description and illustrations of the broad plain bobbinet machine, are delineated here once more, in order to facilitate the view of the whole.) Fig. 373 represents the front ratchet-wheel for the seam-threads; Fig. 375 the back ratchet-wheel for the same purpose; Fig. 376 the back ratchet-wheel for the pickers, and Fig. 377 the front one of this description.

Following in the order of numbers the indentments of the ratchet-wheels, it becomes apparent that during the twelve different movements of the two principal movement-periods, (in which two rows of meshes are completed,) the shiftings of the warp-threads occur simultaneously, and in a successive order. Still more perspicuous the simultaneous operations of the ratchet-wheels will appear by supposing their peripheries to be stretched out into a straight line, as has been done in the following sketch.

By the lateral shiftings of the warp-threads, and by the interchange or traversing of the carriages, the formation of the web is effected; and all the intertwistings and decussations of the threads follow each other in the same order, as has been sufficiently explained above. The connection of the seam-threads with the connecting thread k_3, (Fig. 369,) is not brought on by perhaps a lateral movement of the latter, but only by the lateral movements of the seam-threads. Thus the intertwisting of k_3 and f (in the midst of the figure) is effected by a single shifting of the latter towards the former thread, (explained by Fig. 373,) while the intertwisting of the left seam-thread f_4 is effected by its double-shifting (See Fig. 375.)

The positions of the warp-threads towards each other and towards the carriages in the two principal movement-periods, are exposed in the following statement. In this $a, b, c, d, e, f, g, h, k$ signify the common carriages, k_3 the whipper-carriages; the asterisks (✱) signify the back seam-threads; the simple crosses (+) the front seam-threads; the large points (.) the common front and back warp-threads; and the vertical dashes (|) the void places for the carriages. The statement corresponds to the texture of Fig. 369.

```

Now the second principal movement-period has finished, a fresh row of meshes is completed, and forth with taken up by the back point-bar, and in this manner the cycle of movements is continuing.

The points of the point-bars take up the completed meshes in the usual manner, only two points in the midst are somewhat bent sidewise to give room for the connecting thread. (See Fig. 394.)

The breadth of the stripes is commonly fixed in conformity with numbers which coincide with the number of meshes running diagonally. Thus, for instance, the stripes in Fig. 369 would be marked with No. 8.

Figured bobbinet (or design bobbinet) is manufactured in three different ways:—

The common plain bobbinet is interwoven with embroidering or twisting threads. This interweaving can be done at single spots, as well as in continued lines. The first manner produces points or spots regulated by groups and figures of various descriptions; and the second manner produces ornamental stripes either in serpentine lines, or in zigzag, or otherwise arranged. The ornamental or embroidering threads consist usually of thick or colored yarn, in order that the pattern may have a better relief.

Machines for manufacturing bobbinet of this description, are: *Sneath's* improved single-locker machine; *Heathcoate's* patent machine; *Summer's* lever machine; *Sewell's* roller machine; *Draper's* machine, and *White's* improved machine.—The arrangements of these machines are very different, and it would lead us too far, to give any description whatever of them here. Heathcoate's machine is connected with a so-called *tatting machine*, by which the interweaving of ornamental threads is performed.

The simple intertwisting of threads in the plain bobbinet is altered in such manner, that at certain points of the web, larger holes or meshes are made, surrounded by common smaller ones. Some patterns of this description are called *grecian net*, the *honey-comb open work*, and the *roseau tull.*

The manufacturing of these webs requires, of course, more or less complicated arrangements in the machinery. Their chief peculiarity is, that the warp is to be divided in more than two parts, which have their lateral movements independent of each other. Frequently the movement of the carriages is in certain movement-periods somewhat altered too, similar to the case of the stripe-machine, which may indeed be considered as producing figured or design bobbinet, if the zigzag connection be regarded as a figure.

The arrangements of the first and second systems are combined, by which we obtain patterns with larger, and meshes with ornamental threads. Draper's machine is partly adapted to them. Upon the whole, the machinery is very complicated; and for this reason, almost everywhere the lever and single-locker systems are applied, because machines of this description can be more conveniently arranged and altered than double-locker machines.

BOILERS, for the generation of steam for engines, may be divided into three great classes. The and or stationary boiler, the locomotive boiler, and the marine boiler. In the first the combustion is

the least active, in the second excited by means of the exhaust or artificial draft. In the first the principles of combustion and proportion of parts are pretty accurately determined, but the circumstances under which the marine boiler is placed and the conditions it is required to fulfil are so different that as yet no one form, dimensions, or proportions can be said to be the standard.

Stationary Boilers. The *capacity* of steam-boilers should at least equal one cubic yard, or 27 cubic feet, for each horse-power, being a *minimum* space of 13·5 cubic feet for *steam*, and a *maximum* space of 13·5 cubic feet for *water*. In cylindrical boilers, plain, without any inside flue, and set upon the oven plan—that is, the flame and smoke passing direct from the bottom of the boiler to the chimney without any return flue—the maximum length in feet is 6 times the square root of the horse-power, or, if with a wheel draught, 4 times the square root of the horse-power. In cylindrical boilers with inside flue or flues passing through them, and with split draught, 3¼ times. If flued, and with inside uptake set with split draught, the length in feet should be from 3 to 3¼ times the square root of the horse-power; or, if with wheel draught, 3 times.

The *ash-pit* and entrance to it should be as large and free as possible. The area for entrance of air to ash-pit never less than ¼ the area of grate; 2 feet 6 inches is sufficiently deep for ash-pit.

The *fire-bars* inclining downwards 1 inch per foot, and cast as thin as possible consistent with necessary strength, not more than ¾ inch thick, and with ⅜ or ½ inch spaces between.

The *furnace* should have 3 cubic feet of space above each superficial foot of fire-bar surface.

Flues.—To determine the area of the flue and chimney, it must be considered that 150·35 cubic feet of air are required for the combustion of 1 lb. of coal. Of this air 44·64 feet combine with the gases evolved from the coal, and 105·71 feet with the solid portion of the coal. The combination of the air and gases increases their volume 1-10th. The 44·64 feet thus become 49·104 feet. The sum of 105·35 with the carbon remains the same. The total product of the combustion (without considering the increase of volume resulting from raising the temperature) of 1 lb. of coal, is therefore 105·71 + 49·104 = 154·814 cubic feet. Assuming the temperature of the furnace at 1000° Fahr., at which aëriform bodies are expanded to about three times their original bulk, the product will be 154·814 × 3 = 464·442 feet. Adopting the result of Dr. Ure's experiments, viz., that the products of combustion pass off at a velocity of 36 feet per second, the area to allow this quantity to pass off in an hour will be ·516 square inch. In a furnace in which 13 lbs. are burnt per hour on each square foot of grate, which is, according to Mr. Parkes, the average consumption throughout England, the minimum area over the bridge, or of the flue immediately behind the furnace, would be ·516 × 13 = 6·709 square inches. In practice, however, as a large surplus of air is always admitted, and the exactness supposed in this calculation cannot be secured, it is found advantageous to make the area 2 square inches instead of ·516. This gives 26 square inches of area over the bridge to every foot of grate where 13 lbs. of coal are consumed per hour to every foot of grate. As the temperature and bulk become gradually reduced in proportion to the distance from the fire, the area of the flue towards the chimney may be narrowed; but this should be done without awkward bends or sharp angles.

Proportion of heating or flue surface to size of grate.—In boilers burning 13 lbs. per foot per hour, 18 superficial feet of heating surface to each foot of grate is a good proportion. This proportion omits the *bottom* surface of flat flues, and from ⅓ to ¼ the surface in circular flues, as being inoperative.

Chimneys.—The area of the chimney should be ¾ that of the opening over the bridge, viz., 1½ inch per lb. of coal consumed, or 19½ inches for each foot of fire surface burning 13 lbs. per hour. But the whole diminution of flue should be made gradually, and not by any sudden contraction. A common rule is, that the minimum area of chimneys 24 to 30 yards high, is 4000 square inches for each 20 horse-power.

Furnaces and Boilers.—From a careful examination of some of the best constructed boilers and furnaces in Manchester, the ratio of grate-bar to absorbing surface was found to be 1 : 11·1, which, taken from fifteen boilers of the best construction, and worked with considerable skill, gives a fair average of the proportions of the furnace and the flue surface of each. On comparing the above with the boilers at work in Cornwall, it will be found that their relative proportions are as 1 to 25; and while 6 lbs. of good coal will evaporate in the Cornish boiler about 11½ lbs. of water, the utmost that the best wagon-shaped boiler has been known to accomplish is 8·7 lbs. of water to the lb. of coal. Hence the advantage of a small furnace and large flue surface, united, however, to abundance of boiler space, in order to attain a maximum effect by a slow and progressive rate of combustion.

Taking the amount of flue surface in a boiler exposed to the passing currents of heat as a criterion of its economic value, we shall then have according to computation a summary of comparison as follows;

Numbers.	Description of boiler.	Cubic contents in feet.	Area of heated surface in feet.	Ratio of the area of heating surface to cubic contents.
1	Old hemispherical boiler	420	128	1 : 3·28
2	Common wagon-boiler, without middle flue	1044	320	1 : 3·26
3	Wagon-boiler, with middle flue	894	432	1 : 2·06
4	Cylindrical boiler, without middle flue	789	225	1 : 3·50
5	Cylindrical boiler, with middle flue	579	360	1 : 1·65
6	Cylindrical boiler, with eight 10-inch iron tubes	605	567	1 : 1·06
7	Improved boiler, with two middle flues	575	548	1 : 1·01

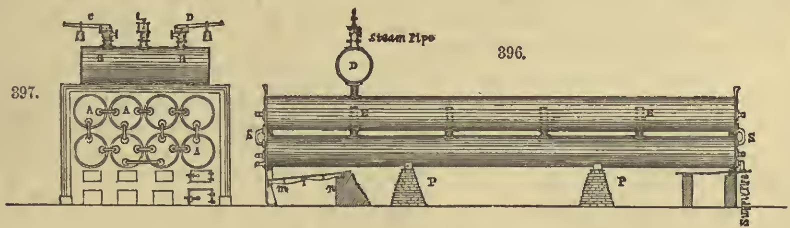
SCALE.—1-12th inch = 1 foot.
Transverse Section.

On the various forms of stationary boilers, Fig. 395, represents the *wagon* boiler, sometimes called the *caravan* or *oblong* boiler. This boiler succeeded the *haystack* boiler, but it is not adapted to resist the pressure of high steam; but up to 5 feet diameter, if provided with one or two or three longitudinal stays, of 1½ inch square from end to end, and cross stays at every two feet in the length, it may be safely worked up to 10 lbs. per square inch, and the evaporative results are economical. Their length is commonly from 16 to 24 feet. They are seldom used in this country.

Plain cylindrical boilers set in brick work, are in very common use for stationary engines, and especially at such places as it is inconvenient to get workmen to make repairs. They are usually from 30 to 40 inches in diameter, and from 30 to 40 feet long. The grate is placed at one end, being of about the width of the boiler and from 3 to 5 feet long. The chimney is at the opposite end. At the end of the grate is placed a bridge, as it is termed, which forms a back for the grate, and being brought within a few inches of the boiler, brings the flame in contact with its under surface.

Cylindrical boilers are often set in connection with each other, side by side. When set in rows, one above the other, or in *nests*, as they are called, the upper row being directly above the lower one, as in figs. 396,397, or better over the spaces, (there being one less boiler in the upper than in the lower row,) the evaporative effects, as instanced below, are excellent.



These boilers, which have now been in use by the Lowell Manufacturing Company at Lowell for two years, were constructed, from directions by Dr. A. A. Hayes, of Boston, by Messrs. Bancroft, Nightingale & Co., of Providence. One row of four boilers are set perpendicularly above another row of the same number, the fires being under the lower tier. The boilers are plain cylinders, 40 feet long and 33 inches diameter, having a surface exposed to the fires of 2,000 square feet, and containing about 1,200 cubic feet of water. The grates are in two heights of 3 feet 2 inches each, with a width of 12½ feet, giving a fire surface of about 80 square feet. Each grate is 1¼ inch thick, having between it and the next one a space of a quarter of an inch wide, giving the whole of the space for the passage of the air to the fires equal to about 10½ square feet. The dampers at the back end of the boilers are usually kept open about four inches, giving an area of four and one-sixth square feet for the exit of the smoke. The upper and lower tiers are connected by thimbles in four places in each boiler between their ends, while at the ends are a number of connections, as shown. The thimbles are of cast-iron, having a socket turned in its upper part, into which a tube is set, reaching to within eight inches of the top of the upper boiler. The connections at the ends are of cast composition metal, and notwithstanding their number no leakages have occurred. A steam drum, 11 feet long and 33 inches diameter, is connected with each of the upper boilers, and is placed above them; from this drum steam is taken to the engines. Accurate measurements and accounts have been kept of the amount of coal used, and of the water evaporated by it, which show that for the last year together, the average amount of water evaporated to one pound of coal consumed was 9.66 lbs.

The amount of coal consumed under each nest of eight boilers per day is about 2½ tons, and by comparing the weekly averages of effect, it appears that, even with this large amount of boiler compared to the fire surface, that the less the amount of coal consumed per day the better the effect.

For example: the amount of coal consumed under two nests of these boilers during the week ending Feb. 18th, 1848, was 65 tons, which evaporated 8.72 lbs. of water for each pound of coal consumed, and during the week ending July 14th, 1848, 21 tons of coal only were burned, and 10.44 lbs. of water were evaporated for each pound of coal consumed. The best result from a week's working was obtained during the week ending May 7th, 1849, when 11.62 lbs. of water were evaporated by each pound of coal consumed.

The steam from two nests of these boilers is used at a pressure of 65 lbs. per square inch, by a double high-pressure engine of 200-horse power, and a single engine of 40-horse power, both of which exhaust into pipes under a pressure of five pounds per square inch, from which it is used for dying, drying, and heating.

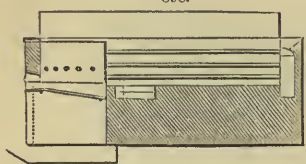
Somewhat similar to the nest boilers are the *elephant* and *retort* boilers. The former consists of two small cylindrical boilers set beneath a larger one, connected by legs at each end, hence probably the

name: the upper boiler being the body, and the connections the four legs. The grate is placed beneath one end, and the fire is brought in contact with the whole surface of the smaller boilers, passes to one end, and returns beneath the bottom of the larger boiler; the legs being sufficiently long to admit a division or arch of brick between the upper and lower boilers. These boilers are very popular in France and on the Continent, but have been used here in few instances. A good proportion for one of these boilers is as follows:—length, 24 feet; upper boiler 4 feet diameter, ends egg shaped; the lower tubes 2 feet 2 inches diameter, and separated from each other about 3 inches; water legs 18 inches diameter, and fire grate 5 feet wide by 6 feet long. The ends of the tubes may be made to project beyond through the brick-work, and have cast iron heads; but the ends of the upper boiler are usually in the flue. At the "India Mill," in Stockport, England, there is one of these boilers 35 feet long by 5 feet diameter in the main barrel; lower tubes, 2 feet 3 inches diameter; water legs, 16 inches diameter and 2 feet 3 inches high. Two of them are capable of exerting about 500 indicated horse power, consuming about 3 lbs. of coal per horse power per hour, and are worked under a pressure of 64 lbs. per square inch.

The Retort boilers consist of several small boilers or tubes, say from 16 to 20 inches diameter, arranged in rows some 2 or 3 inches apart, the spaces being filled in with brick. The steam spaces of these tubes are connected by legs to a steam drum above placed crossways of the tubes. The tubes are short, and are placed crossways of the grate, and the flame is brought in contact with the under surface of the tubes and returned over the top, the one being the water and the other the steam space. In this way the steam becomes super-heated, the intention of the boilers being for the generation of very high steam, as high as 250 lbs. to the inch. Retort boilers somewhat similar to the above were constructed by Dr. Alban on the Continent, of smaller tubes, and worked with much higher pressure.

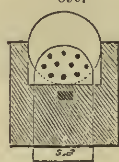
Flue Boilers. Flue boilers are of various forms; the simplest are cylindrical boilers with single or double return flues passing through them. In some the fire is made beneath the boiler at one end, the flame passing beneath the boiler and returning through flues in the boiler to the front end, where the chimney is placed, or making one return through one flue or set of flues, it is again returned by another set to the rear to the chimney. Still in another the boiler is made cylindrical, with the lower half cut away at one end for the reception of the grate, and the flame passes directly through the flues, and returns by one side of the boiler and back by the other, or makes but one return, and that beneath the boiler, the chimney being placed at the front end.

398.



SCALE.—1-20th inch = 1 foot.
Longitudinal Section.

399.

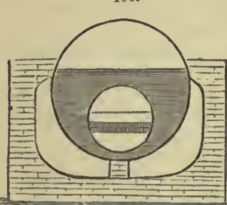


SCALE.—1-20th in. = 1 foot.
Transverse Section.

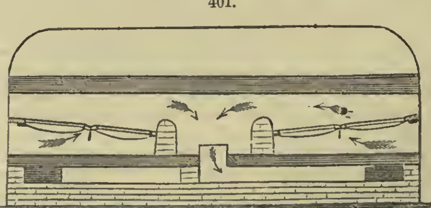
Figs. 398, 399, These flues may be either large and few, or more numerous and smaller; the latter class when tubes are used are called locomotive boilers, although used for stationary purposes. The advantage of this form is, that the hottest part of the flame is brought in contact with the top of the water: desirable whenever the top of the fire-place and flues can be kept covered with water with certainty. The top of the fire-box being a flat or concave surface, it is therefore weak unless very strongly stayed.

The Cornish Boiler, similar to fig. 398, is a cylindrical boiler, with an internal flue or flues passing through the boiler, and thence being returned on one side and back on the other; or making the first return at the sides, is brought back beneath the bottom of the boiler. The diameter of the Cornish boilers is usually about one-sixth of their length, a common proportion is from 36 to 40 feet in length, and from 6 to 7 feet in diameter. The pressure per square inch is from 15 to 35 lbs. The great economy of the Cornish boiler is found in the large proportion of fire in the slow combustion, in the great care taken in firing and keeping a register of the duty, and in the protection of the boiler from radiation.

400.

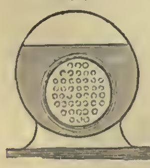


401.

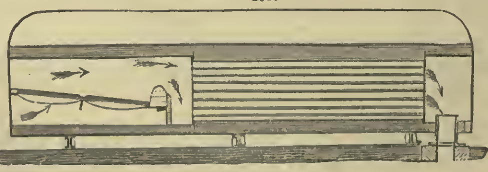


Figs. 400, 401, is a form of boiler prepared and patented by Wm. B. Johnson. The furnaces, two in number, are placed, one at each end of this flue, and the gaseous currents therefrom traverse—as shown by the arrows—meeting and mingling with each other in the central space between the two bridges. There the gasses are well mixed and ignited, prior to the combined current passing off through the outside bottom flues. Figs. 402, and 403, exhibit similar sections of a tubular boiler with a single furnace. The gases here pass from the furnace into the chamber at the back of the bridge, and thence through the flue tubes into an end

402.



403.



smoke-box, in communication with the chimney flue. The smoke-box has an end door for cleaning, and is well surrounded with water.

Figs. 404, 405, 406, 407, represent views of an upright tubular boiler well adapted in some situations for stationary purposes.

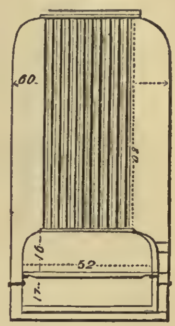
407.



SCALE.—1-8th inch = 1 foot. No. 1. Elevation. Perpendicular Section

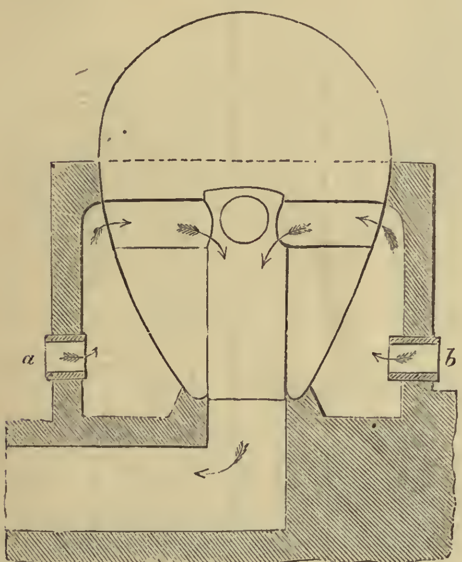
The Egg-Shaped Boiler, Figs. 408, 409. This boiler is known as the "upright egg-boiler," and is much used in Staffordshire, from the circumstance of its being so well adapted to being worked by means of the waste heats of the puddling furnaces. It is not easy to conceive a form of boiler more suitable for such an arrangement, especially where high-pressure steam is required.

Two of these boilers at Messrs. Thorneycroft's Shrubbery Iron-Works, each about 9 feet diameter and 18 high, make sufficient steam to work at about 80 horse-power, entirely from the spare heat or heated gases and smoke proceeding from four puddling furnaces, (two to each boiler,) which heat had previously gone wholly to waste.

From some estimates of the consumption of fuel by Messrs. Thorneycroft's engine, (a 48 inch cylinder,) when worked by boilers of the ordinary horizontal construction, there is every reason to believe that a considerable gain may be made by adopting this construction of boiler generally, for ordinary stationary or manufacturing purposes. Its great economy arises, in a great measure, from the vertical inside flue, the whole of the interior surface of which may be considered as effective in generating steam, in place of the upper half only of the common horizontal flue. And this beneficial efficiency, it is probable, may be further increased, if the lower end of the inside flue was made a few inches wider than the top, thus giving a better position for the generating surface.

a, *b*, *c*, *d*, in the plan show the places, with respect to the inside flues, at which the hot air or flame is discharged from the puddling furnaces.

408.



409.

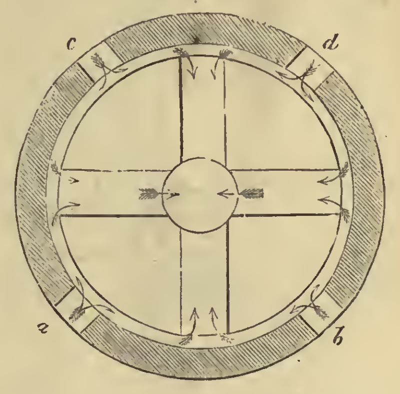


Fig. 410, represents a longitudinal section, and fig. 411, a front view of a single return drop flue, such as is used to drive the pumping engines at the Brooklyn Dry Dock. The boiler itself is 84 inches in diameter; a regular fire-box is made at one end, and the smoke and flame pass through a number of small flues at the upper part of the box, and are returned through larger and less numerous ones at the bottom of the boiler nearly to the fire-box again, where they are taken off laterally into the chimney. All the flues, and boxes at the end of the flues, are included within the shell of the boiler; the boiler is covered with brick-work and ashes. Boilers of this form give very excellent evaporative returns, and are used much in this country both for stationary and marine purposes.

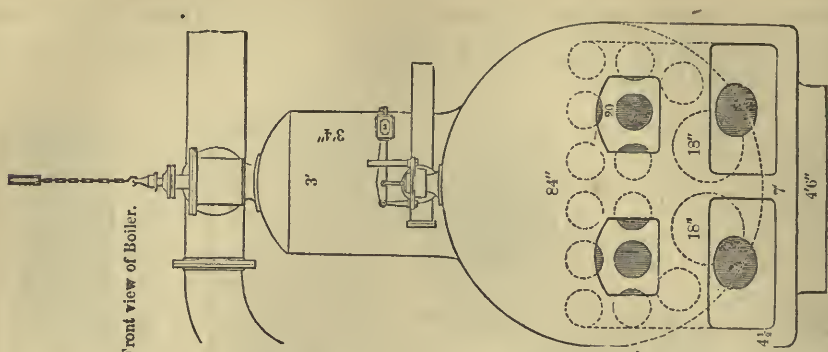
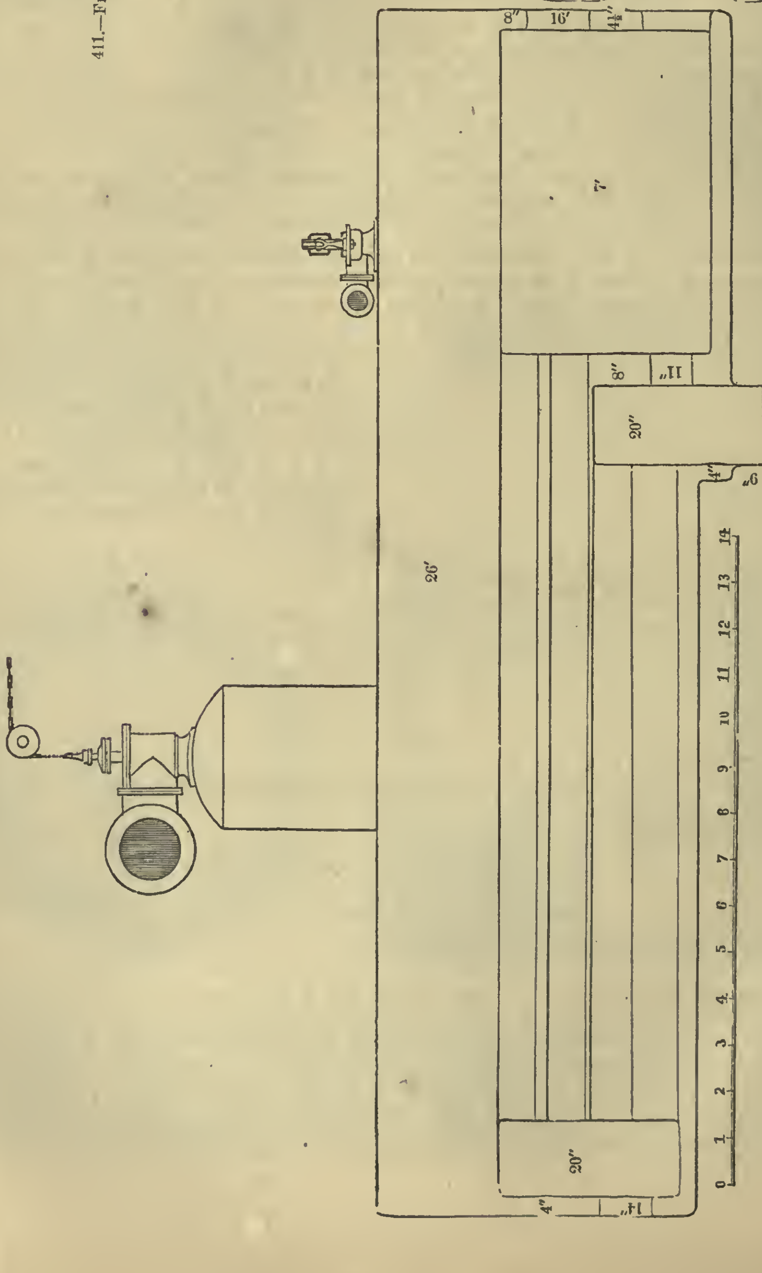
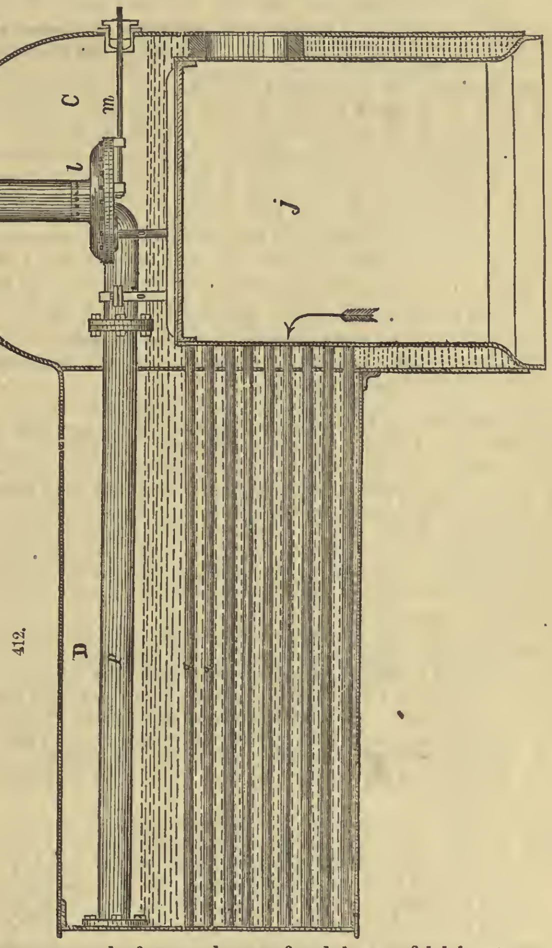


411.—Front view of Boiler.



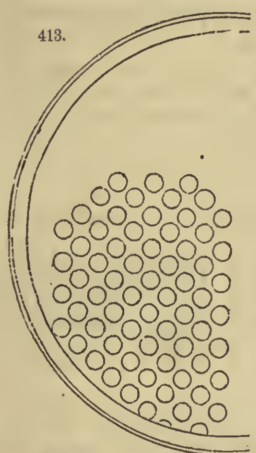
410.—Longitudinal Section of Boiler

The Locomotive Boiler (Fig. 412) represents a section of a common locomotive boiler, and fig. 413 is an end view of one-half of the smoke end. The proportions of locomotives are considerably varied by different makers, but the general arrangement is always preserved. The diameter of the tubes varies from $1\frac{1}{4}$ to 3 inches, and the length of the tubes from 7 to 14 feet. We give the investigations of the Principles of the Locomotive Boiler, by Daniel K. Clark, of Edinburgh, a paper read before the London Ins., C. E., as the most extended and reliable of any yet published; but it must be observed that the engines experimented on were coke engines, a fuel little used in this country; the application of the same principles might not obtain entirely in wood and coal engines. For a comparison of th engines of the different varieties, we subsequently extract from the valuable Report of G. W. Whistler Jr., to the Reading R. R., Pa.



412.

413.



The evaporation of 12 lbs. of water per pound of pure coke was found, by careful laboratory experiments, to be the maximum of evaporative performance; in the best ordinary practice an actual evaporation of 9 lbs. of water per pound of coke, or 75 per cent. of the possible maximum, was readily obtained, the balance being lost by leakage of air and by waste; and it was adopted by the author as the ordinary standard of practical economical evaporation.

A minute analysis was made of the results of numerous authenticated experiments on the evaporative power of locomotive boilers, of very various proportions, on the engines of the Caledonian, Edinburgh, and Glasgow, and Glasgow and Southwestern Railways. It was concluded, that the economical evaporative power of boilers was materially affected by the area of the fire-grate, and by its ratio to the whole heating surface; that an enlargement of the grate had the effect of reducing the economical evaporative power, not necessarily affecting the quality of combustion in any way, but governing the absorbing power of the boiler, as the lower rate of combustion per foot of grate due to a larger area, in burning the same total quantity of fuel per hour, was accompanied by a reduced intensity of combustion, and by a less rapid transmission of heat to the water, in consequence of which a greater quantity of unabsorbed heat must escape by the chimney. An increase of heating surface again, reduced the waste of heat, promoted economy of fuel, and added greatly to the economical evaporative power. In short, the question resolved itself into the mutual adjustment of three elements—the neces-

sary rate of evaporation, the great area, and the heating surface, consistent with the economical generation of steam at the assumed practical standard of 9 lbs of water per pound of good coke. An investigation of the cases of economical evaporation, in the "Table of Experiments," conducted the author to the following important equation, expressing the relation of the three elements of boiler-power; in which c was the maximum economical evaporation, in feet of water per foot of grate per hour; h was the total heating surface in square feet, measured inside; and g was the grate-area in square feet.

$$c = \cdot 00222 \frac{h^2}{g}$$

From this it followed: 1st, that the economical evaporative power decreased directly as the area of grate was increased, even while the heating surface remained the same; 2d, that it increased directly as the square of the heating surface, when the grate remained the same; 3d, that the necessary heating surface increased only as the square root of the economical evaporative power; 4th, that the heating surface must be increased as the square root of the grate-area, for a given evaporative power. It was contended thence, that the heating surface would be economically weakened by an extension of the grate, and would be strengthened by its reduction; and that whereas large grates were commonly thought to be an unmixed good, and being generally recommended were usually adopted, still they might be made too large—not that their extension affected the quality of combustion, but that the economical evaporative power might be reduced. Concentrated and rapid combustion was alike the true practice for the largest and the smallest boilers; and, in locomotives where lightness, compactness, and efficiency were primary objects, the boilers should be designed for the highest average rates of evaporation per foot of grate that might be followed in good practice, consistently with the highest average rate at which coke could be properly consumed; as, in this manner, the smallest grate and the smallest amount of heating surface consistent with good practice might be employed. It was stated that 150 lb. to 160 lb. of good sound coke could be consumed per foot of grate per hour; and, allowing for inferior fuel, an average maximum of 112 lb. per foot of grate was recommended as a general datum. This determined the average maximum of economical evaporation to be 16 feet of water per foot of grate per hour, allowing 9 lb. of water per pound of coke; for which 85 feet of heating surface per foot of grate should be provided. It was accordingly recommended that a heating surface at least 85 times the grate-area should be adopted in practice.

Such experiments as "midfeathers," &c., which were resorted to for specially increasing the fire-box surface, were condemned, as they were considered to be no better than tubes, whilst practically they were inconvenient and costly; as, among other reasons, plates of $\frac{7}{16}$ inch or $\frac{1}{2}$ inch in thickness were employed to do the work of the tubes, which were less than $\frac{1}{8}$ inch in thickness.

A practical rule followed by some engineers, and stated to be founded on extensive experience, was to allow 5 feet of heating surface for 1 foot of water evaporated per hour, and 100 feet of evaporating surface per square foot of grate. Those results were found to agree with the maximum rates recommended in the paper. It was also argued that the intensity of combustion materially affected the amount of heating surface necessary for economical evaporation, being less as the intensity was greater. It was contended, on the other hand, that the formula as stated in the paper would not apply to all engines.

It was further argued that, from various causes, no formula could be framed to be of service unless all the circumstances in each case were properly taken into account.

As an example of the objections to long tubes, the results were given of the work done by a luggage engine on the London and Northwestern Railway, before and after alteration. That engine originally had tubes 14 feet long, with a total surface of upwards of 800 feet; the length of the tubes was diminished to 4 ft. 9 in., and the total surface was reduced to about 500 feet, when it was found that a saving in fuel of 40 per cent. per ton per mile moved was produced, with a saving of 23 per cent. per mile run; the coke used per ton per mile, with long tubes before alteration, being ·504 lb., and with the short tubes, ·298 lb.

The back pressure was contended to be a serious drawback to the long-tube engine, and an example was given of a trial of a single engine on the new plan, against two of the ordinary kind, of 170 tons in both casts, and, although the single engine was 43 per cent. less powerful than the two engines together, and had 20 per cent. less heating surface, yet it had performed the same distance of 111 miles in ten minutes less time, and with 3 lb. per mile less fuel. This, it was argued, was owing to the engine exerting a greater dynamic force, by being relieved from the back pressure of the blast-pipe, which in the case of the other two was applied to force the fire, and to draw the heated air through the long tubes.

By the mode of placing the tube plate some distance within the cylindrical part of the boiler, the tubes were not liable to be choked with cinders, or the draught to be obstructed. This plan also afforded an opportunity of reducing the size of the tubes from $1\frac{7}{8}$ inch diameter to $1\frac{5}{8}$ inch, giving in the same boiler an equal area of flue passage, whilst at the same time the proportion of tube heating surface was increased 34 per cent. per foot of length of tube, and a very large addition of flame surface was gained.

It was further argued that although the evaporation of water per lb. of fuel was the test of the boiler, yet up to this time, few if any experiments could be implicitly relied upon, owing to the quantities being estimated by measurement instead of by weight, and without due regard to the variation of the temperature of the water in the tender.

As to the evaporative powers of marine boilers as compared with that of the best locomotive boilers, if an investigation was instituted it would be found that the general features of the best tubular marine boilers now used in ocean navigation were nearly identical with those of locomotive boilers, but the circumstances under which they were used were very different. In the marine boilers, coal was used instead of coke, and the natural draught of the chimney instead of the urging of the blast-pipe in a

locomotive, worked for many weeks or months consecutively, without the means of stopping for any extensive repair, or even to be cleaned except at long intervals. The following statement showed the comparative proportions and effect of the two descriptions of boilers:

In the Locomotive Boiler,

1 square foot of firegrate consumed about 112 lb. of coke per hour.
1 square foot of firegrate required about 85 square feet of firebox and tube surface.
1 square foot of firegrate with the above surface would evaporate 1008 lb. of water per hour.
1 square foot of flue surface would evaporate 11·7 lb. of water per hour.
1 lb. of coke would evaporate 9 lb. of water.
1 H. P. of 33,000 lb. lifted 1 foot high per minute, required about 4 lb. of coke per hour.

In the Marine Boiler,

1 square foot of firegrate consumed about 20 lb of coal per hour.
1 square foot of firegrate required about 30 square feet of fireplace and tube surface.
1 square foot of firegrate with the above surface would evaporate 170 lb. of water per hour.
1 square foot of flue surface would evaporate 5·66 lb. of water per hour.
1 lb. of coal would evaporate 8·5 lb. of water.
1 H. P. of 33,000 lb. lifted 1 foot high per minute, required about 4·25 lb. of coal per hour.

From this statement it appeared that although the proportion between the firegrate and the flue surfaces was widely different, the quantity of water evaporated, and the power obtained by the consumption of a given weight of fuel, was nearly the same, when allowance was made for the difference in the evaporative power of coal and coke. The possible maximum evaporative power of 1 lb. of carbon, was deduced from the results of chemical experiments, showing that 1 lb. of carbon, converted into carbonic acid, developed 14,000 units of heat, or would raise 14,000 lb. of water through 1°, which was equivalent to the conversion of 12 lb. of water at 60° into steam of 120 lb.

A comparison was drawn between the recent experiments of Mr. Marshall, on the large firebox engine, and those on the long boiler engine, made during the Gage Inquiry, the results being with the former a consumption of 40 lb. per mile with an average load of 64 tons, and with the latter a consumption of 27 lb. per mile with a load of nearly 60 tons. The recorded results of the work of the passenger trains on the Eastern Counties line, for the last half year, showed an average consumption of coke under 18 lb. per mile run.

It was contended, that hitherto no advantages had resulted from the extension of the firebox and the reduction of the length of the tubes, still it was possible that this innovation might, by directing attention to the subject, lead to important modifications of the structure of locomotive boilers, which should possess compactness, lightness, power of raising sufficient steam with rapidity, for performing the required work, strength to resist the chance of explosions, and a form calculated to diminish the disastrous effects of explosions when they occurred, facility of repair, especially of the firebox, which was the part most liable to deterioration, being most severely acted on by the fire, and also requiring more support than the tubes, the latter being at the same time cheaper and of thinner metal, whilst by an extension of their length the diameter of the external shell of the boiler could be diminished; the firegrate should not be larger than would evaporate the required quantity of water into steam, within a given time, with the utmost practical economy of fuel, and if that were accomplished, it was of little importance whether the evaporating heat was communicated through the firebox or by the tube surface; and that up to the present time the results of the experiments upon the boiler with enlarged firebox and shortened tubes, exhibited rather a retrograde step than an onward progressive movement.

From the "Report of G. W. Whistler, Jr.," upon the use of Anthracite Coal in Locomotive Engines on the Reading Rail Road, made to the President and Directors of that company, in 1849, we extract the following:

Tabulated Comparison of Engines on Reading R. R.—Fuel Consumed.

Class of Engines.	Number and diameter of driving wheels.	Weight on driving wheels—tons.	Coal transported per trip—tons.	Total gross load per round trip—tons.	Tons of coal transported pr. t'n of adhesion.	Fuel cons'm'd pr. r'nd trip of 190 miles.	Water evaporated.
Baltimore Anthracite Engines.	8.–46 in.	25	450	900	18	9 tons coal.	14,400 galls.
Wood Engines, Large.	8.– "	22.5	420	840	18·66	13.75 c'ds w'd	16,200 "
" " Small.	6.– "	19.5	375	750	19·23	13. " "	

The total weight of the Baltimore engines with coal, fuel and water, 27 tons; weight on eight driving wheels, 25 tons; do. on two small trailing wheels, 2 tons; diameter of the boiler, 42 inches length of tubes, 14 feet; diameter do. 2⅛ inches; area of grate, 18 feet; fire surface, 957 feet; diameter of cylinders, 16·5 inches; length of stroke, 20 inches. The draft is regulated by the variable exhaust in the smoke stack—steam cut off at half stroke.

The large 8 wheeled wood engines—total weight 22·5 tons; cylinders 15·5 inches in diameter; 20 inch stroke; fire surface about 875 feet; and of grate about 12 feet.

The essential point in which the Baltimore engines differ from the wood engines is in their having a much larger fireplace and area of grate for the combustion of coal.

The principal item of excess of cost for repairs of engines burning coal over those burning wood, is caused by the destructive effects of a coal fire upon the inside sheets of the fire-box; and when iron, (the soundness of which is always uncertain from the manner in which it is at present made,) has been used entirely for fire-boxes, the intense local heat has very soon blistered and burned away the sheets in the immediate vicinity of the coal fire. Another destructive effect from the use of coal is its severity on the laps or joinings of sheets in the fire place. To obviate this, copper sheets were substituted for iron for a distance of two feet above the grate. The experience on the Reading Railroad with anthracite coal has developed a rapid and unexpected destruction to the copper sheets, from the mechanical action of sharp particles of coal, which fleck off from the fresh coal when suddenly heated, and impinge upon and cut away the copper sheets forming the sides of the fire-place. The extent of this mechanical action is very limited, about fourteen inches in width through the entire length of the fire-place, seven inches above and the same below the surface of the coal fire. In the line of the stay bolts both vertically and horizontally, the copper retains its original thickness; and upon the copper sheet below the tube or flue sheet there is no indication of wear, for the particles of coal which are carried towards the tubes bank against, and protect this sheet. On the "Baltimore" the copper lasted fourteen months, about one third of the time experience had proved similar fire-places to last in engines burning bituminous coal on the Baltimore and Ohio Railroad. In addition to the extra wear of fire sheets, the occasional melting of grate bars, the increased liability to leakage, the wear and destruction to the ends of the tubes by caulking, &c., and the accumulation and igniting of fine coal in the smoke box, all produce their share of extra expense for repairs over wood burning engines.

Experience of the Baltimore and Ohio Railroad in the use of coal for locomotive engines.

Table showing the amount of Fuel consumed on the Baltimore and Ohio Railroad, at different periods from 1833 to 1848.

Date.	Weight of Engine on Driving Wheels.	Position of Boiler.	Gross loads.	Miles run.	Fuel consumed.
1833	4 Tons	Upright	23 Tons	80	1.15 Tons Anthracite.
1834	7.5 "	"	45 "	80	1.25 " "
1838	8.5 "	"	50 "	60	1.5 " "
1840	10.5 "	"	60 "	60	1.25 " "
1840	10.5 "	"	60 "	60	1. " Bituminous.
1841	9.75 "	"	60 "	80	1.65 " "
1841	6.5 "	Horizontal	40 "	80	2.05 Cords of Wood.
1841	19.33 "	Upright	140 "	80	3.13 Tons Bituminous.
1841	8.25 "	Horizontal	60 "	80	3.13 Cords of Wood.
1845	23.5 "	"	225 "	80	3.25 Tons Bituminous.
1848	10.5 "	Upright	60 "	80	1.25 " "
1848	10. "	Horizontal	60 "	80	1.03 " "
1848	10. "	"	60 "	80	2.75 Cords of Wood.
1848	10. "	"	60 "	80	1.58 Tons of Coke.
1848	23.5 "	"	200 "	80	2.25 " Bituminous.
1848	23.5 "	"	275 "	98	2.5 " "

1 ton of Bituminous coal = 1.25 tons Anthracite coal.
1 ton of Bituminous coal = 2.12 Cords of Wood.
1 ton of Anthracite coal = 1.75 Cords of Wood.

By an examination of this table, it will be seen what experience alone can do in reducing expenditures; for it will be easy to detect the same engine through a period of years, and see her progressive economy in the consumption of fuel. Time and experience alone have accomplished this, and much may be expected for the Reading Railroad, when by a more general use of anthracite coal, it shall be regarded less as a matter for experiment, than an important element of railway success to be perfected with care and attention.

Extra cost per year over Wood Engines for each 23.5 ton Coal Engine on the Baltimore and Ohio Railroad from the use of Bituminous Coal:

Cost for renewing fire-place	$100.00
Two sets of fire bars, 1000 lbs. cast iron, at $2\frac{1}{2}$ c.	25.00
Renewing ends of Tubes, caulking, &c.	100.00
Extra work, caulking, &c.	25.00
	$250.00.

By these experiments and dates from the Reading and from the Baltimore and Ohio Railroads, it was satisfactorily proved, even at the date of the report, 1849, that in an economical point of view coal engines are superior to those burning wood. Since that time further improvements have been made, and at present almost the entire hauling of the Baltimore and Ohio, the Reading, the Pennsylvania Central and their connections, and the Branch Coal Railroads, is performed by coal engines, either anthracite or bituminous.

Marine Boilers.—We are very much in the dark as to the true principles upon which to design a marine boiler, which shall produce the greatest effect with the least stowage, and first cost, subsequent labor, and fuel. The best that can be done is to determine which of these considerations shall have the least weight, and to be governed accordingly, looking as a guide to practice, rather than any assumed theoretical principles. The object aimed at in marine boilers is, in general, to reduce the space occupied by the boilers to the least possible, consistent with the effect to be produced, and at the same time not to lose sight of the necessity for proper space for cleaning and repairing. A certain proportion between the area of the grate and the total heating surface has been found productive of the best re-

sults, with a given description of fuel, but an alteration in the quality of the fuel used will oe found to affect this result materially.

Again, the famed Cornish boiler, which has exhibited the greatest amount of work with the least fuel, is arranged on the principle of slow combustion, and an extended flue surface, while the locomotive boiler, on the contrary, is dependent for its effect upon a quick combustion and a short and direct draught. Hence we see the improbability that any one form of boiler will ever be likely to fulfil all the varied conditions under which they may be placed. As before remarked, for stationary boilers the general proportions have been measurably determined—that is to say, for every cubic yard of capacity in the boiler, there shall be a square yard of fire-surface, and a square foot of fire-grate, and one-half the contents of boiler to be water, and the other half steam room. These proportions have given good results, but are too bulky for economical stowage on shipboard, and as constructed for land use, are deficient in steam power.

Marine boilers are of necessity either flue or tubular boilers, since the flame must be within the shell of the boiler ; but in this arrangement they are almost as various as the makers. The evaporation of marine boilers per lb. of coal is considerably less than that of stationary boilers; reckoning the latter at from 8 to 10 lbs. of water evaporated per lb. of coal, that of marine boilers will be from 6 to 8. The proportion of fire surface to grate, taken from an average of 65 boilers in Bartol's Marine Boilers, is 28 to 1; of grate to area of chimney, 6.3 to 1; the amount of coal consumed per hour per square foot of grate, 26 lbs. The boilers from which an average is thus taken include about all the varieties used on our river and ocean boats, and of which we now proceed to give examples of some of the most important.

BOILERS, *American.* The intense heat produced by anthracite coal cannot be observed in steam-boilers, except by its effect in the amount of steam generated.

Many persons, remarking the much greater volume of flame in puddling and other furnaces, have attributed the difference to the superior arrangement of the furnaces, and have anticipated great results from the adootion of the same plan in steam-boilers.

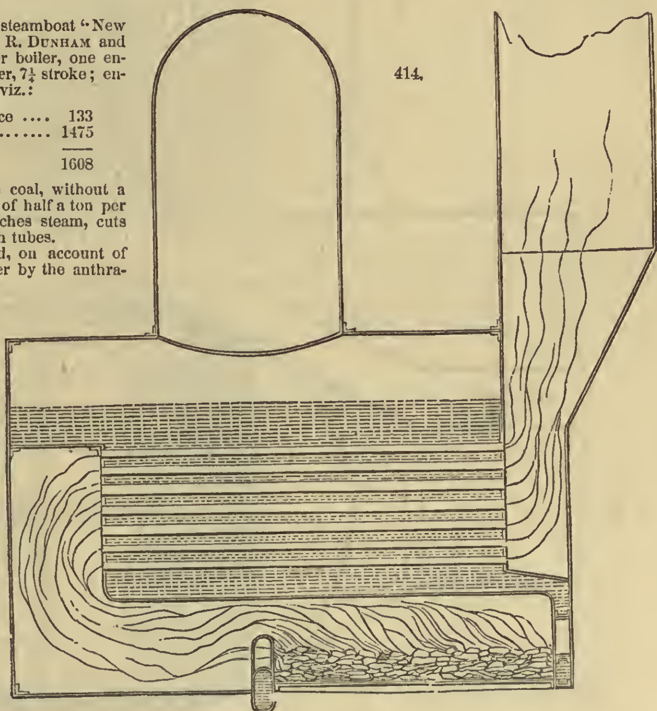
[Fig. 414. The steamboat "New York," built by H. R. Dunham and Co., has one copper boiler, one engine, 40-inch cylinder, $7\frac{1}{4}$ stroke; entire surface, $1608\frac{1}{4}$, viz.:

Direct or furnace	133
Tubular	1475
	1608

Burns anthracite coal, without a blower, at the rate of half a ton per hour; keeps 12 inches steam, cuts off at $\frac{1}{2}$; 250 $2\frac{3}{4}$-inch tubes.

Now burns wood, on account of injury to the copper by the anthracite.]

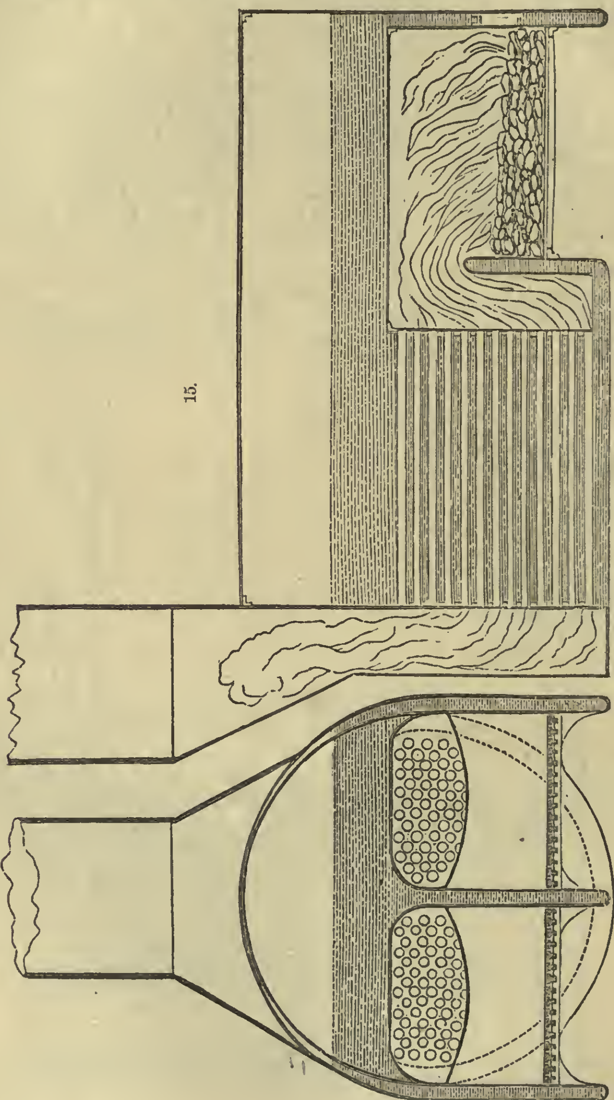
414.



This erroneous conclusion is the result of ignorance, or of inattention to the fact that in steam-boilers the flames are partially extinguished by coming in contact with surfaces, comparatively cold, highly conducting, since the heat of the metallic plates of the boiler can never be much above the boiling point of water; whereas, the walls of the furnace being non-conductors, and of consequence almost of the temperature of the furnace, inclose all the heat, and produce naturally a different appearance in the flame. The intensity of the heat generated in any furnace or boiler by a given amount of fuel, depends alone upon the velocity of the current of air; or, in other words, upon the amount of oxygen brought into contact with it, without any reference whatever to the way in which the heat so generated is dissipated or disposed of.

STEVENS' *boilers.*—A complete revolution has taken place during the last ten years in the form of the boilers of steamboats plying on the lakes and rivers of the Northern States; this change is the result of the introduction of anthracite, and the many experiments made to discover that form of grate and boiler best adapted to its combustion.

The editor has collected, with considerable labor and care, all the best forms, selecting such only as experience has approved and extensively adopted. These are laid down in as plain a manner as pos sible, sections of each showing their general structure.



415.

416.

[Figs. 415 and 416 are copper boilers, 8 feet, made by H. R. DUNHAM and Co., for steamboat "Independence."]

In the year 1837, Robert L. Stevens, Esq., constructed a pair of boilers, of tubular form, for his steamboat "Independence," plying between South Amboy and New York, of which Figs. 415 and 416 are correct representations, the form of which was well adapted to the burning of the new species of fuel by the assistance of bellows, or what is ordinarily termed the fan.

No difficulty was ever found in the accomplishment of the purpose they were intended to effect, and though many improvements have since that time been adopted, they are still working satisfactorily.

To Mr. Stevens belongs the credit of first establishing the water-bridge; which serves the purpose of protecting the mouth of the tubes, and preventing the heat of the furnace from burning them out. This is one of the most important features of Mr. Stevens' arrangement, and has since been adopted by many other engineers.

Another curious and useful form of boiler is shown by Fig. 414, two of which were built by Mr Stevens for the steamboat "New York."

The shell or crown is nearly of the form of a parabola, beautifully adapted to the end designed. See Fig. 417.

With a very great expansion of surface and great breadth of furnace below, there being a small quantity of water for so large a generating surface, saving a great deal of weight, which is of great importance, particularly in river boats, this boiler has the advantage of being easily *braced*, and the centre of gravity being very low down,—a happy and important arrangement in the boats on the Hudson, in which the boilers are placed on the guards of the boat on deck.

Several examples are added to illustrate similar and other methods.

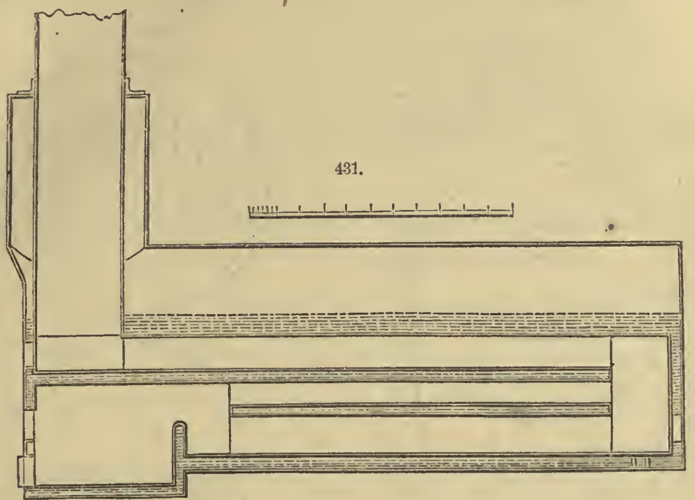
Uses anthracite coal, with a blower.

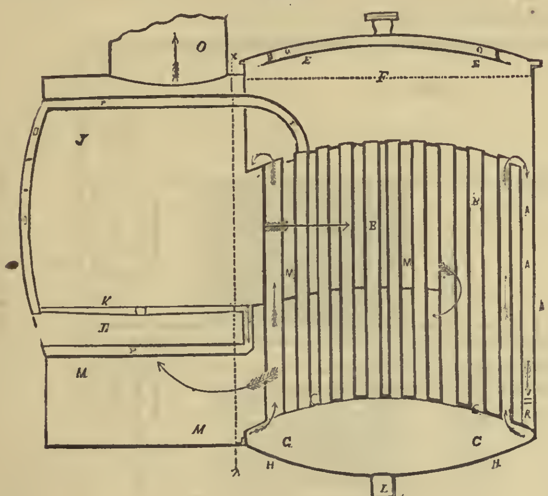


Improvements in steam-boilers—By James Montgomery, Memphis, Tenn. These improvements have in view an economical mode of using the fuel; the establishing of a perfect circulation of the water through the tubes; the depositing of sedimentary matter in a receptacle below the fire, and the preventing of the passing of water, from foaming or other causes, into the steam-pipe and cylinder.

Fig. 432 is a vertical section through the centre of the boiler, and through the furnace attached thereto.

Fig. 433 is a view of a part of the boiler, supposing the furnace part to be removed, and a vertical section to be made of the sectional part in the line X X of Fig. 432 and at right angles thereto

432.



433.

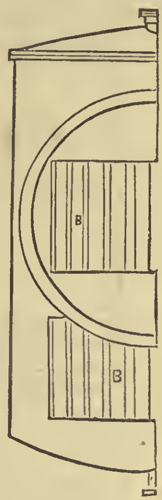


Fig. 434 is a top view of the termination of the boiler-tubes, and of the shell of case by which they are surrounded.

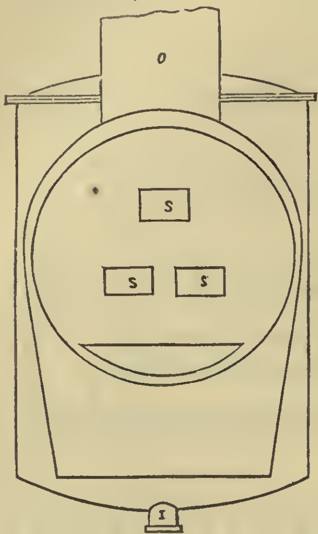
Fig. 435 is a front view of the furnace and boiler. In each of these figures, where the same parts occur, they are designated by the same letters of reference.

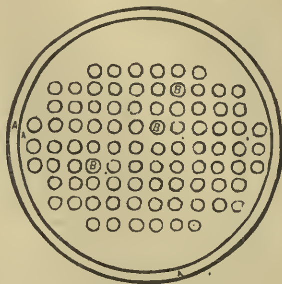
The boiler, in that part which surrounds the tubes, is formed of two concentric vertical cylinders, excepting where the heat and flame from the furnace is introduced, and where the gaseous products of combustion escape to be conducted off by the flue. A is the outer, and A[1] the inner shell of the boiler, with a water space A[2] between them. B B are the tubes, which pass through, and are made fast to

two heads, C C and D D, that are convex upwards. E E is the steam space, and F the water line. G G is that part of the boiler which is below the lower tube-head C C, and H H the bottom of the boiler. This bottom is convex outwards, and may be either spherical or conical; and as the direct heat from the fire is never applied to this bottom, the water contained between it and the lower tube-head C C is in a state of comparative quiescence, in consequence of which the sedimentary matter which

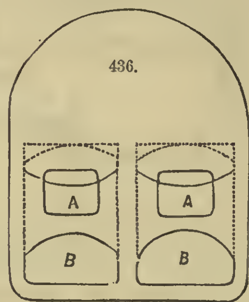
435.



434.



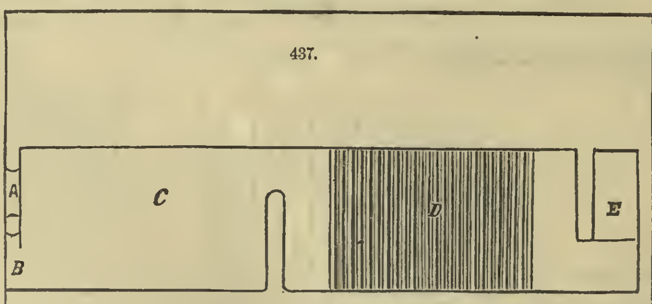
436.



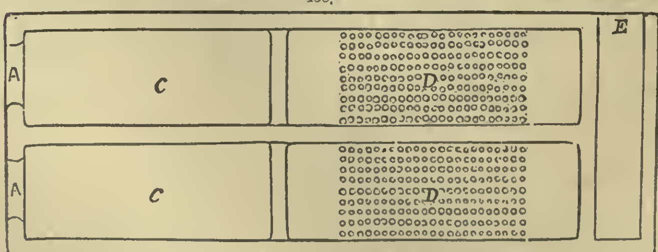
forms incrustations on the bottom and other parts of boilers, as ordinarily constructed, will settle down in this part in a loose unaggregated state. At I, in the centre of this bottom, is placed a blow-off valve, denominated a mud-valve, and which may be opened when requisite, for the purpose of blowing off the accumulated sediment, which it will do effectually without occasioning any considerable waste of water.

J J is the fire-chamber of the furnace, K the grate-bars, and L the ash-pit.

437.



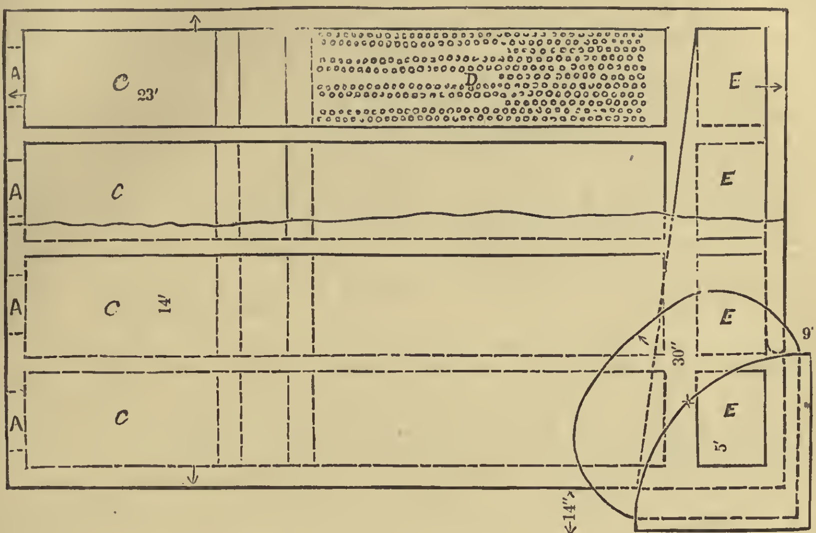
438.



The furnace is placed in such a manner as that the direct heat from it shall enter among the tubes B B, at their upper section, above a diaphragm or partition M M, over which the draft will pass as indicated by the arrows, and then into the lower flue space M' M', and around the furnace to the chimney O

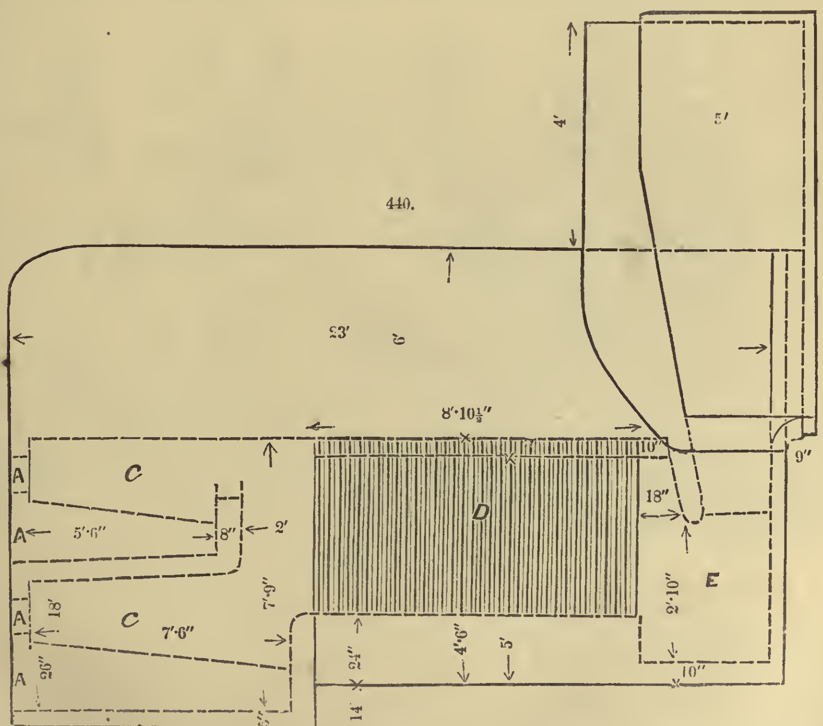
The furnace is surrounded with a water space P P, which communicates with the water in the boilers. This furnace may be placed lower down if desired, and the heat be made to impinge directly on the lower part of the tubes, but we are well assured that the arrangement as represented will be found to be the best.

439.



Below the upper head of the boiler is placed a metallic shield Q Q, leaving an annular steam space of a few inches around it, which will, in a great degree, repress the foaming of the water when the pressure is taken off by the admittance of steam into the cylinder, and will thereby prevent the injuri-

440.



ous, and frequently destructive, result of the entrance of water with the steam. Under this arrangement of the shield, the steam is drawn equally from all parts of the circumference of the boiler.

The production of a free and perfect circulation of the water in a boiler has frequently been aimed

at, but has not, we believe, been heretofore attained. But by this plan of arranging the parts of the boiler in such a way as that its bottom shall not be subjected to the direct action of the heat, and of introducing it laterally among the vertical tubes, we not only allow of the depositing of the sediment as stated, but cause a decided and rapid circulation, preventing all incrustation on the interior of the tubes, and augmenting the generation of steam. To clean out any ashes that may accumulate around the lower ends of the tubes, an opening, closed in the manner of a man-hole, must be prepared, as at R, or in any other convenient situation. S S S, Fig. 435 are the ordinary openings into the fire-chamber.

The improvements in this patent consist in arranging the fire-chamber or furnace of a tubular boiler at the side, so that the heat shall act on the upper half of the tubes, in combination with a diaphragm or partition, and flue to carry off the flame, heated air, &c., to act on the lower half of the tubes after acting on the upper half, as herein described.

The patentee also claims the making of the bottom of the boiler of a conical or dished form, with a mud or blow-off valve in the lowest part of the concavity, in combination with the vertical tubes communicating with the bottom in the manner herein described, to permit the deposit of the sediment, there being a water space surrounding them to induce a circulation of the water up the tubes and down the surrounding water space, to wash the sediment towards the mud or blow-off valve, as herein described.

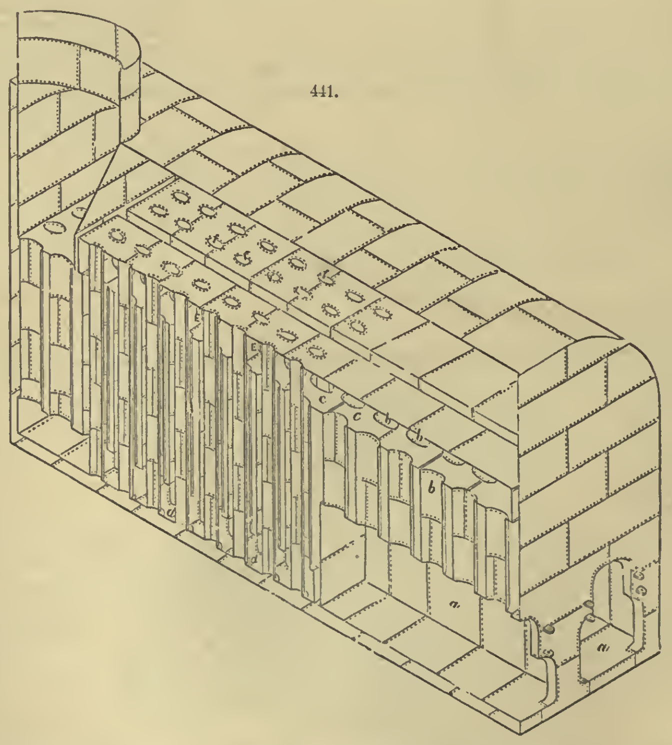
Steamship Osprey's boilers.—These boilers, represented in Figs. 436, 437, and 438, were built early in the spring of 1850, and are the same, in general arrangement, as that of the Earl of Dundonald.

A A, fire-doors; B B, ash-pits; C C, furnaces; D, vertical tubes; E, flue, in all the figures.

Boilers of the steam-ships Atlantic, Pacific, Baltic, and Arctic—Figs. 439 and 440.—The only difference between these boilers and those of Dundonald is in the furnaces, which are here double, one being above the other, caused by the necessity of obtaining more grate surface than could be obtained with one range of furnaces, the objection that had been urged against allowing the heat to act against the whole length of the tube having, by experiment, been found to be without cause.

A A, fire-doors; B B, ash-pits; C C, furnaces; D, vertical tubes; E, flue, in both figures

441.



Improved steam-boiler—By Wm. E. Milligan, New York City. Fig. 441 represents the boiler. The nature of this invention consists in a new arrangement of flues, tubes, and water spaces within a boiler for generating steam, whereby is presented a much enlarged amount of surface to the action of heat.

The construction is as follows: The general external appearance of this boiler is as of usual make, as is also the construction and arrangement of the furnace within it, but upon the upper side of the fire-place *a* is placed a series of flues *b*, of a number and capacity sufficient to carry off readily the products

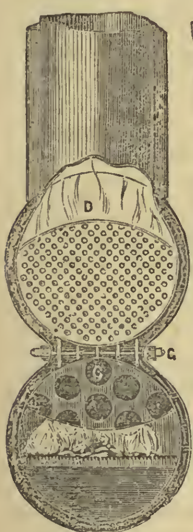
of combustion from the furnace. These flues open into a horizontal flue *c*, which is placed above the furnace and below the water line of the boiler. Back of the furnace *a*, and near to the bottom of the boiler, is another horizontal flue *d*, and between these horizontal flues is a series of vertical flues, similar to the flues *b*, but necessarily longer, as shown at E, and these flues are for the purpose of conveying the products of combustion from the upper to the lower horizontal flue. Through the centre of each of the vertical flues E is placed a tube *f*, of, say, one half the diameter of the flue, and these tubes extend from the upper tube-sheet of the horizontal flue *c*, through the lower tube-sheet of the flue *d*, as shown. The water passes through these tubes, and the purpose of them is to present greater surface for the absorption of heat, as well as to insure the circulation of the water within the boiler. From the lower horizontal flue *d*, the product of combustion is either conveyed directly into the chimney, or it may be returned to another upper flue *c'*, through the flues E'; thence again to another lower flue *d'*, through the flue E''; and thence into the chimney by means of the flues *b'*, as shown; one, two, or more furnaces arranged with flues and tubes thus constructed, may be placed within the same shell, sufficient space being left between them, as shown, for the circulation of the water.

The practical operation is this: The water in the boiler rising above the upper horizontal flue fills the tubes *f*, and surrounds all the flues. The product of combustion passes from the flue *c* through the vertical flues E, parting with its heat on the one side to the water surrounding those, and on the other to the water within the tubes *f*. The water contained in the tubes is much more rapidly heated than that surrounding the flues, as its volume is less, and hence by known laws a regular and perfect circulation takes place within the boiler.

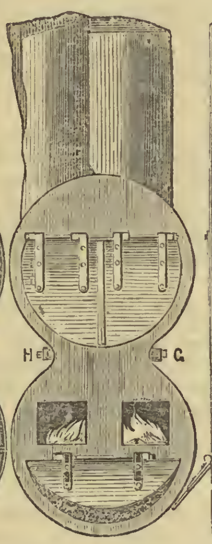
The patentee does not mean or intend to limit himself to the precise form of construction herein set forth, as it is obvious that if desirable the flues *c* and *d* may be placed vertically, and the others may be horizontal.

What the patentee claims as his own invention is the general arrangement of the tubes and flues of the boiler in the manner described; that is to say, the water tubes connected with an upper and lower tube-sheet, in combination with the flues of less length than the tubes, which flues are also connected with an upper and lower flue-sheet, whereby two horizontal flues are formed in such connection with each other by means of the vertical flues, that the product of combustion from the fireplace shall pass into the upper horizontal flue, and thence down the vertical flues into the lower horizontal flue, having thus the facility of parting with its heat on the one hand by radiation through the flues to the water spaces surrounding them, and on the other through the tubes to the water circulating through those; and this whether the said tubes and flues are placed vertically or horizontally

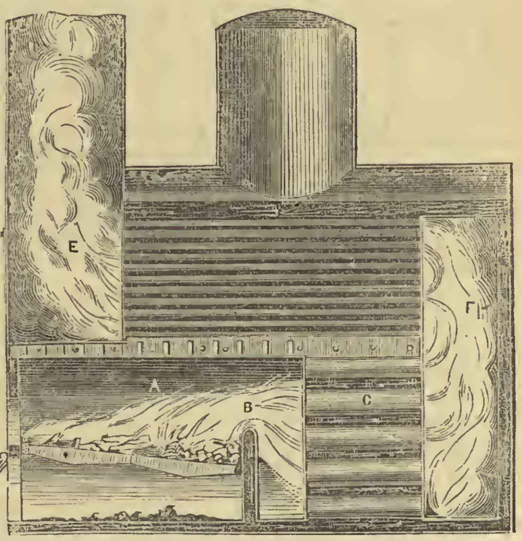
A. 442.



B. 443.



C. 444.



Boiler invented by E. A. Bourry. Figs. 442, 443, 444.

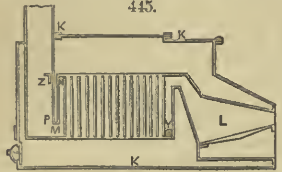
The aim of the inventor of this boiler has not been, like with many others, to obtain an incredible saving of fuel, but to insure great safety, combined with restriction of space and cost.

The cylindrical form of boilers is the best adapted for high-pressure steam: and the smaller the diameter, the more the boiler will be able to stand. Boilers of small diameter have been in use these many years with great success, for the working of stationary engines, but on board of vessels they are scarcely applicable, because—1st, Boilers are required with internal fire; 2d, such boilers must be in great number, which occasions a very awkward disposition and management; and, 3d, a given quantity of fuel is burned more economically on one large grate, than on several small ones, as with the former it requires less draught, and the combustion is more complete.

Now, to combine a boiler of a small diameter, with a large heating and grate surface and internal fire, seems at the first sight to be next to impossible, and yet this boiler embraces all those qualities.

A is a cross-section through the fire and smoke box; B is a front view; and C is a longitudinal section, showing the whole internal arrangement. The boiler consists of two cylindrical parts, placed above each other: the lower part contains the fire-box, bridge-wall, and main-flues; the upper one contains the return-flues, smoke-box, and steam-room. If space or convenience require it, the boiler may be made much shorter, in dispensing with the main-flues, in which case the return-flues can be made of a smaller diameter. It will be seen in the drawing, that the two cylinders are not entire, but are as if a slit was cut out on each of them, all the way along, and both joined there together, which leaves a free passage to both water and steam. But as, at the junction of both cylinders, the boiler would have a tendency to open outwards, this is prevented by a strong iron bar being placed in each hollow, and both kept securely together by a number of traversing bolts *a*.

445.



The boilers of the Atlantic and Pacific, of the Collins line of ocean steamers, are designed from that of Lord Dundonald, patented in England, Jan. 19, 1843, a longitudinal section of which is here shown, (Fig. 445.)

The earl says, "This figure shows a section of apparatus for generating steam for steam engines, constructed according to this part of my invention, and the apparatus is composed partly of tubes or hollow surfaces, the interior of which are open to the water spaces of the boiler, with which the tubes are combined. Such boiler or outer vessel may be varied in shape so long as there be a chamber as hereafter described, between the furnace and the fire-place and the chimney. K K is a steam boiler, which may be of a square or cylindrical section, or other convenient figure; L is the fire-place, M M M M is a rectangular chamber, there being a number of tubes or hollow surfaces in the upright position, through which the water flows in consequence of the water therein becoming hotter than other parts of the boiler. The heat of the fire passes into the chamber M at N, over the bridge O, at the end of the furnace or fire-place; and the passage P, from the chamber M into the flue or chimney, is situated as low as possible, in order that the greater heat of the vapors may be retained in the chamber M M, for it will be readily understood that the more highly heated vapors or products of combustion will occupy the upper part of the chamber M M, and the draught into the chimney will only carry off the cooler parts of the vapors, the more highly heated being comparatively in a quiescent state, at the upper part of the chamber M; and it is the peculiar arrangement of the chamber M within a steam boiler, when containing tubes or hollow surfaces, and combined with the outlet P into the chimney, so as to leave a considerable space above it (for the more highly heated vapors to be retained in the chamber M), which constitutes the peculiar character of my invention. Z is an opening into the chimney at the upper part of the chamber M M, to facilitate the getting up of a draught when first lighting a fire, it being closed at all other times; Y is a steam pipe in connection with the upper part of the boiler, having a stop-cock; this pipe is drilled with many small holes in the direction towards the chimney, by which numerous jets of steam can be projected amongst the tubes, in order to sweep away the dust and ashes when required. I would remark that it is not necessary to have the tubes in an upright position."

Such is the Earl of Dundonald's account of his invention. This boiler is superior to all that have preceded it, and is *identical* with those now in use on board the steamer Osprey, with the exception that her boilers have not the opening Z, or the steam pipe Y, both of which would be an improvement.

In December, 1845, Jas. Montgomery took out his patent for a tubular boiler, of which a description has already been given, the distinguishing feature of which is a horizontal diaphragm placed about midway in the tubes. Several of these boilers were introduced into vessels of moderate size, and several were employed for stationary purposes, and effected a considerable saving of fuel when they had supplanted other boilers.

The success attending the Montgomery boiler in this country called the attention of those interested in marine navigation to them; and when the steamers Atlantic and Pacific were begun under the direction of Mr. E. K. Collins, of New York, he caused a large number of experiments to be made with vertical tubular boilers for use in salt water. The performance of the steamboat Jonas C. Heartt, with Montgomery's boiler, was carefully noted for several days, being equal in time to a trip to Europe.

It being satisfactorily ascertained that the tubes would not choke up, but, on the contrary, would keep perfectly free from scale, Mr. Collins concluded to adopt some form of vertical tubular boiler, and determined to test the use of vertical tubular boilers—in fact, the boiler of Dundonald. After a series of experiments, proving that there was no objection, the boilers of the Atlantic and Pacific were designed by his chief engineer, John Farron, jr.

The only difference between these boilers and those of Dundonald is in the furnaces, which are here doubled, one being above the other, caused by the necessity of obtaining more grate surface than could be obtained with one range of furnaces, the objection that had been urged against allowing the heat to act against the whole length of the tube having, by experiment, been found to be without cause.

Tubular boilers have suffered much in reputation by being made too contracted in the water-ways, the tubes too close together, and the plates not sufficiently strong to resist the increased pressure used in them. They save both in weight and space, and are now designed quite free from the general objections made to them; they are not more expensive in fuel when a due proportion exists between the absorbent surface and the surface of the grates; and there is no reason why they should not be as durable as the ordinary flue boiler; they perhaps require more attention in blowing off, and keeping free from salt and earthy incrustations.

English Marine Boilers.—Figs. 446, 447, 448 and 449 are different views of the boilers of the steamer Phœnix, a steamer constructed by Messrs. Scott, Sinclair & Co., for plying between Capetown and Algoa Bay, at the Cape of Good Hope. This vessel was provided with collecting vessels within the boiler for obviating the deposition of scale.

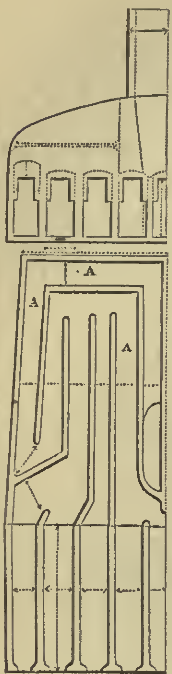
Horizontal Sections and Bird's-Eye View.

Fig. 453 represents the boilers of the sister ship, the Eagle, also by the same makers. There is nothing of peculiar excellence in these plans; and, for steam vessels, we believe boilers of this kind will be superseded by the tubular plan of boiler, of which we shall give all the best specimens. But a good number of boilers upon the common flue plan are still made, so that some specimens of them are indispensable; and, indeed, there are still far more flue-boilers in use than there are of any other description. In most of these boilers it is a fault that the furnaces are made too long and narrow, and the consequence is, that it is impossible to fire them on a long sea-voyage, especially in stormy weather. It is much preferable to restrict the furnaces to a moderate length, and give the bars a considerable elevation, so that they may always be well covered with coal at the after ends. When the furnaces are very long, a good deal of air generally escapes into the flues at the after end of the bars, the effect of which is materially to lessen the generation of steam.

Figs. 454, 455, and 456 represent the boilers of the Thames and Medway, two vessels of large size, constructed by Messrs. Maudslay & Field for the Mail Steam Packet Company. The boilers of these vessels have been very successful, and are among the best specimens of the flue-boiler as applicable to

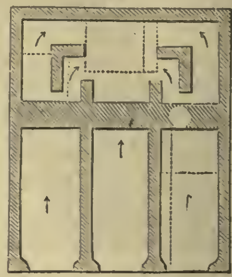
453.



Scale.—3-20th inch = 2 feet.—Elevation and Horizontal Section.

marine engines hitherto produced. We do not know of any boiler of this kind that engineers may imitate with greater safety, as regards their power of generating steam, though there are many specimens distinguished by a greater durability. In some of the boilers recently introduced in the Mail Steamers, the furnaces stand athwartships, and the plan is attended with the material advantage that the coals trim more easily; for the coal reserve in this arrangement situated behind the boilers, and another depot standing between the boilers and the engines, communicate immediately with the stoke-holes, whereby an easy transfer of the coal becomes accomplishable.

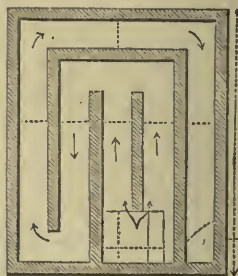
454.



Horizontal Section through Flues.

Figs. 457 and 458 are also views of the boilers of the Thames and Medway. These views are perpendicular sections through the lines A B and C D, shown in the horizontal section through the furnaces, and the horizontal section through the flues. The dotted sweeps at the two upper corners represent the ascent of the flue into the funnel. The flue narrows in width and rises in height as it approaches the chimney, for the same area is not required for the transmission of the smoke after its volume has been contracted by the communication of heat to the water, and a less depth of water above the flue suffices after the heat of the smoke traversing it has been well-nigh expended. The bridges are water bridges, and their superior ridges do not run in a horizontal, but in an oblique direction, the design of which is to facilitate the extrication of the steam. There are four boilers in all, and the boilers are fired from both ends.

455.



Horizontal Section through Furnaces.

In furnaces with two lengths of furnace-bars, it is a good plan to make the centre-bearer double, so that the ends of the bars may have a space between them through which the ashes will be precipitated; the space thus left enables the bars to expand without injury on the application of heat, whereas, without some such provision, the bars are very liable to get burned out by their centres bending up into the furnace, or else the lugs which carry the bearer-bars will be perpetually being carried away. A similar space should be left between the fore end of the bars and the dead plate at the furnace mouth, and care should be taken that not only the ends of the bars do not touch, but that the heels of the bars do not rest against the furnace-bearers.

456.

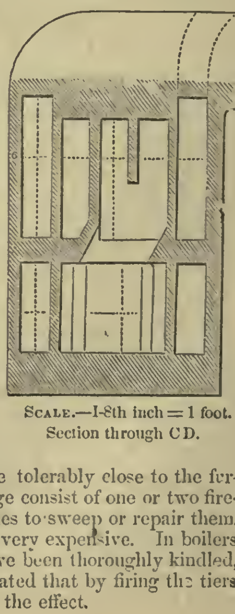
458.



Scale.—1-8th inch = 1 foot.
Section through C D.

The bridges of these boilers are, it will be observed, of brick, and come tolerably close to the furnace top. In such cases it is expedient to make the upper part of the bridge consist of one or two fire-brick blocks, which may be lifted off when a person requires to enter the flues to sweep or repair them. The continual knocking down and building up of bridges becomes otherwise very expensive. In boilers of this construction it is difficult to light one tier of fires after the others have been thoroughly kindled, as the fires first lighted keep the lead in the draught. It might be anticipated that by firing the tiers of fires alternately, the smoke would be burned, but such is not found to be the effect.

Provision has been made in these boilers for the introduction of a fan-blast, which would at once cure the evil of a defective draught. The furnaces would, in this plan, be made close, and the blast would be introduced into a chamber at the back of the ashpit A, Fig. 461, from whence it would pass into the ashpits by necks A A A, Fig. 459. One inconvenience, however, of a fan-blast thus applied is, that the smoke comes out of the furnace-doors very much when they are opened.

Almost every engineer has made tubular boilers that were short of steam, but we never before met with one who acknowledged it.

The original boilers of the Great Western contained of flue surface 2950 square feet, and of furnace surface 890 square feet, making 3840 square feet of heating surface; area of fire-grate 202 square feet; capacity of steam-room 1150 cubic feet; weight of boilers and steam-pipes 202 tons; weight of water 80 tons; average consumption of coal 1000 tons per voyage, out and home, of 27 or 28 days. In the tubular boilers, Figs. 459 to 461 the tube surface is 5900 square feet, smoke-box surface 830 square feet; furnaces 420 square feet; making 7150 square feet of heating surface; area of fire-grate 145 square feet; weight of boilers 56 tons; weight of water 52 tons; capacity of steam-room 1320 cubic feet; average consumption of coal per voyage out and home, of 29 days, 696 tons. The speed of the vessel, it will be observed, has somewhat declined with the new boilers, but there is a greater economy in fuel upon the same distance. The horse power of the Great Western is about 400; the particulars of the two boilers will therefore stand as follows:—

	Old Boiler.	New Boiler.
Heating surface per horse power	9·6	17·875
Fire-grate per horse power	·5	·3625
Steam-room per horse power	2·875	3·3
Coal per hour per horse power	8·333	5·6

The consumption of fuel, as here set down, it must be borne in mind is that of the old boiler in its super annuated state, and of the new boiler in its best state. The old boiler, when new, did not consume more than 6 lbs. of coal per horse power per hour.

The tubes of these tubular boilers are of iron of 3 inches internal diameter, and 8 feet in length. The furnaces are 8 feet 3 inches in length, which is, in our judgment, a greater length than can be fired effectually on so long a voyage as the Great Western has to perform. The water within the boiler rises some distance above the top tubes. It would be better, we think, to let the return tubes go through the steam, which would dry it very effectually, and surcharge it in some degree with heat. This could easily be done by lowering the water-level, and the hot air will be sufficiently cooled, after passing through the lower tier of tubes, to prevent any injury to the upper tier from an excess of heat. One of the advantages of iron tubes is, that they can be subjected to a degree of heat, with impunity, that would be unsafe to apply in the case of brass tubes. It is said, however, that the scale adheres to them with greater tenacity than to brass, but this objection is not likely to prove of much weight if the boilers be well blown out, for in that case very little scale will be formed at all.

Figs. 462 and 463 represent the boilers of the British Queen steamer, constructed to ply between London and New York. There is nothing very peculiar in this kind of boiler; and, indeed, it is nothing more than the common marine boiler, as used for the ordinary coasting vessels, constructed upon a larger scale. There are four boilers in the vessel, ranging athwartships, containing in all fourteen furnaces, the wing boilers containing four furnaces each, and the midship boilers three furnaces each. The projection of the water-space into the flues at the after-end of the wing boiler is to obviate a back-draught in the furnaces, in consequence of the currents of hot air meeting one another in a direct antagonism at the point where they coalesce, and which they would do but for this protuberance, which deflects each of them sufficiently to make it enter, without conflict, the longitudinal flue. These boilers were kept supplied with fresh water, as the engines are fitted with Hall's condensers, which return the condensed steam to the boiler to maintain the water-level. This species of condenser is now discontinued in most vessels, as its weight and expense are formidable objections, and it does not act as a preservative of the iron of the boiler from corrosion. One government vessel, some time since, fitted with Hall's condenser, had no less than 22 miles of copper pipe for accomplishing the condensation of the steam. The use of salt water in boilers is attended with very little inconvenience if they be often blown out, and their durability is little, if at all, increased by the employment of fresh water.

Figs. 464 and 465 represent the boilers of the City of London steamer, a vessel lately constructed by Mr. Napier, of Glasgow, to ply between Aberdeen and London. These boilers are much upon the plan of the boilers of the Thames and Medway, and are fired from both ends instead of from one end, as in the boilers of the British Queen. There is a hanging water-bridge, it will be observed, at the end of the furnace, Fig. 464, beneath which the flame has to descend before it can enter the flues. This arrangement we look upon as very judicious. The hot air, by virtue of its specific levity, ascends into the upper part of the furnace-chamber, where it remains until it has given out a considerable portion of its heat, and it is only after its specific gravity has been increased by the extraction of heat that it can overflow into the flues. It is also a good practice to place a hanging bridge of sheet-iron at the after-end of the flue, where it enters the chimney.

Figs. 466, 467, and 468, represent the original boilers of the steamer Tagus, constructed by Messrs. Scott, Sinclair & Co. The following are some of the dimensions of the original boilers:—Length 24 feet 3 inches, height 10 feet; breadth of each boiler 7 feet 6 inches, making the total breadth of the boilers about 22 feet 8 inches, with projections of rivet-heads. Length of under furnaces 8 feet; length of upper furnaces 7 feet 6 inches. Breadth of furnaces 3 feet; total number of furnaces 12. Each boiler contains 14 iron pipes of about 10 inches in diameter, and 10 feet in length, through which the smoke passes on its way to the chimney. These pipes are formed of boiler-plate, with turned rings or collars attached to each end, which are inserted into holes in the smoke-box plates, and then riveted over. These rivets are liable to get burned away by the action of the flame, as the collars within pre

vents the water from getting across to the angle, and the plates into which they are fixed then get pressed out by the force of the steam. It would be a good plan to cover these rivets with another perforated plate placed above them, the holes in which should be of a somewhat smaller diameter than that of the tubes.

Figs. 469, 470, 471, 472, 473, and 474, represent the boilers of the Queen steamer, a river vessel, constructed by Messrs Rennie, and well known for her swiftness and efficiency. The object this boiler

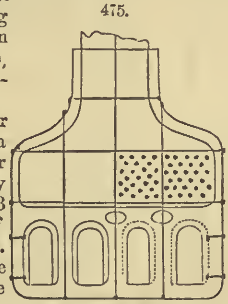
seeks to attain is lightness, and it is therefore made so as to hold very little water. It does not, however, appear to be well calculated to sustain any considerable pressure, though this is an object of importance in vessels intended to go fast. The following are some of the principal dimensions:—Length 13′ 8″; breadth 12′ 8″; height 6′ 0″; length of furnaces 5′ 2″; length of tubes 5′ 7″; breadth of furnaces 2′ 8″; diameter of tubes 2′ 6″; material of tubes brass. Total number of tubes 228. Diameter of cylinder of engines 29′ 3″; length of stroke 4′ 6″. There are two engines on the direct action plan. Collective power 76 horses.

If any considerable pressure of steam be employed in this boiler, it will be necessary to stay down the boiler top very firmly, both to the tops of the furnaces and the bottom of the boiler; for the force acting against the boiler-top, and tending to raise it upwards, will be immense, if a high pressure be adopted. To stay the boiler-top to the tops of the furnaces alone would not be sufficient, for the tops of the furnaces might alter their form, and the stays would then be of very little avail. The stays to the bottom of the boiler, however, if carried in the usual way, would have to be attached to the bottoms of the water spaces, and there they would be much in the way when the boilers are being cleaned. Indeed, it would be almost impossible to clean out the water legs effectually with stays so situated. and the best method, therefore, appears to be either to stay the boiler-top to a strong inverted arch spanning the water spaces, or to place a succession of iron arches over the furnace tops, to keep them in shape, after the fashion practised in Stephenson's locomotives, and to stay the boiler-top to these.

Figs. 475 and 476 represent a small tubular boiler constructed by Messrs. Horton & Son for a coasting steamer called the Zephyr. This boiler has been found to perform well, and is, in every respect, satisfactory. The tubes are of iron, 3 inches in diameter, and 6 feet long. Length of furnace, 6 feet; number of tubes, 168. 2 engines. Consumption of coal per hour, about 6 cwt. The pressure of steam is about 5 lbs. on the square inch.

475.



SCALE.—1-10th inch=1 foot.

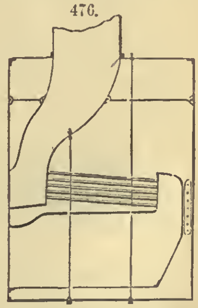
476.



SCALE.—1-10th inch=1 foot.
Longitudinal Section.

Figs. 477 478, and 479, represent a boiler, by Messrs. Miller, Ravenhill & Co., of the tubular

kind. It has been found expedient to introduce a jet of steam into the chimney of this vessel to quicken the draught. The tubes are of brass, $3\frac{1}{4}$ inches in diameter, and the tube-plates are of iron. A galvanic action between the brass and the iron has been found to arise in some boilers, which shows itself, not at the ends of the tubes, but at the ends of the athwartship stays which bind the sides of the boilers together; and the iron plate around these stays very soon acquires the appearance of having been scooped out by a knife; but in other boilers no action of this kind has been found to take place, and it has been doubted whether a leakage caused by the inadequate fastening of the stays has not had something to do with its production. The evil would probably be obviated by the application of a washer of zinc. Experience in the use of tubular boilers certainly shows that brass tubes are on the whole the most eligible. Iron tubes are speedily eaten into holes by corrosion, and it is remarkable that the corrosion chiefly takes place upon the under side. Brass tubes, on the contrary, are found to last many years. It appears to be the best plan to refrain from attempts at scaling brass tubes, but they may be withdrawn once a year, cleaned, and reinserted.

Figs. 480, 481, and 482, represent the boilers of the steam vessel Ocean. The tubes of these boilers are of iron, $3\frac{1}{4}$ inches in diameter, and 9 feet long; furnaces 7 feet long, and 2′ 1″ wide. There are three boilers in all: the centre one with three furnaces, and the two wing ones with two furnaces each. Total breadth of boilers $19\frac{1}{2}$ feet; total length 14 feet; total number of tubes, 378; two engines—diameter of cylinder, 56 inches; length of stroke, $5\frac{1}{2}$ feet; pressure of steam about $4\frac{1}{2}$ lbs.; consumption of coal about 18 cwt per hour. In ordinary coasting vessels the plan of firing from each end is objectionable, as the length in the vessel occupied by an additional firing space is a manifest waste of room; and there will be no difficulty in short voyages, about maintaining the trim of the ship on account of the stowage of so evanescent a cargo as coal in the wake of the furnaces.

boilers, with three furnaces in each, making 12 furnaces in all. Length of each boiler, 13′ 6″; breadth, 9′ 10″; height, 14′ 11″. There is a fore-and aft passage between the boilers, 2 feet wide, and an athwart passage 18 inches wide. Length of furnace, 7′ 4″; breadth of furnace, 31⅝ inches; diameter of chimney, 67 inches; height of flues, 5 feet.

Figs. 486, 487, and 488, represent two sets of boilers constructed by Messrs. Bury, Curtis & Kennedy, for the two steam vessels Wladimir and Der Greuss Adler, the one belonging to the Russian and the other to the Prussian government, and both of the power of 320 horses: the boilers for the Russian vessel being of the tubular variety, while those for the Prussian vessel are on the common flue plan. The shape and dimensions of the tubular boiler are shown in the figures by means of dotted lines; and a just conception may thus be arrived at of the amount of space occupied by a tubular and a flue boiler of the same efficacy in raising steam.

Figs. 489, 490, and 491, represent the boilers of the Retribution, a steamer of 800-horse power; the engines being on the double cylinder plan of Messrs Maudslay. There is nothing very peculiar in these boilers, except their size; in other respects they very much resemble the boilers of the Great Western, and of the Thames and Medway, also by Messrs. Maudslay & Field, of which we have already given delineations.

Miscellaneous observations on the construction and proportion of boilers, and the accidents to which they are liable.

The water-spaces.—The water-spaces between the furnaces should not be less than 5 to 6 inches wide, and between the flues 4 to 5 inches. The bottom water-spaces should be 8 inches, for the convenience of cleaning. It is usual to allow a space of 1 inch between the tubes of a tubular boiler, and these are best arranged in perpendicular rows, one over the other, by which means the steam escapes from their surface more readily than when arranged zig-zag. When water-bridges are used, they should not be less than 10 to 12 inches wide, and their tops should incline about 3 inches to the foot, to allow of the steam escaping more readily from the interior surface.

Heating surface arranged to permit the easy escape of the steam—Care must be taken, in proportioning the boiler, that no part of the heating surface may be so situated that the steam will not readily escape from it to the surface of the water, as in such case the plate, being left in contact with steam in place of water, becomes intensely heated and destroyed, and an explosion is not an unfrequent result. It is found in practice that perpendicular heating surface, such as the sides of the rectangular flues in a flue boiler, is by no means so efficient for raising steam as an equal amount of horizontal surface, such as the tops of the same flues. The reason of this is sufficiently obvious; as the steam, in the first case, rising perpendicularly from each portion of the surface of the metal, forms a film or stratum of vapor in contact with the sides of the flue, thus preventing the free access of the water to the hot metal; but in the other case, the steam, leaving the iron as soon as generated, allows the water to be constantly in

contact with it. From the same cause, the flat bottom of an internal metal flue is very inefficient as heating surface; and it is also found that plates which are liable to be exposed in this manner to imperfect contact with the water, either as side or bottom surface, are subject to a much quicker wear than the tops of the flues of the same boilers.

Strength of boilers.—1st. To know the force which tends to burst a cylindrical vessel crossways, or, in other words, to separate the *head* from the curved *sides*, we have only to consider the actual area of the head, and to multiply the units of *surface* by the number of units of *force* applied to each superficial unit. This will give the total *divellent* force in that direction.

2d. The amount of force which would tend to divide the cylinder in halves lengthways, by separating it along two lines on opposite sides, would be represented by multiplying the diameter by the force exerted on each unit of surface, and this product by the length of the cylinder. But even without regarding the length, we may consider the force requisite to rupture a *single band* in the direction now supposed, and of one lineal unit in breadth; since it obviously makes no difference whether the cylinder be long or short, in respect to the ease or difficulty of separating the sides. The *divellent* force in this direction is truly represented by the diameter multiplied by the pressure per unit of surface. *Hence, the thickness of the plates of cylindrical boilers should be in proportion to their diameters.* Ordinary boiler-plates will not bear more than 23 tons to the square inch; and as nearly one-third of the material is punched out for the reception of rivets, we must still further reduce the strength, and take 15 tons, or about 34,000 lbs. on the square inch, as the tenacity of the material, or the pressure at which a boiler would burst.

Strength of the plates.—A practical limit is imposed to increasing the thickness of the plates of an iron boiler, by the defective conducting power of the material; and it not unfrequently happens that boilers are weakened and destroyed by the very means adopted for securing additional strength, viz., by giving an injudicious thickness to those plates exposed to the greatest heat.

It is now generally understood that if the plates of the furnaces are made thicker than about $\frac{3}{8}$ of an inch, they are liable to be warped and "burnt" by the action of the flame, in consequence of the conducting power of the metal being insufficient to transmit the heat of the flame through the plate with such rapidity as to prevent the exposed side of the plate being softened and weakened by the intense heat, even although the other side of the plate may be in perfect contact with the water. From this cause, lapped joints, or rows of rivet-heads, should be avoided as much as possible in parts of the boiler exposed to *flame*, which is much hotter than *radiated heat.* The best position for the joints of the plates in the fire-boxes is in a slanting line, just below the fire-bars, in the ash-pit; and the plates for this part should be made as large as it is possible to have them rolled sound.

The usual thickness of iron plates for boilers is as follows: for fire-boxes, $\frac{3}{8}$ in.; flues, sides and tops, $\frac{5}{16}$ (the tops are sometimes $\frac{1}{4}$ in.); bottoms, $\frac{3}{8}$, and sometimes $\frac{7}{16}$ in. Outside shell of boiler, $\frac{3}{8}$ in. throughout, although the bottom is sometimes made $\frac{7}{16}$ in.; the up-takes to the bottom of the funnel should be $\frac{3}{8}$ in. The tube plates in tubular boilers are made from $\frac{1}{2}$ to $\frac{5}{8}$ in., charcoal iron. The funnel may be made with $\frac{1}{4}$ in. plate round the bottom, then $\frac{3}{16}$ in. and $\frac{1}{8}$ in. at the top. It should be divided by plates at the bottom, for 6 or 8 feet, into as many divisions as there are distinct boilers led into it.

Construction of boilers.—The whole of the shells of boilers intended to withstand any considerable pressure, should be double riveted, with rivets $2\frac{3}{8}$ inches from centre to centre, the weakening effect of double riveting being much less than that of single riveting. The furnaces above the line of the bars should be of the very best plates, three-eighths thick, and each furnace above the bars should consist of three plates, one for the top and one for each side, the underseam of the side plates being beneath the level of the furnace-bars. The tube plates of tubular boilers should be also of the best iron, $\frac{7}{8}$ to 1 inch thick; the shells should be of the best iron, and $\frac{7}{16}$ thick, at the least. Angle iron should not be used in any part of a boiler, as in the manufacture it becomes reedy, like wire, and is apt to split in the direction of its length. It is a much safer dependence to bend the plates, if it be carefully done, and without any more sharp turns than can be helped; but it is convenient to use a little angle iron about the furnace mouths, which should be of the very first quality. The whole of the plates of boilers should be punched with a double punch, one nipple of which enters the hole last punched, while the other punches the hole; and it is very convenient to have the punching-press provided with a travelling table, whereby the operation of punching and paring the edges of the plates is made a self-acting one. The use of drifts and screw-jacks in putting the parts of boilers together should not be permitted. The rivets should be of the best iron, $\frac{11}{16}$ in diameter. The whole of the work should be caulked both inside and outside, so far as it is accessible. It is very desirable that the space between the furnaces and tubes of tubular boilers should be sufficiently large to enable a man or boy to get in. The bend joining the top of the furnace at the after end with the bottom of the tube plate is very liable to get burnt away, and its repair will be most difficult, unless made accessible from the inside to hold on the rivets.

Division of the boilers.—In the case of engines of large power it is preferable to divide the boilers into several distinct pieces, each complete in itself, and capable of being used either in conjunction with the others or separately. This affords facilities for examining, repairing, if necessary, and cleaning the boilers in succession.

Staying and tubing of boilers.—It is usual to stay the flat portions of tubular boilers with about $1\frac{1}{8}$ inch round rods, from 16 to 18 inches apart each way, and flue boilers not quite so heavily. It is highly injurious to stay weak plates at long distances, as the alternate distension and contraction of the plate between the stays causes it to buckle round each stay every time that the pressure of steam is added or removed. This action, in time, wears a furrow round the fastening of the stay by throwing off the scale from the surface of the plate and opening the fibre of the iron, the circular piece of plate to which the stay-rod is attached remaining at the same time quite sound

By the English method, the tubes of boilers are most generally secured at the ends by means of ferules driven tight into them, the holes in the end plates being usually countersunk, and a corresponding projection being made on the ferules. The ferules next the furnace are best made of steel, while, for the other ends, malleable-iron ferules answer as well. The tool in which the ferules are made consists of three pieces; one piece is set in the anvil, and consists of a flat plate with a nipple on it, rising to half the depth of the ferule, and rounded at the corners; the next piece consists of a ring furnished with a handle, and with its lower edge recessed slightly into the flat plate so as to steady it, and this ring is larger in its internal diameter than the nipple by twice the thickness of the ferule; the last piece consists of another nipple made like the first, but formed with a head like a punch. A small hoop is formed by welding a piece of steel or iron, and is dropped into the space between the interior of the ring and the lower nipple; the upper nipple is then forced down by striking the punch-head with a forge-hammer, whereby the ferule is moulded to the right form; the parts are finally taken asunder, whereby the ferule is liberated.

In brass tubes the use of ferules appears to be indispensable, but in the case of stout iron tubes they are unnecessary; and the best plan, when iron tubes are used, appears to be to widen one end of the tube slightly, and to drive the tube in from the front of the boiler into both tube plates, the holes in the front plate being made one-sixteenth wider than those in the back plate, and the tube being widened correspondingly. Before the tubes are driven in, the holes in the tube plates must be slightly countersunk, and the tubes must finally be carefully riveted in. It will be expedient to screw a few of the tubes into the tube plates instead of riveting them, so as to serve as stays, and also as abutments to rivet the rest of the tubes against. The screwed tubes should be left a little longer than the others; and thin nuts made of boiler-plate should be screwed upon the projecting ends to prevent leakage, and add to the security of the staying. In fitting in the tubes in this way, great care is necessary to make them perfectly tight; and it will be expedient to turn the ends slightly in the lathe to give them a trifling taper, and make them all precisely of the same size. In driving them in, each tube should not be driven home at once, as that will spring out the iron between the holes; but they should be all fitted in first with the common chipping hammer, and when thus all equally fitted, they should be driven home by a heavy hammer, or ram. The countersink in the holes must be but slight, and must be filled rather by riveting up endways than by riveting over. In some cases boilers are made with collars riveted on the tubes immediately behind the tube plates, but this plan is attended with the objection that a tube cannot be renewed without taking the boiler asunder; and with the still greater defect, as it appears to us, that the ends of the tubes will be liable to get burned away in consequence of the internal collar preventing the access of the water. Boilers formed on this plan, therefore, will, we believe, be found to become leaky at the ends of the tubes; and unless stayed, independently of the tubes, the tube plates will be forced asunder by the pressure of the steam.

Galvanic Action. It is very necessary, however, in designing marine engines and boilers, to guard against the destructive effects of galvanic action in all cases where two metals of different degrees of solubility in salt water (such as iron and brass) are placed in juxtaposition; when the iron, being the most oxidable metal, suffers a rapid corrosion. To prevent this action, as well as for economy, it is now usual to furnish marine boilers with iron tubes in place of brass, from $2\frac{1}{2}$ to $3\frac{1}{4}$ inches external diameter, and about $\frac{3}{32}$ to $\frac{1}{8}$ inch thick.

Clothing of boilers. Although it must be allowed that in all cases the clothing of marine boilers with non-conducting substances, such as hair-felt, wood, &c., is highly advantageous for the production of steam, yet this practice is alleged in some instances to have induced a rapid wear in the plates of the boiler. This unlooked-for result is most apparent in boilers which are frequently used and disused alternately, the corrosion taking place on the interior surface. The conjecture as to its cause is, that owing to the alternate wetting and drying of the plates of the *clothed* boiler, the rust may be more apt to scale off, and thus constantly present a clean surface for corrosion, this action recurring each time that the water is blown out of the boiler; but when, on the other hand, the boiler is *naked*, the internal surface never thoroughly dries, owing to the evaporation being checked by the low temperature, and the saturation of the confined air. The clothing of marine boilers which make long voyages is never attended with these injurious results, nor are they ever experienced in land boilers.

Bedding of boilers. The manner of *bedding* marine boilers is a point of much importance, and will materially affect the durability of the bottom plates. A good practice, in the English service as well as in our own, is to form a close platform of 2-inch fir deals over the keelsons, upon which the boiler is then bedded with a cement or mastic of lime and drying oil, laid about 1 inch thick over the timber. This sets quite hard, and prevents the bilge-water (which in wooden ships is highly acid) from washing up to and corroding the plates of the bottom. The cement is also intended to stop any leaks which may break out in the bottom of the boiler, as well as to strengthen it in the event of a rapid corrosion taking place inside. Unfortunately, a perfectly close contact cannot be maintained between the iron and the cement, from the unequal degree of expansion of the two materials by heat, so that the effect of a leak in the bottom plates is frequently that the brine extends itself for a large space between the two surfaces, and the wear of the boiler is increased instead of diminished. The best practice is, perhaps, that of resting the boiler on saddles of cast iron fixed on the boiler bearers, which leaves the bottom exposed for examination, painting, and small repairs if necessary, the bottom of the vessel under the boilers being at the same time kept clean and dry by the bilge-pumps.

Duration of iron boilers. As will be easily understood from the preceding remarks, the duration of an iron boiler varies according to the treatment it has received, and the facilities afforded by its construction for thoroughly examining, cleaning, and repairing the parts. Thus, while some have been worn out with three years' service, others of the same thickness of plate have lasted six and eight years. A government steamer is seldom in commission longer than three years at one time, and at the end of this period the boilers very frequently require renewal; or if they are not much worn, and if the vessel

be of such a class that she will probably not be sent on foreign service, the boilers are repaired and made to serve another two, or it may be, four years.

Miscellaneous remarks about boilers. All the rough nuts about a steam vessel which require to be screwed and unscrewed frequently, such as the bolts of the man-hole and mud-hole doors of the boiler, should have large square nuts, and the bolts should be strong and have coarse threads. Hexagonal nuts speedily become round in the hands of the firemen, by whom the mud-hole and man-hole doors are generally taken off, and fine threads soon get stripped and overrun. It is much the safest way to put on both mud-hole and man-hole doors from the inside, with cross-bars on the outside to keep them closed. The plan sometimes followed of putting on mud-hole doors from the outside, and securing them by one or two bolts, is a practice to be reprehended as full of danger, as, if the thread strips or the bolt breaks, the door will fly off, and the boiling water rush out, scalding every one in the vicinity. Mud-hole doors of this kind, even if they leak, cannot be screwed up to tighten them when the steam is up, as there is a perpetual risk, in tightening the doors, of stripping the thread or breaking the bolt.

The tops and steam-chests of boilers, and the bottoms of the ash-pits, are the first parts to give way. The steam-chest wears chiefly from internal action; in some cases the iron exfoliates in the form of a black oxide, which separates in flakes like the leaves of a book; while in other cases the iron is, as it were, gouged away, and the heads of the rivets are worn off as if by an acid. It is most important that a remedy should be found for this evil. The ash-pits are worn away chiefly by the wetting of the ashes in the stoke-hole, and it is expedient to apply shield-plates to those places when the boilers are made, which plates only will be exposed to wear, and may be easily renewed, leaving the ash-pits untouched. The best method of setting boilers appears to be to set them on a platform, and care must be taken that no projecting copper bolts touch the boilers in any part, as they will be very likely to corrode the points of contact into holes. The platform may consist of 3-inch planking, laid across the keelsons, nailed with iron nails, and caulked and puttied like a deck. The surface may then be painted over with thin putty, and fore and aft boards of about half the thickness may then be laid down, the heads of the nails being well punched down. This platform must next be covered with mastic cement, and the cement must be caulked beneath the boiler by means of wooden caulking tools, so as completely to fill every vacuity. Coomings of wood must next be laid round the boiler, to confine the cement; and the space between the cement and the boiler must be caulked full of cement and be smoothed off with a slope to shed the water.

The large rivets sometimes used as stays for the shells of boilers, are objectionable, as the heads very often come off, and if the fracture be between the boilers in a position not accessible from the outside, it will be necessary to empty the faulty boiler of its water, in order to repair the defect. The sides of furnaces should always be made to incline to each other, so that the crown is not so wide as the fire-bars, and it is a good arrangement to place the bars adjoining the sides close against the sides throughout their length, so as to leave no air-space in that situation. By this arrangement, the intensity of the heat acting immediately against the plates of the sides is diminished. A crack in a plate is most conveniently closed by boring several holes along its length, and closing them with rivets having large heads, which cover over the defects. If a patch be applied to the top of a furnace or flue, it is better to apply it from the inside of the boiler rather than from the flue, as in the latter case a recess is left into which deposit falls, and a hole is likely then to be burnt again in the same place. If the furnace mouth be contracted by bending in the sides of the furnace, as is the general practice, it is necessary to be very careful that scale does not accumulate in these corners, else they will be very liable to be burnt into holes.

Respecting fire-bridges, the preferable practice, on the whole, appears to be to construct them of brick, rather than to make them water bridges, as with water bridges there is often trouble from the cracking of the plates. If water bridges, however, be used, they should be made with a great inclination in the breadth of the furnace, to facilitate the escape of the steam. Flame-bridges have been introduced into the furnace flues of steam vessels on some occasions, consisting of a pile of fire-brick, between which and the sides of the flue only a space of about three inches is left for the flame and smoke to pass through, and the flame is spread in a sheet over the interior of the flue. Where the flue is very large, the use of a flame-bridge appears to be expedient, and in land boilers with large internal tubes, its use has been attended with beneficial results; but in the majority of marine boilers, we believe that it will prove of but little service.

Explosion. Most explosions are found to arise either from undue pressure of the steam, or from the overheating of the plates composing the boiler. The plates of the boiler may become overheated either in consequence of a want of water in the boiler, or from such a configuration of the internal parts of the boiler that the steam when formed cannot escape freely to the surface. The bottoms of large flues upon which the flame beats down are very liable to injury from this cause; and the iron in such a case will probably be softened by the heat, and in all probability will collapse upwards.

The plugs of fusible metal sometimes introduced into boilers to obviate explosions by melting out before the steam can reach any high temperature, are found in practice to be of little avail. The compound metal is not homogeneous, and the more fusible of the metals is melted first, and is forced by the pressure of the steam out of the interstices of the less fusible metal, leaving its place to be supplied by the debris which all water supplies. The consequence is that the plug ceases to be fusible metal of the kind originally introduced, and cannot be melted by the steam even at a pressure and temperature much above that fixed as the requisite fusing point. In tubular boilers, however, it is a good plan to introduce lead plugs in the tops of the fireboxes—not with the idea that they will be melted by the steam where its pressure gets high, but to be melted out, and give notice of danger, should the water fall too low.

Every boiler should be furnished with a steam-gauge, which may give indication of danger should the pressure become too great, and the passages leading to the safety-valves should have no connection

with the pipes leading to the stop-valves. In some cases stop-valves have been lifted from their seats and forced into the mouth of the pipe, so that no steam could escape thereby; and in consequence of the safety-valve pipe springing from the pipe connecting the boilers, the boiler thus blocked up was in great danger of bursting, and would have burst if the fires had not been immediately drawn. In the case of any derangement of the safety-valve, or of the cone in the waste steam-pipe of a steam vessel getting loose, and blocking up the mouth of the pipe, the pressure in the boiler may be eased by opening the blow-through valves of the engines, and the steam-gauge will in all cases tell whether any undue pressure exists. See Gauge.

Extract from a report made by the Association in Manchester, for preventing steam boiler explosions, and for effecting economy in the raising and use of steam: "The chief inspector has reported several cases of imperfection tending to accidents, and, in particular, has found many flues so constructed as to transmit heat directly to the steam in the boiler, not only when the water is deficient, but when at its daily working level, thus surcharging the steam with heat, and endowing it with one essential element of explosive power, which may be instantly developed by the admixture of water, by agitation or otherwise. The fact that steam, in contact with water in a quiescent state, may be heated to 500° or upwards, without any corresponding effect on the steam gauge, or proportionate increase of pressure, appears to be established on good authority. But the precise condition under which the surplus heat thus accumulated in the steam may combine with water to produce explosion, is not fully known.

"Our attention has been directed—1. To an examination of all boilers placed under our inspection, with a view to ascertain, as correctly as possible, their actual condition, and whether they were adapted to their ordinary working pressure; also, whether they were provided with the requisite mountings, and if the same were kept in good working order.—2. In those cases of explosions which have taken place in the neighborhood, to an investigation of the peculiar circumstances connected therewith, in order, if possible, to ascertain the real cause, and the best means of preventing the recurrence of such accidents.—3. To ascertain by comparison the most advantageous construction, dimensions, and working of boilers in regard to safety, economy of fuel, and durability.—4. To ascertain the most economical system of employing steam as a motive power.

"The number and description of boilers at present under our inspection are as follows, viz.:—

Description.	Pressure per square inch. 15 ℔ or under.	16 ℔ to 30.	31 ℔ to 45.	46 ℔ to 60.	61 ℔ to 75.	76 ℔ to 80.	Number.
Cylindrical, with internal flues	83	274	144	60	28	—	589
Cylindrical, without do.	10	12	10	6	7	—	45
Galloway's patent boilers	2	35	48	12	—	—	97
Multitubular "	12	9	31	32	2	1	87
Butterley "	43	20	1	—	—	—	64
Wagon "	38	—	—	—	—	—	38
Total	188	350	234	110	37	1	920

Of the above, 81, or nearly nine per cent., have been found to be in a dangerous state, from the following causes, viz.:—

Construction or strength not adapted to the working pressure	24
Defects in the plates or angle iron	9
Defects in the boiler mountings	26
Injury sustained from deficiency of water	19
Ditto " deposit of scale	3
Total	81

In addition to the above 19, rendered dangerous from deficiency of water, there are 14 others which have been injured to a less extent from the same cause. This is evidently the most frequent cause of explosion, as will be explained hereafter; and as it is important to provide such means of prevention as will be effective in cases of negligence on the part of the fireman, we would suggest, first, the general adoption of open stand-pipes, where applicable, or safety valves, in connection with a float, to allow the escape of steam, whenever the water falls below the fixed limit.—2. The use of fusible metal plugs, fixed on the top of the flues above the fire. These should stand sufficiently high to melt before any part of the flues could be uncovered with water. The usual practice of inserting a lead rivet or plug in one of the plates is worse than useless, inasmuch as owing to the inclination usually given in setting boilers, a considerable portion of the flue must be exposed, and may even become red-hot, before such lead plug can be melted; under which circumstances an explosion is the probable consequence.

"Although the possibility of surcharging steam, while in contact with water, is still disputed by many engineers in this country, this question was satisfactorily solved by a committee of the Franklin Institute, in America, above twenty years ago. In the report of this committee, it is stated that 'the temperature was carried to 533 degrees Faht., when the pressure, shown by the gauge, was 6·82 atmospheres: while saturated steam, at that temperature, would have had a pressure of more than 60 atmospheres;' and further, 'these experiments, which lasted more than two hours, show that the surcharged steam remained in contact with water without acquiring from it the water necessary to convert it into saturated steam, but retaining its surcharged state.' Several instances which have come under our own observation might be adduced in confirmation of the experiments of these gentlemen, but we shall only mention one, which lately occurred, as sufficient for our present purpose. The boiler

referred to, contained two internal furnaces, uniting in one flue, and had been filled with water to the usual height by a pipe leading from a reservoir. The end of this pipe was about 9 inches below the top of the furnaces. About two hours after lighting the fires, the steam (being at 8 lb, as indicated by the gauge) was turned into the mill for the purpose of warming it. Shortly after this the attendant observed that the water had disappeared from the gauge glass, and was forced back into the reservoir, the valve on the feed-pipe not having been entirely closed. At this time the upper part of the furnaces, above the surface of the water, had become red-hot, and the temperature of the steam was such that a block of wood, resting on the top of the boiler, was converted into black charcoal, and yet the pressure never exceeded 8 lb. The communication with the reservoir having been closed, the fire doors opened, and the damper shut, the boiler was allowed gradually to cool; and although the tops of the furnaces were depressed, no explosion took place. From this it is evident that steam may be raised to a high temperature, while in contact with water, and yet remain at a low pressure. And this condition can only arise from a deficiency of water in such steam; we may reasonably infer, that if this could by any means be supplied, we should have an almost instantaneous increase of density and pressure proportionate to the degree of saturation. This will fully account for the difference in intensity of many explosions, and why these should so frequently occur immediately after starting the engine, admitting water into the boiler, or lifting the safety valve, all of which tend to produce agitation of the water, and to promote its diffusion amongst the steam. Although this theory of boiler explosions, which was advanced by the late Mr. Perkins many years ago, has not hitherto been generally admitted, certainly the facts which have come under our own observation seem fully to confirm its accuracy. The two last subjects which have been proposed for investigation require a greater amount of data than we have as yet been able to obtain; and although we have had occasion to remark great errors in many of the present modes of employing high-pressure steam, we should not now be justified in expressing a decided opinion as to which system is positively the best, nor which is the best construction of boiler. In connection with the working of boilers, the subject of smoke-prevention has not been overlooked. Our experience on this subject tends to the conclusion, that without much difficulty or expense the smoke nuisance may be greatly abated, in almost every description of boiler, and that this will be accompanied by a saving of fuel, provided such attention as might reasonably be expected be given by the fireman."

**Explosions from Incrustations.*—A boiler bottom getting *red* hot is not likely to take place gradually while the engine is at work, the water-feeding apparatus in order, and the boiler kept clean. But if a boiler is allowed to become dirty, or covered with indurated or incrusted earthy matter, interposed between the iron and the water, there is then no difficulty in accounting for such circumstances producing an explosion at any time; and the way in which it operates towards that end appears to be something like the following:

It is known that an internal coating of incrustation, or boiler scale, is liable to crack and separate into large pieces, which are thrown off from the boiler bottom at some particular degree of temperature, depending upon the thickness of the scale and the kind of substance of which it is formed. We can easily suppose that by a little hard firing, and unduly heating the boiler, a large portion of scale may be suddenly detached, uncovering a considerable area at a temperature something exceeding the *maximum evaporating point*, which is well known to be considerably under the lowest red heat of iron. Now, the first effect produced will evidently be a certain amount of repulsion between the overheated iron and the water, which may continue for several seconds, and perhaps for a few minutes; this may account for the sudden *decrease* in the supply of steam that has sometimes been observed just before the explosion of a boiler has taken place. There must also be a gradual diminution of temperature during this short space of time, in that part of the overheated iron which is exposed to the water—creating a contraction of the metal—increasing as the decreasing temperature of the iron approaches the maximum evaporating point, which is at about 350° to 400° Fahrenheit, and causing a corresponding strain on the rivets in the boiler bottom. The direction of this strain may generally be traced on examining the bottom plates of any old boiler, and will be found to radiate in lines proceeding from the part which has been most acted on by the fire.

The next and concluding step, in case of the metal not being able to withstand the strain caused by its own contraction, will either be a sudden crack or fracture in some direction across this exposed part, or, what most generally happens when an explosion results, the sudden giving way of some bad seam of rivets, which the most nearly coincides or is parallel with the direction of what would otherwise be the true line of fracture. This may possibly be at some distance from the part which has been overheated, thereby giving the increased effect of great leverage to the pressure acting upon all that portion of the boiler included between the overheated part and the actual line of fracture. Now the consequence is, not perhaps that this portion is blown out, as would most probably be the case with very *bad* iron, but it will be bent or doubled back, the line of flexure running across the hottest or the weakest part of the iron. This may help to account for the remarkable way in which we sometimes find exploded boilers twisted and doubled up. A rupture being thus effected, an explosion is inevitable, if the hole be sufficiently large.

When an incrusted boiler bottom becomes highly heated, and the water at the same time too low, it very commonly happens that a large quantity of water is immediately let in, when the consequences are similar to those just described: for the internal coating of scale being suddenly contracted by the cooling effect of the water admitted, it is detached in the same manner as it would have been by the expansion of the iron, and the same effects produced, although perhaps more speedily, as the water admitted will reduce the temperature of the exposed part of the boiler bottom more rapidly to the maximum evaporating point.

Whenever a boiler bottom is seen, or supposed to be, approaching to redness—and that can only

* Armstrong on steam boilers, 1856.

happen when the water is *not* boiling, or when the engine is standing—the engine-man should be cautioned against allowing a fresh supply of water to go into the boiler, whether the boiler is short of water or not, until after the engine has been some time at work. My advice to engine-men in such cases is *not to start the engine at all*, but to open the fire-doors and stand at a safe distance until all goes cool. I would not have him stop to pull the fires out, and on no account to open the safety valve, as being little less hazardous than starting the engine. If, indeed, he knows the safety valve to be overloaded or made fast, and the steam still continues to rise with the fire-doors open, the fires may then be quenched by a jet of water from a hose pipe, or other safe means.

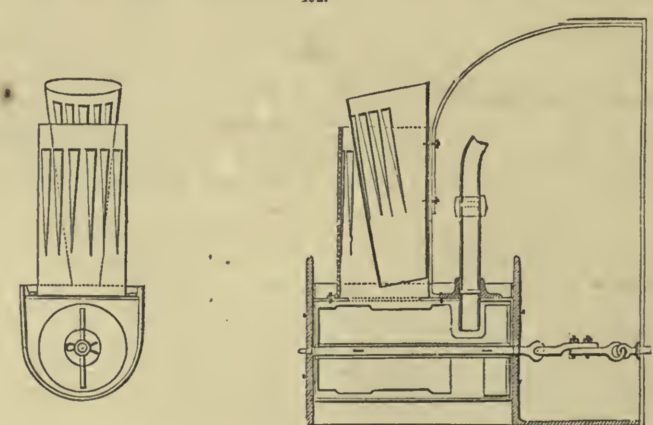
Deposit of Sediment.—All natural waters hold various solid matters in solution or suspension; when in the latter state they admit of being removed by filtration; but no system of filtration, on a scale sufficiently large to supply a moderate-sized steam engine at a light expense, has yet come into practical use. However, it occurred to a gentleman several years ago to hit upon a very simple and effectual substitute. And that was, instead of separating the water from the dirt, before passing it into the boiler, he separates and *collects* the dirt from the water, after it is in the boiler, by means of a series of vessels, shelves, or trays, placed up and down the boiler, constituting, in fact, so many portions of what collectively might be considered a substitute for a false bottom, upon or into which all the matters held in suspension are deposited. This, in fact, is the whole of the principle of Mr. Anthony Scott's patent of 1827, which has been so frequently re-patented and re-registered since that time, like many bad copies of good pictures, some of them so very bad that the patentee, if he were living, would not know that they were even meant for imitations.

These sediment vessels operate much after the same manner as certain quiet still places do along the banks of rivers, in causing sand or mud to accumulate in them; making so many places of shelter, where any movable matters being accidentally deposited, they remain free from agitation and not disposed to move out. In a boiler containing *boiling* water, of course the same principle prevails; the steam rising from the boiler bottom—the sole cause of ebullition in all cases—being the agitating agent. In fact the water never boils within the internal vessel or sediment receiver, however violently it may boil externally; and the more violently the water boils the more rapidly the internal vessel collects all loose sediment floating about in the water. Excepting for calcareous incrustations, the process was perfectly successful in keeping a boiler clean. The only difficulty in its practical application was liability to neglect in cleaning out the collectors themselves when they got filled with deposit, and the necessity of emptying the boiler for that purpose.

For the above reasons it appeared desirable to the patentee to have his cleansing apparatus made *self-acting*, that is, to *clean itself out*, without interruption to the working of the engine, or letting down the steam; which improvement R. Armstrong effected in 1829, when the first complete boiler-cleansing *machine* was executed and applied to a boiler at the calico-printing works of Messrs. Thomas Marsland and Son, in Stockport, who afterwards had fifteen boilers so fitted. Since the above period they have continued in general use in Lancashire.

The general form of this apparatus is shown by fig. 492. Many hundreds have been made and adapted to various kinds of boilers, including those of railway locomotives and steamboats. In the

492.



SCALE.—⅛th inch = 1 foot.
Longitudinal Section and Elevation of Collectors.

last-mentioned cases, and in all cases where there is no fire *under* the boiler bottom, they are, generally speaking, unnecessary, except for the purpose of preventing priming, which they most effectually do when that arises from dirty water. For this purpose the upper conical-shaped vessel is made with the narrow collecting apertures adjusted partly above and partly below the surface of the water. In this way it is used by opening the valve at the end of the boiler, and putting the handle of the agitator in motion for half a minute, by which the contents of the receiver at the bottom of the boiler are dis-

charged upwards through the pipe on the right hand. This operation creates a current, which draws all the *scum* and *froth* that *cause* the *priming*, from all parts of the water surface into the collecting vessel and down into the receiver, whence they are discharged to the outside of the boiler by a repetition of the process.

By thus *skimming* the dirt from the top of the water, clean *dry* steam is supplied to the cylinder of an engine instead of a mixture of steam and dirty water, causing, in ordinary cases, such great waste of power by friction on the piston and piston-rod, and unnecessary consumption of tallow.

Great consumption of lubricating material is always proof of imperfection in machinery. Instances are not wanting of large stationary engines working for months together without grease of any kind to the piston-rod, contrasting greatly with the lavish use of that material in marine engines, rendered necessary mainly by the greater liability to prime. The old device of throwing tallow into a steam-boat boiler, in order to *prevent* priming, is still without a satisfactory theory. The only suggestion to account for it worth attention, is one by Mr. W. Keld Whytehead, C. E., in an article on the priming of boilers, in the "Artizan Journal" for December, 1848, in which he supposes that, as the tallow requires a very high temperature to vaporise it, it "consequently floats *like a hot plate on the surface of the water*, and tends to separate the particles of water from the steam as they rise."

Calcareous Incrustations.—When the incrustation forming on the inside of boilers consists principally of argillaceous or silicious matters, it is easily prevented by the use of one or the other of the above described apparatus. When, however, any considerable proportion is either *carbonate* or *sulphate of lime*, considerable difficulty is experienced in preventing its formation to an injurious extent. The latter substance more especially, it is well known, has withstood all attempts at complete prevention by chemical means, except such as would be also injurious to the iron. The principal remedial agent that has been found beneficial in any degree to mitigate the effects of this substance, is *crushed potato*, which does not act chemically, but mechanically, the pulp of the potato being supposed to envelope the crystals of the sulphate of lime as they form, and prevent their adhesion to each other.

With respect to the incrustations of carbonate of lime, the case is very different. It admits of various methods of preventing its formation by chemical reagents. The most popular of the patent remedies is that of Dr. Ritterbandt. This plan is to put into the boiler daily a small quantity of muriate of ammonia, or sal-ammoniac, the effect of which is, that any bi-carbonate of lime in solution in the water is decomposed, the muriatic acid of the muriate of ammonia taking the lime and *keeping it in solution*, while the carbonic acid joins the ammonia, forming carbonate of ammonia, which passes off along with the steam. It need not be observed that this remedy can have no effect whatever in preventing the sulphate of lime incrustation.

The theory of the following remedy is something like the reverse of the foregoing. It is to put into the boiler daily or weekly a quantity of quick or newly-slacked lime, the effect of which is to convert the *soluble bi-carbonate* into the *insoluble carbonate* of lime, which, instead of being kept in solution as muriate of lime is in Dr. Ritterbandt's remedy, is precipitated and collected without any trouble by sediment collectors, or collected and discharged from the boiler by the cleansing machine. This putting in of lime to take out lime is a nice application of Dr. Clark's simple and efficacious method for purifying water on a large scale, now so well known and generally approved by water-works companies.

In Lancashire, where generally a great portion of the boiler scale is sulphate of lime, it has long been a practice to use ox-feet, or any animal substance convertible into jelly by boiling, with good effect. But they are liable to promote priming, and, like potatoes, they require frequent renewal. One English patent, now expired, specified the use of all kinds of vegetable matter or extract without exception, preferring that which gives out the greatest quantity of *coloring matter*, as logwood, bark, or tan. Also turf, peat, manure, leaves, saw-dust, and charcoal. Other patentees recommend urine, glue, blood, dung, and night-soil. Also sugar, starch, treacle, flour, malt, and the bottoms or settlings of beer barrels. Most of the above articles may be used with advantage where there is not much of the sulphate, but they all act mechanically. Tan and salt are the principal ingredients in some of the best of the foreign patents, which generally also contain some corrosive materials that are difficult to particularise and hazardous to use.

Incrustation.—The incrustation of boilers by saline deposits was a much more important subject at one time than it is now, as nothing has been more clearly established, of late years, than that boilers may be preserved effectually from any injurious incrustation by abundant blowing off. Brine-pumps are now in extensive use for withdrawing a certain quantity of water at every stroke of the engine; and the water so withdrawn has to pass through or among pipes carrying the feed-water to the boiler, so that some interchange of heat is there effected. These refrigerators, however, as they are grotesquely called, are in some respects bad things: the quantity of heat they save is, we believe, inappreciable; and the small pipes of which they are built up are liable to get choked, thereby endangering the boiler by the unconscious concentration of its contents. To guard against this danger, every engine fitted with brine-pumps should be provided with an hydrometer for telling the specific gravity of the water in the boiler, so that the engineer may not be cheated by the defective action of the pumps, or suppose that they are operating when they are really inert. In the case of blowing out a boiler in the usual way, the engineer looks at his glass gauge-tube, and keeps the blow-off cock open until the water-level has descended through the required distance, so that, under these circumstances, no doubt can arise that the boiler has been emptied of a certain quantity of water; but there is no such assurance in the case of the continuous extraction of the water, either by brine-pumps or by a continuous blow-off; and all boilers using either of these expedients should be fitted with hydrometer gauges as a precaution against the contents of the boiler being suffered to reach an injurious concentration. The prevailing fault among engineers, however, is that they do not blow off enough, the idea probably being that a considerable check is given to the generation of the steam by the introduction of colder water in lieu of the water abstracted; but the waste of heat by effectual blowing off is very inconsiderable—much less, in-

deed, than is occasioned by the difficulty of getting steam from brine, or of transmitting heat to the water through flues covered with incrustation, much of which heat, in consequence, ascends the chimney. There is no gain, therefore, in any respect, by penuriousness in blowing off; and there is much injury to the boiler, for incrusted plates become overheated; they blister, crack, and get burned out, and make expensive repairs indispensable. Proprietors of engines should accept of *no excuse* for the accumulation of salt or incrustation within their boilers; for such deposits arise altogether from insufficient blowing off.

The best method of scaling boilers appears to be by lighting a train of shavings in the furnaces and flues after the boilers have been emptied of water. The rapid expansion of the metal, thus occasioned, causes the scale to crack off; and, if the flues be then washed down with a hose, the scale will fall to the bottom of the boiler, and will issue out with the water on taking off the mud-hole doors. This plan of scaling, however, is one that the engineer must execute himself, and must not intrust to firemen or other subordinates, as the metal of the boiler might be damaged if the heat were made too great. The safety-valve should, obviously, be kept open while the boiler is being heated and cooled, to obviate any pressure or exhaustion within it. This plan of scaling, however, will seldom be necessary if due attention be paid to blowing off by the engineer; and if the quantity of scale be inconsiderable, or partial in its attachment, the best plan will be to chip it off with a hatchet-faced hammer, and then wash down the flues with the hose, as before described.

Corrosion.—The corrosion of boilers is one of the most obscure subjects in the whole range of engineering. Marine boilers seldom last more than four or five years, whereas land boilers, made of the same quality of iron, often last eighteen or twenty years; yet the difference in durability is not the effect of any chemical action upon the iron by the contact of sea-water, for the flues of marine boilers rarely show any deterioration from this cause, and, even in worn-out marine boilers, the hammer-marks on the flues are as conspicuous as at the time of their formation. The thin film of scale spread over the internal parts of the boiler would, of itself, preserve that part of the iron from corrosion which is situated below the water-level; but, whatever be the cause, it is a rare thing to find any internal corrosion of a boiler using salt water in those parts of the boiler with which the water comes in contact. The cause, therefore, of the rapid wearing out of marine boilers is not traceable to the chemical action of salt water, and steamers provided with Hall's condensers, which supply the boilers with fresh water, have not reaped much benefit in the durability of their boilers. The operation of the steam in corroding the interior of the boiler is most capricious—the parts which are most rapidly worn away in one boiler being untouched in another, and in some cases one side of a steam-chest will be very much wasted away while the opposite side remains uninjured. Sometimes the iron exfoliates in the shape of a black oxide which comes away in flakes like the leaves of a book, while in other cases the iron appears as if eaten away by a strong acid which had a solvent action upon it. The application of felt to the outside of a boiler, has in several cases been found to accelerate sensibly its internal corrosion. Boilers in which there is a large accumulation of scale appear to be more corroded than where there is no such deposite, and where the funnel passes through the steam-chest the iron of the steam-chest is invariably much more corroded than where the funnel does not pass through it. These facts appear to indicate that the internal corrosion of marine boilers is attributable chiefly to the existence of surcharged steam within them, which is steam to which an additional quantity of heat has been communicated subsequently to its generation, so that its temperature is greater than is due to its elastic force; and on this hypothesis the observed facts relative to corrosion become easily explicable. Felt applied to the outside of a boiler may accelerate its internal corrosion by keeping the steam in a surcharged state, when by the dispersion of a part of the heat it would cease to be in that state. Boilers in which there is a large accumulation of scale must have worked with the water very salt, which necessarily produces surcharged steam; for the temperature of steam cannot be less than that of the water from which it is generated, and inasmuch as the boiling point of water, under any given pressure, rises with the saltness of the water, the temperature of the steam must rise with the saltness of the water, the pressure remaining the same; or in other words the steam must have a higher temperature than is due to its elastic force, or be in the state of surcharged steam. The circumstance of the chimney-flue passing through the steam will manifestly surcharge the steam with heat, so that all the circumstances which are found to accelerate corrosion are, it appears, such as would also induce the formation of surcharged steam. Besides, the natural effect of surcharged steam is to oxidate the iron with which it is in contact, as is illustrated by the familiar process for making hydrogen gas by sending steam through a red-hot tube filled with pieces of iron; and although the action of the surcharged steam in a boiler is necessarily very much weaker than where the iron is red-hot, it manifestly must have *some* oxidizing effect, and the amount of corrosion produced may be very material where the action is perpetual. Boilers with a large extent of heating-surface, or with descending flues circulating through the cooler water in the bottom of the boiler before ascending the chimney, will be less corroded internally than boilers in which a large quantity of the heat passes away in the smoke. If these views be correct, then to prevent the internal corrosion of marine boilers it is only necessary to take care that the water in the boiler shall be as fresh as possible, and that the root of the chimney shall either be lined with fire-brick, or not go through the steam at all.

Priming is the tendency of the water in the boiler to foam and pass in a state of spray into the cylinder along with the steam, and when in too great a quantity to escape through the steam port in the return stroke, it infallibly breaks down the engine. This effect must invariably follow the priming of a sufficient quantity of water in the cylinder of a beam engine in a factory, because it is not and cannot be expected to be calculated to withstand a sudden *blow*, and such it is in reality. For if the water primes into the cylinder in the down stroke, it must remain on the top of the piston until it strikes against the cylinder cover in the up stroke, with more or less violence according to the quantity. From the incompressibility of water, the effect is the same as if a piece of iron of equal thickness to the

depth of water on the piston was suddenly inserted in its place. The tremendous effect sometimes produced when a large engine breaks down from this cause, may easily be conceived; for as the vacant space left for clearance at the top of the cylinder is generally about the same depth in large as in small engines, the intruding body of water strikes the cylinder cover with a proportionally greater force. Generally the accident does not end with merely straining or breaking the crank-pin, which may be the extent of the injury in small engines; but the momentum of the beam is added to that of the fly-wheel, and their combined force is exerted directly in splitting the cylinder, or tearing off the cylinder cover, thence effectually demolishing all the rods and gearing. Priming arises from insufficient steam room, an inadequate area of water-level, or the use of dirty water in the boiler; the last of these instigations may be remedied by the use of collecting vessels, but the other defects are only to be corrected either by a suitable enlargement of the boiler, or by increasing the pressure and working more expansively. Closing the throttle-valves of an engine partially will generally diminish the amount of priming, and opening the safety-valve suddenly will generally set it astir. A steam vessel coming from salt into fresh water is much more liable to prime than if she had remained in salt water, or never ventured out of fresh. This is to be accounted for by the higher heat at which salt water boils, so that casting fresh water among it is in some measure like casting water among molten metal, and the priming is in this case the effect of the rapid production of steam. One of the best palliatives of priming appears to be the interposition of a perforated plate between the steam space and the water. The water appears to be broken up in dashing against a plate of this description, and the steam is liberated from its embrace. In cases in which an addition is made to a boiler or steam-chest, it will be the best way not to cut out a large hole in the boiler-shell for establishing a communication with the new chamber, but to bore a number of small holes for this purpose, so as to form a kind of sieve, through which a rush of water cannot ascend. In locomotives the same end is attained by the use of a perforated steam-pipe extending from end to end of the boiler. Such a contrivance draws the steam off equally from the surface instead of taking it from any one part; and boilers provided with it are enabled to work with so small a steam-space that the steam-domes are now being taken away from locomotives altogether. This expedient has not yet been adopted in steam vessels, though it appears to be applicable to them also with advantage. In some boilers priming appears to be mainly caused by a malformation which prevents the water from circulating freely, and the steam has therefore to pass up through the water, occasioning a great agitation, instead of the water being enabled to circulate with the ascending steam. The evil may be mitigated in such cases by the addition of pipes to the exterior of the boiler, which will permit a descending current to be established, to replace the water carried upward by the steam. This tendency of the water to rise into the cylinder is always considerably promoted by the very usual situation of the steam induction-pipe at the back end of the boiler, and seems to arise partly from the constant circulation of the water, which causes a current at the surface to set in the direction of the length of the boiler from the front end to the back. This circulation of water takes place in all oblong boilers, with a certain velocity depending on the ratio that the intensity of the heat in the furnace bears to the quantity of water to be kept heated, and is entirely independent of other causes, producing *waves*, which take their rise over the fire, and gradually increase in height as they pass towards the back part of the boiler.

That *waves* are always generated within a long boiler, when the engine is about to prime, is a singular but well-ascertained fact, as is shown by the frequent great and sudden depressions of the float at such times, especially if the latter happens to be placed at the contrary end of the boiler to that where the steam-pipe is fixed. In watching the rapidly-successive alternate elevations and depressions of the indicator, buoy, or float of a boiler in this condition, the priming may frequently be observed to recur periodically after intervals of a certain number of strokes, provided that the state of the fire and the load on the engine continue perfectly uniform. For the economical combustion of fuel, and arrangement of grates, see Fuel.

Smoke Prevention.—Hitherto, the practice has been to exclude as much air and heap on as much coal as possible, thus preventing a sufficient quantity of the common atmosphere getting into the furnace to secure complete combustion. The consequence was the gases were too slowly evolved, and passed away into the chimney in dense black columns, to poison the air of the surrounding neighborhood. This is prevented now, however, by a moderate enlargement of the fire-beds and flues, and the introduction of air to the surface of the fire through perforated doors, and plates placed between them and the fire. The furnace itself being constructed to admit the quantity of air required, for perfect combustion, the perforated plates secure such a mechanical division and distribution of the common atmosphere as to insure its becoming instantaneously heated, and promoting instead of retarding, as a column of cold air does, in a great degree the combustion sought. The whole mystery of all the smoke-preventing apparatuses now in public favor lies in this simple secret. The following is an analysis of experiments which have been made with Mr. Williams' Smoke Prevention apparatus. With the air wholly excluded, 251 lbs. of coal were consumed per hour, 1,239 lbs. of water were evaporated, the Pyrometrical heat being 381°; whereas, with the air admitted, the consumption of coal was only 236 lbs. per hour, the water evaporated 1662 lbs., and the temperature, as indicated by the Pyrometer, 901°; thus showing an immense saving of fuel and an extraordinary increase in the quantity of water evaporated, as indicated by the Pyrometric action.

BOILER PLATES, *Machine for punching.*—Fig. 493 is an elevation, Fig. 494 a plan, and Fig. 495 a side view of a punching-machine on a very improved principle, whereby the plates required for boilers and other purposes may be punched with the greatest possible accuracy, insuring at the same time very superior workmanship and great dispatch. It is usual in all ordinary punching-machines, first of all to mark out all the rivet-holes in the plate, by a template, with white paint, and then to place it as near as the eye will permit under the punch; by the contrivance of this machine, this operation is entirely dispensed with, it being only necessary to fix the plate to a travelling table, and then to adjust the various parts of the machine to the proper distance required between the rivets.

The large cast-iron frame *p* carries the several parts of the machinery, and also the two plummer-blocks for supporting the bearings of the lying shaft *a*, running the whole length of the building, for the purpose of working other machines; this frame is securely bolted to the wall which, added to its own weight, gives it great stability.

On the shafts *a*, connected together by the two coupling-boxes, is placed the crank *b*, the motion being communicated through the crank-pin to a connecting-rod *c*, to which is attached the upper lever *d*, being always at work, while the shaft *a* is revolving; the fulcrum of this lever is on the frame *p*. A lower lever *e* for raising and depressing the punching frame *f* has also its fulcrum on the same frame this last lever working only when the punching operation is being performed. On the top of th frame *p* is a lever and long rods *e'* for engaging and disengaging the machinery. The side view represented by Fig. 495, shows the machine at work, and by drawing down the lever *e'*, connected by the rods to the counterbalance weight, which will allow it to remain steady in any position, they are disengaged from the pin on the lever *d*, which at once ceases to communicate the motion to the lower or punching lever *e*; thus it will easily be understood that those parts of the machine constantly at work, are the lying shaft *a*, the crank *b*, the connecting-rod *c*, and the upper lever *d*.

The slide *f* for carrying the punches, works between V's, Fig. 494; one is fixed to the frame *p* by adjusting-screws, both on its face and sides, and by the curious shape given to the end of the lever *e*, this slide is made to rise and fall, the counterbalance weight and lever *g* being connected by two short links; on the bottom of the slide is screwed a small frame for carrying the punches, which may be taken out and replaced by others. The dies *i*, in which the punches work, are placed in a frame bolted to the frame *p*, and by unscrewing the small adjusting-screws, these may be taken out and replaced by others suitable to the different-sized punches that may be required. On the under side of the frame *p* is screwed a small stop, by which the circle punched from the plate is forced out as the slide rises.

In the front of the machine is placed a long table, supported by the carriages *o*, consisting of two columns and diagonal frame, having bolted to them two long bars, upon which the moveable table is made to slide; this table, as will be seen by Fig. 494, has a number of holes by which the plate to be punched is secured by clamps; it is advanced by the rope or chain *n* passing under the pulley, Figs. 493 and 494, and over a second one hung from the ceiling of the building, to which is connected a weight sufficiently heavy to draw forward the table and plate fixed to it; after travelling the length of the table *o*, it may be brought back by turning the winch-handle and spindle *l*, on which is a pinion for working the rack, fixed to the under side of the moveable table *m*.

By a very ingenious contrivance, forming part of this machine, the rivet-holes of boilers may be punched to very different pitches, a thing very much wanted in such cases as the repairing of old boilers, or replacing an old plate by a new one, where it is of the utmost importance to have the rivet-holes coinciding with the greatest accuracy, which may be better understood by supposing that in the length of a plate, one, two, or three additional rivet-holes may be required, which distance would have to be equally divided in the whole length of the plate. A description of this part of the machine will fully show how this operation is performed. On the end of the punching-lever *e* is screwed a small plate with a pin *j'*, adjustable by a screw working in the short mortise, Fig. 495; on the frame *p* is bolted a fulcrum piece for the lever and counterbalance weight *j*; to this lever a long rod is connected at its lower end, passing under the table *m*, and the lever *r* is fixed to it, as will be seen by the dotted lines in Fig. 494; it has also two stops or projecting pieces *r' r'* on its surface. A second lever *s* has its fulcrum fixed to the table *o*, one end of this lever being connected to the lever *r*, while the opposite end has on its surface two small pins *s' s'*; the fulcrum *s''* of this lever is adjustable by the two small screws shown in the plan, Fig. 494. A long notched bar *k* is fixed to the under side of the table *m* by screws, and the bar *t* has its fulcrum *t'* also fixed to it; this latter bar *t* is moveable on its centre, and may be placed at any angle by an adjusting-screw working in a mortise *t''*, where it may be fixed in any required position, as will be seen; it is by the angle given to this bar, that the regular increase of distance is obtained between the rivets. This is effected in the following manner:—As the lever *e* works on its centre, the pin *j'* to which it is fixed, strikes as it descends on the end of the lever *j*; its motion is then communicated to the long rod, passing under the table, for working the lever *r* backwards and forwards, it being fixed to the rod; as the latter lever moves, it alternately engages and disengages the stop or projecting pieces *r' r'* from the notched bar, allowing it at the same time to slide forward the distance between the rivets; while the bar *t* placed at the required angle, and working between the pins *s' s'* on the lever *s*, immediately effects the distance travelled by the lever *r*, which it shortens; by this arrangement the machine is made quite self-acting, but it may also be worked by the handle on the end of the rod *j*.

When it is required to change the punches *h* for different-sized holes, it is necessary, when replaced, to adjust them to the greatest possible accuracy in the dies *i*; this could not be done without stopping the whole line of shaft *a*, were it not for a provision made for that purpose; in such a case, the key in the upper part of the connecting-rod *c* is withdrawn; a block of wood is then placed between the frame and the lever *d*, whose fulcrum is on the side of the frame *p*, upon which it rests. It is of course understood that the punching-lever *d* is at rest, being disengaged from the pin *e'*; the result of this is the working of the long mortise of the connecting-rod up and down on the pin, without communicating any motion whatever; and by the lever *q*, worked gently by hand, and shown dotted in Figs. 494 and 495, the punching-lever *e* can be raised and lowered, communicating its alternate motion to the slide-frame, by which means the punches are with great facility adjusted in the dies *i*.

The jaws in the frame *p* are much strengthened by placing a square wrought-iron bar between them, in places provided for the purpose.

From the above description, it will be seen that the advantages possessed by this machine, more than compensate for the increased number of its parts, which are but few when compared with its superiority over those of ordinary construction.

o Fixed table supported by columns.
p Frame for carrying machinery.
q Lever for raising punching-lever when the punch is required to be changed without stopping the length of shaft.
r Lever fixed at one end to rod *j*; on this lever is fixed two small projecting pieces *r' r'*.
s Lever with two guide-pins *s'*, having a moveable centre at *s''*.
t Bar for regulating the pitch of rivet-holes, working between pins *s' s'*; it has a fixed centre at *t'*, and may be placed at any angle by sliding in groove *t''*.

BOLTING-MILL, *for flour.*—A bolting-mill is the general name of a place where meal is sifted. But here the subject in question is particularly a dressing or bolting *machine* in common mills, by which either the bran is separated from the flour or meal, or the ground grain, ore, &c., is refined. The bolting machines most in use are—1st. The *common bolter ;* 2d. The *rotative* cylindric or prismatic *bolter ;* and 3d. the *brush-bolter.* Though they differ from each other in structure, the substantial arrangement consists in a kind of sieve of wire or horsehair, or of cotton or silk texture, of bolting cloth or of silk-gauze, either of which stuff is used according to the fineness of the meal required; the meshes or perforations of the one being smaller than those of another.

The peculiarity of the common bolter is, that the sifting is produced by its *shaking* motion; that of the cylindrical or prismatic bolter is, that the sifting is effected by its *rotative* motion, either alone, or by co-operation of the centrifugal power, or of beaters or similar apparatus.

The peculiarity of the brush-bolter is, that the sifting is effected by *brushes* placed in the interior of the bolter itself, which latter discharges its coarser contents into the bran-chest; while the meal or flour is taken up to the bolting-hutch.

The arrangement of the improved bolter in general use, will be perceived by Figs. 463, 464, 465, and 466, where Fig. 463 represents the bolting-machine in longitudinal section; Fig. 464 ground-plan, (but without the lid of the bolting-hutch :) Fig. 465 front, and Fig. 466 side-view of the hind part, together with the mechanism for effecting the shaking motion.

The oblong and closed bolting-hutch, marked by *a a*, is fastened to the meal-bench *b ;* and in its interior, at an angle of 15, or, at the most, 30 degrees, is placed the bolter or sifter *c c*, whose upper end is fastened to the scuttle *d*, Figs. 463 and 464, and whose lower end discharges its contents at the fore side of the hutch *a a.*

The bolter consists commonly of bolting-cloth or silk-gauze, of which two strips from 6 to 7 feet in length, and from 14 to 16 inches in breadth each, are sewed together lengthwise. The seams are edged, two inches broad; and the two ends of the bolter are likewise bordered with leather, for the purpose of fixing iron rings. The ring at the upper end is quadrangular, yet with rounded corners; it is 8 inches broad, and from 5 to 6 inches diameter. At about 2 feet down from the upper end of the bolter, two handles, (called bolter-ears, and marked by the letter *e*,) of strong sole-leather, are sewed to the sides, to serve for the reception of two arms *f f*, of the apparatus for effecting the shaking motion. The lower end of the tight-stretched bolter is placed in the aperture cut out in the slide *g* on the outside of the bolting-hutch; the shaking-arms *f f*, which are either covered with tin-plate, or with ends of cast-iron, are to be put through the two bolter-ears *e*; and the upper end of the sifter is to be placed on the outside of the scuttle *d*, in the notch of the wooden ledge *h*, Fig. 463, and fixed by the iron cramp *i*. At the lower end the screws *k k* of the slide *g* are designed to stretch the bolter as required.

The motion of the bolter may either be horizontal or perpendicular. The former is most general, as the bolter is more worn by the perpendicular motion. But it may be asserted that the case is almost entirely the reverse. For by the lateral motion the sides of the bolter are very much tossed, and so their threads too much stretched, especially when the shaking-arms *f f* stand out straight from the shaking-axis, forming thus an acute angle with the bolter. By the perpendicular motion the bolter is also violently tossed; however, this inconvenience may be removed by using curved arms, (like that marked by *f* in Fig. 463,) instead of rectilinear ones, and made either of timber or iron.

The vertical shaking motion of the bolter is produced in the following simple way: At the axis *l*, placed horizontally beneath the sifter, are fixed the two shaking-arms *f f ;* also at its projection the bent arm *m*, called the *bolter*, in which the *bolter-tongue* is, by means of a peg, fastened in a manner which allows of its turning. The bolter-tongue is pressed against the horizontal arm *o* of a vertical axis *p*, by the wooden or steel spring *q*, so firmly and continually that a retrograde motion results from the rebounding of this spring, while the advancing motion is effected by a second arm *r* of the axis *p*, which beats against three tenons *t*, and is pushed off again by them.

The power of this shaking motion can be modified according to the required fineness of the flour, or to the more or less fine bolting-cloth; and this is effected by displacing the bolter-tongue *n* in the wheel-scissors *m*, for which purpose both are perforated. However, the bolter is not suffered to move more than 3 inches up and down, as this is sufficient even for the coarsest grit, while a more vigorous movement would wear the bolter too much.

The upper millstone in a common mill, of 3 feet in diameter, making from 140 to 180 rotations a minute, each bolter, brought in connection with a set of such stones, will be moved up and down thrice so often, or 420 to 540 times in a minute. In order to be enabled to look frequently at the bolter, there is made in one of the side partitions of the bolting-hutch a large square aperture *u u*, commonly covered with a linen cloth *v*, Fig. 464. Another aperture *w*, about 6 inches high and wide, at the bottom of the hutch, is provided with a slide of wood or tin-plate, and serves as an outlet for the flour.

Beneath the lower end, or mouth of the bolter, is a small gutter *x*, made of wood or tin-plate, in order to facilitate the emptying of the grit or bran into the bran-chest below. The mouth of the bolter is covered with a cloth *y*, Fig. 465, pressed towards the mouth of the bow *z*, to prevent the flour-dust, joined to the grit and bran, from dusting away. The aperture in the side-partition, fig. 463, *u u*, is beside the curtain, fig. 464, *v*, closed with a door or slide, while on the other hand, the bran-chest is 1½ feet in length, and closed tightly.

The bolting-cloth used in bolting-mills consists generally of woollen, more seldom of silk texture, and is glued or gummed in a particular manner. According to the species of corn to be bolted, and to the fineness of the flour, the cloth is coarse or fine, both in the threads and the size of its perforations or meshes. There are more than a dozen sorts of cloth, which are selected according to the quantity of meshes in an inch square. The cloth is commonly from 14 to 16 inches broad, thus being adapted for the use of bolters from 10 to 12 inches in diameter. The English manufacture bolting-cloth noted for its good quality and durability; there are also in Germany superior manufacturers of this article especially at Linz, Berlin, and Breslau. The best quality bolting-cloth and silk-gauze is fabricated by

Dufour & Co., at Thal, in the Swiss canton of St. Gall, by *Hennecart*, at St. Quentin, in France, and by *Harlem Star*, in Holland.

We shall now describe those bolting-mills where the *cylindrical bolter* is used.

Formerly, in England and the United States, a bolting-mill of this description was used, in which the cylindrical bolter, put in circular motion with great celerity, consists of a kind of *reel*, framed in the following manner:—From a somewhat inclined axis, like radii, six arms or spokes project, which are connected with each other by six laths running parallel with the axis. This cylindrical frame is commonly, at the upper end, 22½ inches diameter, but at the lower end only 20½ inches, (in this case it is called *taper-reel;*) sometimes it is at both ends 22½ inches diameter, in which case it is called an *equal-reel*. The wider cylindrical bolter encloses the frame, and is at both ends (which are lined with leather) fastened to it. In the bolting-hutch are placed six wooden *beaters*, whose points stand off half an inch from those of the spokes. Now, as soon as the bolting-cloth is swelled by the rotation and centrifugal power, it strikes violently upon these beaters, and thus the finer elements of the flour are forced through the sides of the bolter, while the grit and bran proceed along the whole bolter into the bran-chest at the outside of the bolting-hutch.

Yet this bolting apparatus was not much adapted to the purpose, because the ends of the bolter could not be fixed firmly enough to prevent its unsteady, swinging motion, and its too violent striking upon the beaters, by which the bolting-cloth soon became defective. However, at present this bolting-mill is substantially improved by *James Ayton*.

Fig. 467 gives a side view of this improved machine, without the bolter, and without the front of the hutch. In the frame of the bolting-hutch *a a*, the apparatus is placed obliquely. By the axis *b b*, (made of forged iron,) and the disk *c*, the bolting-machine is brought in rotation. At the axis *b b* are fixed the two naves *d* and *e*, in a proper manner, and into both are placed four spokes *f f*, at right angles with each other. From each spoke to the corresponding opposite one, or from *f* to *f*, is distended a strip of bolting-cloth or duck *g*, 5 to 6 inches broad, fixed at the extremities of the spokes. The strips in the interior of the bolter form a kind of fanning-machine of about 20 inches diameter. Above the nave *d* is another one *h*, from which project six iron spokes, bent upwards, and connected with each other at their points by the wooden ring *k*, whose diameter is equal to that of the fanning-machine. Below the board partition *l l*, that separates the flour-hutch *m* from the bran-chest *n*, is a third nave *o*, from which project six steel springs *p*, whose points are bent into hooks, carefully rounded off and polished, that the handles of the bolter (which are fixed to them) may be spared as much as possible. This nave, which by Fig. 468 is twice represented on a larger scale, consists of three hoops *o q r*, of which the inner *q* is fastened to the square axis *b b;* the middle *o* revolves round the hoop *q*, and the outer *r* is fastened to the hoop *q* by four screws.

The bolter surrounding the fan-shaped reel is, by means of its handles at the lower end, fixed at the hooks of the six steel springs *p;* while its upper end, above the wooden ring *k*, is simply drawn together by a cord or string. As soon as the reel is in rapid rotation, the pressure of the air, produced by the fans and the centrifugal power, will swell the bolter, which at the same time is kept at a uniform concentric tension by the elasticity of the steel springs *p*.

Another substantial improvement of Ayton's bolting-mill is, that the six beaters *s*, lying round the bolter may, according to circumstances, be placed more or less near to it, even during the rotation. The manner of this arrangement may be perceived by Fig. 469, where the machinery, Fig. 467, is represented in a view from behind or before. On the outside of each of the partitions *l l* and *t t*, Fig. 467, is a broad iron ring *u*, Fig. 469, revolving round the axis *b*, in the small furrows of the six cramps marked with *v*. In both of these rings (on the front and back) are cut six eccentric slits *w w*, behind which, in the board partitions, there are cut out as many other slits, like radii of the axis *b b*, so that both kinds of slits are crossing each other. The beaters *s s*, Fig. 467, are (by means of screws *x*) brought into connection with the slits in such a manner, that they are moved to and fro in the slits of the partitions *l l* and *t t*, and thus approach and turn off from the bolter, as soon as the outside rings *u* (which are not connected with the axis *b b* itself) are turned round by the dented wheels *y*, Fig. 469. The whole perimeter of the rings is dented; only a part of it is shown in Fig. 469. The dented wheels are connected with another axis different from that marked with *b b*.

Through the hopper *z*, Fig. 467, is constantly running the ground grain as required for bolting; so that from the other end of the bolting-hutch only grit or bran, without mixture of flour, runs out.

This improved bolting-mill has this substantial advantage over the older one—that the movement of the air within the bolter is produced by the fans instead of the reel, and drives the flour towards the periphery in a more complete manner. Thus the flour gets easily through the perforations of the bolting-cloth, whose obstruction is almost entirely prevented by the trembling motion of the steel springs *p*. The beaters are also arranged so that they cannot much wear out the bolter.

While by the older machinery (with 170 to 200 rotations a minute) only two and a half to three sacks (measuring three bushels each) of grit are said to have been bolted in an hour, Ayton's improved mill bolts four sacks in the same time.

Notwithstanding this favorable result, the improved bolting-mill is not much used, for the reason that the bolter (as the weakest and most expensive part) is yet damaged by the beaters. The cylindrical bolter has recently been supplanted by a hexagonal or octagonal one, with great success.

Figs. 470 and 471 show the frame of this bolting-machine (which is in very general use in this country) in longitudinal section and front view. The front partition is omitted, to get a better view of the interior.

These bolters are made exclusively of silk bolting-cloth, manufactured by *Harlem Star*, in Holland. For two sets of five-feet millstones there are generally made bolters of 28 inches in diameter and of 90 feet in length, and of three different sorts of cloth; that is, 60 feet of the finest sort, No. 10 or 11; 24 feet of the middling sort, No. 5 or 9; and the remaining 6 feet (60+24+6=90) of the third or coarsest sort. No. 2, which latter is intended for separating the finer bran from the coarser.

The cloth is tentered round wooden frames similar to the above-described reels, of hexagonal or octagonal form, 20 inches in diameter, and from 18 to 20 feet in length. The cloth is fastened with pins to the wooden rings at both ends of the frame, and to six or eight laths running parallel with the axis, and resting on spokes.

Such bolters, as *a a*, Figs. 470 and 471, are commonly placed four in one hutch *b b*, that is, two above and two below, as in Figs. 470 and 471. They are placed somewhat obliquely, and, by means of the motive power *c c*, revolved all together by the wheel *d* of the axis, which also turns the wheel *e*. Each bolter makes generally 25 rotations in a minute. The flour-conveyers, *f* and *g*, are commonly put in motion by straps, (like the strap *h*, in Fig. 470,) they being highly adapted to the purpose, and moreover simple and cheap. The conveyers are intended to remove immediately the bolted flour from the hutch of each pair of bolters without opening the hutch.

The ground grain passes through the common plate-iron gutters *i i* into the two superior bolters, (where the cloth is of finer quality,) in such quantity as may be easily bolted by them. The mechanism applied for this purpose will be described below. The flour bolted in the upper half of these two bolters is somewhat finer than that bolted in their lower half, the former therefore being called extra-superfine, and the latter superfine. All this flour falls through the oblique partitions *k k*, Fig. 471, into the trough *l* of the upper conveyer. The wheels *m n*, Fig. 470, moving this conveyer, are covered by the roof *o*. The coarser parts, or the grit and bran, issuing from the mouth of the bolter, fall into the partition *p* of the bolting-hutch, and then, by means of the oblique board partition *q*, into the two lower bolters of coarser cloth a_1. Thence the bolted flour goes into the trough *r* of the lower conveyers *g*, and the bran goes from the bolter's mouth through the gutter *s*, Fig. 470.

The above-mentioned *extra-superfine* flour is, by means of the conveyer *f*, pushed to the wooden channel *t*, through which it then goes off into the flour-box, while the *superfine* flour is, by the channel *u*, conveyed into the upper partition of the hutch, enclosing the two lower bolters a_1 a_1. Hence, mixed with the flour of these bolters, it is by the lower conveyer *g* pushed to the channel *v*, through which it goes off into the *meal-elevator*, that brings it back to the *hopper-boy*. Thence, having been mingled with grit, it is conveyed once more into the bolter. In the case when the middling flour (or seconds) is ground for the second time, the flour bolted by the upper and lower bolters is intermixed and not reconveyed into the hopper-boy; but the gutter or channel *v* is shut, and the strap *h* (moving the conveyer *g*) crossed, which has the effect of conveying the flour to the gutter or channel *w*, (which then is to be shut up,) from whence it goes, together with the flour coming from the upper bolters down the gutter *x*, into the flour-box.

The mechanism by which the ground grain or meal is conveyed into each of the two superior bolters, is to be seen in Fig. 472, longitudinal section, and Fig. 473, front view, on a larger scale. The letter *y* marks a funnel, into which the ground mass falls down from a hopper-boy in a higher story, and thence upon the moveable spout *α*, resting on the axis *z*. The channel *i*, Fig. 471, is connected with this spout. At the fore part of the spout's side-boards are the cross-rails *β β*, by which, and by wedges, the shaking-bolt *γ* is fastened. At the upper mouth of the bolters is a cast-iron cross *δ*, Figs. 470 and 471, fastened to the axis, whose points are provided with heads, the forms of which may be seen by Figs. 471 and 472. During the rotation of the bolters, these heads touch upon the end point of the shaking-bolt *γ*, Fig. 472, which lifts the spout *α* up and down. Thus the spout is constantly in a shaking motion, and the mass heaped in the funnel *y* is conveyed by the gutter *i* into the bolter *a*. By means of the shutter *ε* the aperture at the bottom of the front partition of the funnel *y* can be widened or narrowed, according to circumstances.

The *conveyers f* and *g* consist of a screw, as may be perceived by Fig. 474, where they are represented on a larger scale. The chief part is commonly an octagonal strong wooden axis 1, round which, in a helix, are put small wooden square tables 2, 2, at right angles to the axis.

These tables are generally 2¾ inches high and broad, and at the foot end half an inch thick, while the back lessens to a sharp edge. The front sides (which retain their right angle with the axis) take hold of the flour contained in the trough 3, and push it gradually on to the respective gutters. Beside the slides, shutting the gutters *u*, *x*, *t*, *v*, *w*, there are in the bottom of the conveyer-trough as many slides as possible, in order to prevent its obstruction during the movement of the conveyer.

In the above-described bolters the pushing of the flour through the perforations of the bolting-cloth is produced in such a manner that the contents of the bolter are during its rotation cast up, and then by their own weight fall upon the under side of the bolter; whereas, in the following rotative bolters (which in all other respects are arranged like the other just mentioned) the bolting is effected by *beaters* or other similar instruments. By this arrangement, the obstruction of the perforations is prevented with more success.

Figs. 482 and 483 represent a bolter of this kind and its hutch in longitudinal and transverse sections; and Figs. 484 and 485 represent the bolter in transverse section, and in a side view. The hexagonal wooden axis is marked by *a a*. From each of its six flat sides project six cylindrical staves *b*, of hard timber, and one inch in diameter, and placed at the distance of two or three feet from each other. The staves of every row are at their points connected with each other by a lath *c*, over which the bolting-cloth is tentered, and to which it is fastened with pins. Upon each staff is put a little tube of cast-iron, 1½ to 2 pounds weight, 3 to 4 inches long, 2 inches in the outer diameter, and called beaters. During the rotation of the bolter, produced by the wheels *e* and *f*, Fig. 482, these beaters run up and down the staves, Fig. 484, and by their beating against the hard-wood supports *g*, Fig. 484, underneath the laths *c*, they prevent the obstruction of the perforations of the bolter. That the laths may not be knocked off by this beating, there are commonly laid round bands either of leather or thin hoop-iron, see *h h*, Fig. 485.

While the lower end of the bolter is left open to let out the grit or bran, the upper end is provided with a wooden crown *i*, Figs. 482 and 483, whose interior diameter leaves only as much room as is required for the plate-iron gutter *k*, Fig. 482, by which the ground mass goes into the bolter. The crown

i is provided with a funnel *l* of tin-plate, for the purpose of retaining the grit or flour within the bolter.

A bolter of this kind is commonly from 16 to 26 feet long, and 24 to 30 inches diameter, and inclines in the ratio of one-fifteenth to one-eighth of its length. Its silk bolting-cloth is selected out of two to five, and even still more numbers. The first sort covers the greatest part of the bolter from above, and then follow in succession the coarser qualities. According to the variety of the flour to be obtained, there are brought into connection with a set of 4 or 5 feet millstones, either one, or two, or more bolters, which are placed in the above manner, (see Figs. 470 and 471.) The most proper arrangement is, that the upper parts of the bolter (covered with the finer sorts of bolting-cloth) furnish the flour at once completely bolted, while the less fine grit of the other parts is to be ground and again bolted.

The different qualities of flour or grit are taken up in separate partitions of the bolting-hutch, of which a simple arrangement is represented by Figs. 482 and 483. The partitions *n* separate the lower part of the bolting-hutch *m m* into the partitions 1, 2, 3, and 4, of which the first three take up three different sorts of flour, while the partition 4 takes up the grit or bran issuing from the mouth of the bolter, and has on its outside a hole (with the slide *o*) through which the grit or bran comes out. The oblique tables *p p*, Fig. 483, leave below an opening from 6 to 12 inches wide, through which the bolted flour falls into the partitions. Each of the latter, 1, 2, and 3, is provided with a valve, consisting of a frame covered with cloth, (see *q*, Fig. 482,) and whose hinges are marked by *r r*. The valve may be kept open by fastening it to the buttons *s s*, Fig. 483.

Another proper arrangement for taking up the flour or grit, is shown by Figs. 486 and 487. Here the bottom *b* of the bolting-hutch *a a*, (which contains the same partitions as the other ones just described,) runs out in a slope sidewise, through which the flour falling from the bolter accumulates at the side-wall *c c*, Fig. 487, and thus runs easily through the opening *d*, into the bag *f*, as soon as the slide *e* is shut up. As many as convenient are placed before a flour-partition, Fig. 486. They are put up and taken away in the following simple manner: At the sack-mouth *i*, beneath the opening *d*, on which rests the sloping bottom *b*, are put in two screws *h h*. Their ends are crooked into hooks which grasp the leather rim *i* of the sack. (See *h* beneath the opening *d*, Fig. 487.) About 3 or 5 feet above each sack projects a rafter *k*, from which hangs down a thong *l*, with forceps *m* and *n*, to take hold of the rim of the sack.

It may be finally remarked, that it has been tried to supplant the beaters above described, (see Fig. 484,) by another contrivance represented by Figs. 488 and 489 in side and front views. The chief part consists of a thick steel button marked *b*, Fig. 488, fixed at the upper pivot of the bolter's axis *b*, Fig. 488. The steel button turns round on a strong and well-polished steel plate *c*, inserted into the pivot-base *d*. Now the axis in turning round is by the three protuberances lifted up and down, and thus constantly kept in a shaking motion. In this way the obstruction of the perforations of the bolting-cloth is prevented as well as by the beaters.

The *brush-bolter*, or cylindrical dressing-machine, as it is styled, is in many mills used conjointly with Ayton's improved bolting-machine, into which latter the grit and bran is brought after they have been bolted in the dressing-machine.

Fig. 475 gives a side view of the common brush-bolter, while Figs. 476 and 477 represent an improved machine of this kind in transverse and longitudinal section, several parts of which are illustrated by Figs. 478 and 479, (on a large scale,) and 480 and 481.

The bolter, both of the common and improved machine, is cylindrical, covered by a bolting-cloth made of wire-texture, and placed obliquely in the bolting-hutch. (See Figs. 475, 476, and 477.) The bolting-cloth in Fig. 475 is directly fixed to the bolting-frame; but in Figs. 476 and 477 it is kept suspended by long screw-bolts *q q*, fixed at the roof of the bolting-hutch. (See Figs. 476, 477, 480, and 481.) The cylindrical sieve-frame of the common machine, Fig. 475, consists of staves *b b*, fixed round the disks *c c* and at the felloes *d*. The interior periphery of this frame is covered with wire-gauze of different fineness—the first number fixed at the upper end, and the less fine sorts following in succession, just in the same way as has been mentioned.

The sieve-frame of the improved machine consists of two semi-cylinders, (see Figs. 477, 480, and 481,) whose side-boards *e e* are laid and screwed together, thus forming a full cylinder.

Within this cylindrical sieve is, exactly in its axis, placed the shaft *f f*, (made of wrought-iron in the machines represented in Figs. 475 and 476,) which is provided with three disk-wheels *g g g*, Fig. 477. On the periphery of these wheels are put in eight brushes of hog's bristles *h*, (see Figs. 478 and 479,) in the manner illustrated, not only by Fig. 477, but also by Fig. 478, where the wheel-periphery is marked by *g g*, and the brushes by *h h;* while the outer circle signifies the inner periphery of the cylindrical sieve. The shaft *f f*, Fig. 477, is turned by the disk *i*, and during its rotation the brushes touch the inner periphery of the cylindrical sieve as much as required, to prevent the obstruction of the perforations by flour. In case the brushes should be worn, they can be screwed more forward by boxes *k k*, Fig. 478.

At the upper and lower end of the cylindrical sieve are the wooden rings *l* and *m*, Fig. 477, fastened by means of screws. They are in the periphery somewhat notched, as may be seen by *m*, Fig. 481 To the upper ring *l*, Fig. 477 is tied, by means of a cord, the leather strip *n*, which is glued or nailed on the bolting-hutch *a a*. By this arrangement the ground mass, coming out by the spout *o*, is taken up here, and conveyed to the cylinder. The ring *m*, at the lower end, serves as a link between the partition-boards *p p*.

In order to establish equality in the brushing of the sieve, this latter, or the cylindrical bolter, is, by means of four screw-bolts *q q*, kept in suspension, and may, according to circumstances, be wound up and lowered, for which purpose the nuts are winged. The screw-bolts are at their ends provided with hooks *r r*, Figs. 480 and 481, which take hold of two side-laths *b b*, Fig. 481, of the cylindrical frame of the sieve. On the other hand the brush-cylinder, whose shaft *f f* rests on the sliding-rail *s*, can also be displaced, either up or down, by the nut of the screw *t*.

The hopper, which holds the ground grain, is marked by *u*, Fig. 477, and the moveable spout con-

nected with it by *o*. This spout is shaken by a nave *v*, fixed at the shaft *ff*, which beats during the rotation against a tack at the bottom of the shoe. By the slide at *w*, the quantity of ground grain in the shoe can be increased or decreased. The slide *x*, which in Fig. 477 is closed, is shut up in Fig. 476.

A cylindrical sieve or bolter of this kind is commonly covered with four or five different numbers of wire-texture, through which the different qualities are bolted, and taken up by the corresponding partitions 1, 2, 3, 4, and 5, whence the flour is easily taken out through the side-openings, until then closed by slides. The bran falls into the partition 6.

The fineness of the texture is commonly in the ratio of 64, 60, 56, 38, and 16 meshes to the square inch. Experience has taught, that the best arrangement is to cover the frame from above, first with gauze or texture of 60 meshes, and to follow in succession that of 64, 56, 38, and 16 meshes. The gauze of 60 meshes furnishes as fine flour as that of 64, which is owing to the circumstance that the flour in the uppermost part of the bolter is not so much exposed to the influence of the brushes, and that the finest quality of flour is more sticky or viscous than the coarser qualities.

By the rotation in one and the same direction, the bristles of the brushes must at last be bent to one side, and thus lose their efficacy. To remedy this, an arrangement is made by which the brush-reel turns alternately to the right and left. This is easily effected by double wheels or thong-disks.

A small brush-cylinder has been invented by James Murphy, of Zanesville, O., which is to be placed at the outside of the above-described cylindrical sieve, that is, everywhere on its periphery brushed by it. By this operation the obstruction of the meshes is completely prevented. Mr. Murphy uses thin hoops and ribs of cast-iron for constructing the sieve-frames, instead of the above-described wooden felloes and laths.

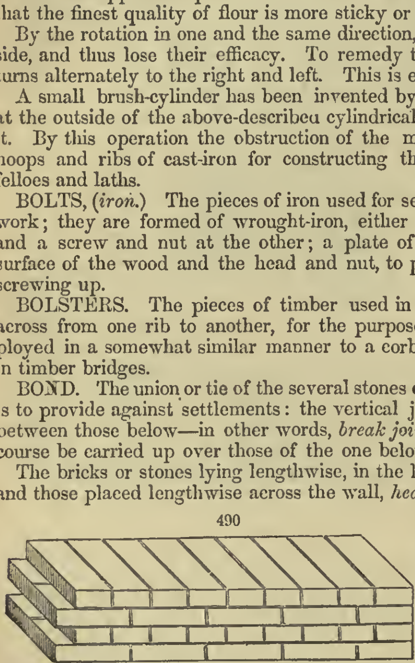
BOLTS, (*iron.*) The pieces of iron used for securing framing together, and much employed in timber work; they are formed of wrought-iron, either square or cylindrical, with a square head at one end, and a screw and nut at the other; a plate of iron, termed a *washer*, being interposed between the surface of the wood and the head and nut, to protect the former from damage during the process of screwing up.

BOLSTERS. The pieces of timber used in the construction of the centres of arches, and running across from one rib to another, for the purpose of supporting the voussoirs. A piece of timber, employed in a somewhat similar manner to a corbel, is also termed a *bolster;* which are much employed in timber bridges.

BOND. The union or tie of the several stones or bricks forming a wall. The great principle in all bond is to provide against settlements: the vertical joints of a course should, therefore, be exactly midway between those below—in other words, *break joint* with them; and in no case should the joints of one course be carried up over those of the one below it.

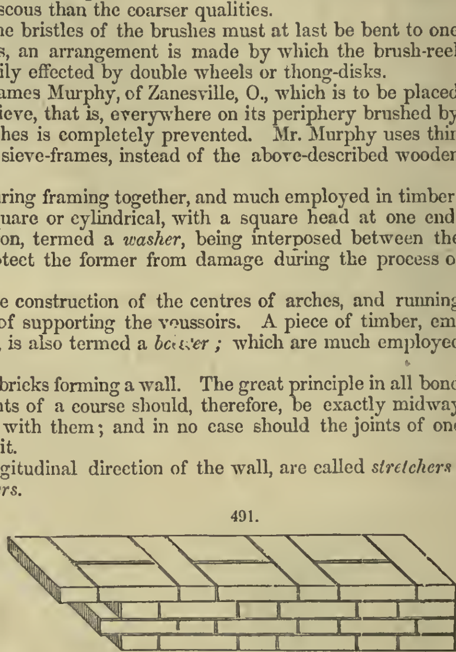
The bricks or stones lying lengthwise, in the longitudinal direction of the wall, are called *stretchers*, and those placed lengthwise across the wall, *headers*.

490



Old English Bond, or Block-bond.

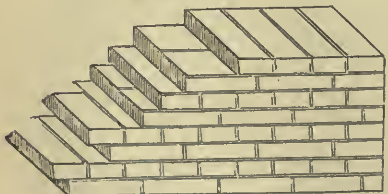
491.



Flemish Bond.

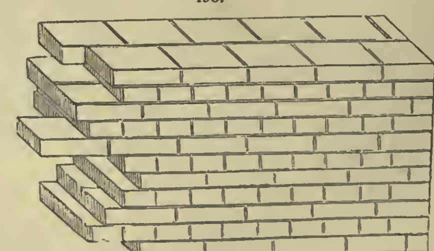
Bond may be described generally to be of three kinds. In English bond the courses are alternately all headers and all stretchers, and when the backs of each course are laid alternately header and stretcher it is called Flemish Bond; this description of tie is also known by the name of *header and stretcher* particularly in stone-work.

492.



Cross-bond.

493.



Combined Cross and Block bond.

The *cross-bond*—mostly used in Germany by bricklayers—differs from the old English or block bond, by the change of the second stretcher-line, so that the joints of the second come in the middle of the first, and the same position of stretchers comes back only every fifth line. This bond gives besides a very neat appearance, and is therefore used wherever a nice building is to be erected. The strongest tie is given to a wall by combining the block and cross-bond, so that the extrados is put up in cross-bond, the intrados in block-bond, as shown in the figure. The reason of it is, if a settling of the wall happens, so that the joints open, all other bonds give only in the vertical, a crooked breaking line; but this combined-bond requires a crooked breaking-line in the horizontal direction besides; it is therefore applied where a neat appearance and great strength are required.

BONES. See ANIMAL KINGDOM, *materials from used in the mechanical and ornamental arts.*

BORING MACHINE, *Vertical:* by Messrs. Nasmyth, Gaskell & Co. The many advantages derived by this arrangement of a vertical boring machine over those where the work is placed in a horizontal position, may perhaps be unknown to persons unacquainted with the general character of machinery; it may not be unadvisable to point out a few of the principal features showing the superiority of this machine.

In the first place, the arrangements of its parts; the manner in which the cylinder is placed, namely, its vertical position, thereby doing away entirely with all the injurious effects produced by the weight of the body being planed or bored; thus obviating all tendency to distort its figure, which is the case where the operation is performed by the horizontal system, and where the sides are bulged out from the weight of the upper part; this may be better understood by forming a cylinder of thin paper, which will be found to widen in the middle and assume an oval form from its own weight.

This alteration of form is found to be quite sensible when the cylinders are of large diameters. Another great advantage of this system of vertical boring, is avoiding all risk of flexure in the boring-bar, upon which the cutter wheel or head is fixed for carrying the boring-tools; this bar has a tendency to bend down in the centre to a curve, instead of keeping a perfectly straight line, transferring the figure assumed by the bar to the surface of the cylinder; but this will much depend both on its length and diameter.

Another advantage of this machine is, that the cutters are kept clear of the borings, which fall to the bottom of the cylinder as fast as they are cut. By this superior arrangement all these objections are entirely removed, thus avoiding all the tendency gravity has in altering the trueness of the cylinder or the bar; added to these, the power requisite to bore the cylinder is found to be much less than in those placed horizontally, a very desirable object in a large establishment.

A short description of its several parts will enable the reader more fully to understand the advantages already alluded to.

Fig. 494 represents a cross-section of this machine, and Fig. 497 a plan showing its position in a corner of the building where it is placed. In these two views it will be seen that the driving part of the machinery is situated below the ground-line on suitably strong foundations, in which it is enclosed. These parts are rendered accessible by the steps *t*, which are found to be necessary in cases where the machinery is likely to get out of order, a precaution never to be neglected.

The two riggers *k k* receive their motion from the main shaft by means of a leather strap: one of these runs loose on the shaft, and the strap is thrown on it when the machine is not at work; this is done at pleasure with the greatest possible facility; by a bevel-wheel and pinion *j*, it is then conveyed through the shaft *i* to the endless worm *n*, working in a large worm-wheel *o*, which is fixed on the great vertical boring-bar *a*, whereby a very easy motion is obtained, and all jerks avoided. It will be seen by the series of wheels in Fig. 497, how much the speed of the boring-bar is reduced. The shaft *i* is placed at an angle, and works in a bearing or plummer block and a step *h*, both of these being made of brass.

The vertical bar is made in two parts *a* and *c*, the upper one *a* for carrying the cutter-head or boring-wheel *r*, while to the lower one is connected the driving apparatus; they are coupled together by the upper one resting, as is shown in Fig. 496, in a socket on the top of the lower one; a steel key *l* is then driven in, which entirely prevents it from turning; the toe of the bar *c* rests in a step or socket shown by Fig. 498; the entire weight of this bar and its appendages is thrown on the hardened cast-steel disks *s*, which are constantly kept supplied with oil. Both extremities of the bar *c* are rendered adjustable to the greatest possible accuracy by means of the small set-screws *q q*, Figs. 496 and 498, which, by being tightened, press against the conical brass segments, the upper one forming part of the great base or floor-plate *b*, which is materially strengthened by six strong ribs on its under side. The cross-beam *g* is well fitted to the sockets *f*, built into the wall of the building, where they are bolted by strong bolts, Figs. 494, 495, and 497. It has an additional stay in the bolt *u*.

There are four standards or supports, *d d*, Fig. 494, for carrying the cylinder to be bored, which can be altered to any convenient position by unscrewing the bolts which fix them to the base-plate. After the cylinder has been properly placed in its right position, it is fixed to these supports by clamps *e* and bolts; and thus rendered quite immoveable.

In the boring-bar *a* is a deep socket *m*, Fig. 494, which allows the bar to slide up and down by means of the screw *p* and the nut *l*; upon the lower side of this socket is a flange *m*, upon which the cutter-head or wheel *r* rests, receiving its motion from the bar by means of a nut, answering both the purpose of nut and key. By the different arrangements of the sun and planet motion of the wheels on the upper part of the bar, any degree of motion can be given to the screw for the descent of the cutter-wheel. After the cylinder has been once bored through, the cutter-wheel is raised by means of a small crane, and the chains, Fig. 495, and by the peculiar arrangement of the nut *l* in the socket *m*, the cutter-wheel can be drawn up the cylinder without turning the screw *p*, as it leaves the nut behind, which is afterwards screwed up, there being no other weight to raise but that of the nut. The cutters are then set afresh to the new or finishing cut, after which the cylinder may be considered perfectly true. The position occupied by the crane enables the cylinder to be placed, and the bar lifted in and out with most perfect ease; while the space occupied by this machine is very small compared with those where the work is performed horizontally; it is, however, important that the base-plate *b* should be well secured to the foundations by strong bolts.

The speed of this machine may very easily be varied, by having different-sized riggers or pulleys on the driving-shaft which conveys the motion to the riggers *k k*, Figs. 494 and 497.

BORING MACHINE, *Great.* By Messrs. Nasmyth, Gaskell and Co. The machine represented by Fig. 499 is, with few exceptions, the same as that last described, where the cylinder to be bored is placed in a vertical position, whereby numerous advantages are derived, as already explained.

The motion is communicated by the driving-pulley *c* to a bevel pinion working the bevel wheel *d*

the shaft on which this wheel is fixed, has on its opposite end a worm for communicating the motion through the worm-wheel to the upright shaft *f* and boring-bar *a*, having on its circumference the grooves *a'* in which the cutter-head is moveable, sliding up and down according to the progress of the work; *k* is a tool-carrier fixed to the cutter-head. The foundation plate *h* forms a bearing for the upright shaft, the lower end of which rests in the step *g*, while the cylinder *l* is secured by the clamps *j j* to the supports *i i* fixed to the foundation plate. These parts are in every respect similar to the boring machine shown by Fig. 494, by which they are more fully described.

Two strong piers of masonry *m'* support the entablature *m*, (for carrying the self-acting apparatus for raising and lowering the cutter-head *b*,) to which it is bolted by strong holding-down bolts *m''*. This apparatus consists of a rack *n* worked by a pinion, the motion being transmitted from a trullion-wheel through two spur-wheels and pinions *o*. The whole of this upper machinery revolves with the boring-bar, with the exception of the internal wheel or screwed hoop *p*; the consequence of which is, the small trullion-wheel is made to turn on its axis by the thread of the wheel *p* in which it works, and thereby ultimately raises the cutter-head *b*, the two side-slings connecting it to the upper frame *q'*, to which is fixed the rack *n*.

This machine is of the largest dimensions, and was made for the purpose of boring the large cylinders, 10 feet in diameter, for the Great Western Steam Navigation Company's vessel the Mammoth, at their works at Bristol.

x Crank being bored.
y Piston having its face ground.

the upper parts of the three different machines, consisting of the requisite driving machinery for communicating to them their respective motions.

That in the centre, A, is a vertical boring machine for boring cylinders of large diameters, which are fixed in the usual way on the six moveable supports h by the clamps i; in addition to which it is rendered perfectly steady by the circular frame or ring j, sliding up and down in grooves on the back of the two middle columns, the adjusting-screws j being tightened when the cylinder is properly placed under the centre of the boring-bar c, which receives its motion from the leather strap and pulleys d, whence it is conveyed through the bevel pinion and wheel e on the upright shaft f, upon which is also keyed the spur-pinion for driving the wheel g fixed to the lower part of the boring-bar c, and working in the step m; the rack and wheel k gives the cutter-head the requisite feed while boring out the cylinder. The six supports h are made to slide in grooves on the foundation plate n, according to the different diameters of the cylinders being operated upon; these, when properly placed, are bolted to the plate n.

The second machine, B, is a vertical drilling and boring machine for work of smaller dimensions than the machine A. It is shown in the drawing boring out the centre of a crank x, fixed to the travelling table p, and slides on V's on the frame o', which has also a motion at right angles, on the bed o fixed to the foundation plate. The drilling-bar u' is lowered by the screw u'' according to the feed, its motion being conveyed to it from the pulley q and strap q' to a spur-wheel and pinion not shown in the drawing; the pinion is on the same spindle as the pulley, and the wheel on that of the reversed cone u, by which it is carried to the square-threaded screw u'' by two pairs of small bevel-wheels u, fixed on a horizontal spindle and working in suitable bearings on the carriages u''' u'''. The apparatus for raising the drilling-bar, Fig. 500, consists simply of two small chains fixed to the bar u' and working round the pulleys, its opposite end being attached to a weight v.

The third machine C, is for the purpose of grinding up the faces of rings for metallic pistons, conical valves, &c.; the travelling table p of this machine is in every respect similar to that of B, and upon it is placed the piston y to be ground; the upright rod, receiving its motion from the pulley and strap q', is kept in a vertical position by the cross-frame s, while the shaft r and grinding-plate are connected to the lower end of the rod, and are occasionally raised for examining the surface being ground.

The different motions given to these machines are quite independent the one of the other, by which means any one of them can be worked separately. The whole is placed on a suitable strong foundation of stone. After the large cylinder is bored, it is raised from its position by a crane placed on the floor above.

BORING MACHINES, for cannon. See CANNON.

BORING FOR WELLS, and Tools therefor. See ARTESIAN WELLS.

BORING TOOLS.* The process of boring holes may be viewed as an inversion of that of turning; generally the work remains at rest, and the tool is revolved and advanced. Many of the boring and drilling tools have angular points, which serve alike for the removal of the material, and the guidance of the instrument; others have blunt guides of various kinds for directing them, whilst the cutting is performed by the end of the tool.

Commencing as usual with the tools for wood, the brad-awl, Fig. 502, may be noticed as the most simple of its kind; it is a cylindrical wire with a chisel edge, which rather displaces than removes the material; it is sometimes sharpened with three facets as a triangular prism. The awl, Fig. 503, used by the wire-workers, is less disposed to split the wood; it is square and sharp on all four edges, and tapers off very gradually until near the point, where the sides meet rather more abruptly.

The generality of the boring instruments used in carpentry are fluted, like reeds split in two parts, to give room for the shavings, and they are sharpened in various ways, as shown by Figs. 504 to 508. Fig. 504 is known as the *shell-bit*, and also as the *gouge-bit*, or *quill-bit*; it is sharpened at the end like a gouge, and when revolved it shears the fibres around the margin of the hole, and removes the wood almost as a solid core. The shell-bits are in very general use, and when made very small, they are used for boring the holes in some brushes.

502. 503. 504. 505. 506. 507. 508.

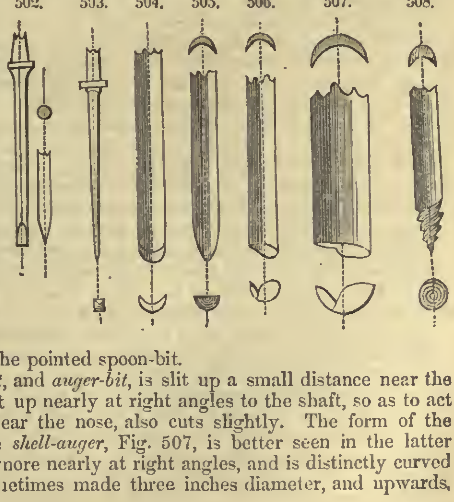

Fig. 505, the *spoon-bit*, is generally bent up at the end to make a taper point, terminating on the diametrical line; it acts something after the manner of a common pointed drill, except that it possesses the keen edge suitable for wood. The spoon-bit is in very common use; the *coopers' dowel-bit*, and the *table-bit*, for making the holes for the wooden joints of tables, are of this kind. Occasionally the end is bent in a semicircular form; such are called *duck-nose-bits* from their resemblance, and also *brush-bits* from their use; the diameter of the hole continues undiminished for a greater depth than with the pointed spoon-bit.

The *nose-bit*, Fig. 506, called also the *slit-nose-bit*, and *auger-bit*, is slit up a small distance near the centre, and the larger piece of the end is then bent up nearly at right angles to the shaft, so as to act like a paring-chisel; and the corner of the reed, near the nose, also cuts slightly. The form of the nose-bit, which is very nearly a diminutive of the *shell-auger*, Fig. 507, is better seen in the latter instrument, in which the transverse cutter lies still more nearly at right angles, and is distinctly curved on the edge instead of radial. The augers are sometimes made three inches diameter, and upwards,

* Holtzapffel's Turning and Mechanical Manipulation.

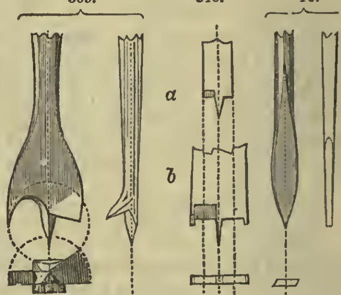
and with long removeable shanks, for the purpose of boring wooden pump-barrels; they are then called *pump-bits.*

There is some little uncertainty of the nose-bits entering exactly at any required spot, unless a small commencement is previously made with another instrument, as a spoon-bit, a gouge, a brad-awl, a centre-punch, or some other tool; with augers a preparatory hole is invariably made, either with a gouge, or with a centre-bit exactly of the size of the auger. When the nose-bits are used for making the holes in sash bars, for the wooden pins or dowels, the bit is made exactly parallel, and it has a square brass socket which fits the bit; so that the work and socket being fixed in their respective situations, the *guide-principle* is perfectly applied. A "*guide-tube*" built up as a tripod, which the workman steadies with his foot, has been recently applied by Mr. Charles May, of Ipswich, for boring the auger-holes in railway sleepers exactly perpendicular.

The gimlet, Fig. 508, is also a fluted tool, but it terminates in a sharp worm or screw, beginning as a point and extending to the full diameter of the tool, which is drawn by the screw into the wood. The principal part of the cutting is done by the angular corner intermediate between the worm and shell, which acts much like the auger. The gimlet is worked until the shell is full of wood, when it is unwound and withdrawn to empty it.

The centre-bit, Fig. 509, shown in three views, is a very beautiful instrument; it consists of three parts, a centre-point or *pin*, filed triangularly, which serves as a guide for position; a thin shearing-point or *nicker*, that cuts through the fibres like the point of a knife; and a broad chisel-edge or *cutter*, placed obliquely to pare up the wood within the circle marked out by the point. The cutter should have both a little less radius and less length than the nicker, upon the keen edge of which last the correct action of the tool principally depends.

509. 510. 11.

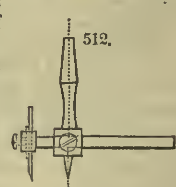


Many variations are made from the ordinary centre-bit, Fig. 509; sometimes the centre-point is enlarged into a stout cylindrical plug, so that it may exactly fill a hole previously made, and cut out a cylindrical countersink around the same, as for the head of a screw-bolt. This tool, known as the *plug centre-bit*, is much used in making frames and furniture, held together by screw-bolts. Similar tools, but with loose cutters inserted in a diametrical mortise, in a stout shaft, are also used in ship-building for inlaying the heads of bolts and washers, in the timbers and planking.

The *wine-cooper's centre-bit* is very short, and is enlarged behind into a cone, so that immediately a full cask has been bored, the cone plugs up the hole until the tap is inserted. The centre-bit deprived of its chisel-edge, or possessing only the pin and nicker, is called a *button-tool;* it is used for boring and cutting out, at one process, the little leather disks or *buttons*, which serve as nuts for the screwed wires in the mechanism connected with the keys of the organ and pianoforte.

The *expanding centre-bit*, shown on a much smaller scale in Fig. 512, is a very useful instrument; it has a central stem with a conical point, and across the end of the stem is fitted a transverse bar adjustable for radius. When the latter carries only a lancet-shaped cutter it is used for making the margins of circular recesses, and also for cutting out disks of wood and thin materials generally; when, as in Mr. James Stone's modification, the expanding centre-bit has two shearing-points or nickers, and one chisel-formed cutter, it serves for making grooves for inlaying rings of metal or wood in cabinet-work, and other purposes.

512.



The above tools being generally used for woods of the softer kinds, and the plankway of the grain, the shearing-point and oblique chisel of the centre-bit, Fig. 509, are constantly retained, but the corresponding tools used for the hard woods assume the characters of the hard-wood tools generally. For instance, *a*, Fig. 510, has a square point, also two cutting edges, which are nearly diametrical, and sharpened with a single chamfer at about 60 degrees; this is the ordinary *drill* used for boring the finger-holes in flutes and clarionets, which are afterwards chamfered on the inner side with a stout knife, the edge of which measures about 50 degrees. The key-holes are first scored with the *cup-key tool*, *b*, and then drilled, the tools *a* and *b* being represented of corresponding sizes, and forming between them the annular ridge which indents the leather of the valve or key.

When *a*, Fig. 510, is made exactly parallel and sharpened up the sides, it cuts hard mahogany very cleanly in all directions of the grain, and is used for drilling the various holes in the small machinery of pianofortes; this drill (and also the last two) is put in motion in the lathe; and in Fig. 511, the lathe-drill for hard woods, called by the French *langue de carpe*, the centre-point and the two sides melt into an easy curve, which is sharpened all the way round and a little beyond its largest part.

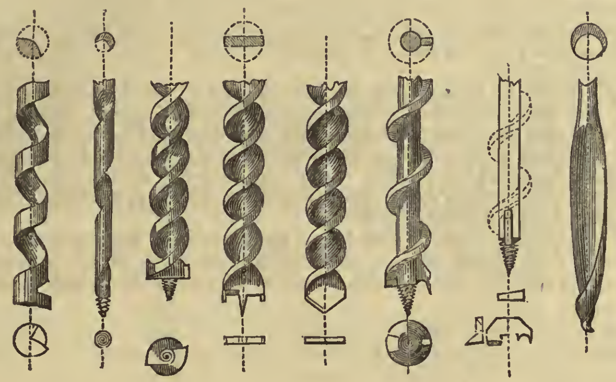
Various tools for boring wood have been made with spiral stems, in order that the shavings may be enabled to ascend the hollow worm, and thereby save the trouble of so frequently withdrawing the bit. For example, the shaft of Fig. 513, the *single-lip auger*, is forged as a half-round bar, nearly as in the section above; it is then coiled into an open spiral with the flat side outwards, to constitute the cylindrical surface, and the end is formed almost the same as that of the shell-auger, Fig. 507. The *twisted gimlet*, Fig. 514, is made with a conical shaft, around which is filed a half-round groove, the one edge of which becomes thereby sharpened, so as gradually to enlarge the hole after the first penetration of the worm, which, from being smaller than in the common gimlet, acts with less risk of splitting.

The ordinary screw-auger, Fig. 515, is forged as a parallel blade of steel, (seen in Fig. 516, which also refers to 515 and 517;) it is twisted red-hot, the end terminates in a worm by which the auger is

gradually drawn into the work, as in the gimlet, and the two angles or lips are sharpened to cut at the extreme ends, and a little up the sides also.

The same kind of shaft is sometimes made as in Fig. 516, with a plain conical point, with two scoring cutters and two chisel edges, which receive their obliquity from the slope of the worm: it is as it were a double centre-bit, or one with two lips grafted on a spiral shaft. The same shaft has been also made, as in Fig. 517, with a common drill-point, and proposed for metal, but this seems scarcely called for;

513. 514. 515. 516. 517. 518. 519. 520.



but it is in this form very effective in Hunter's patent stone-boring machine, intended for stones not harder than sandstones; the drill is worked by a cross, guided by a tube, and forced in by a screw cut upon the shaft carrying the drill; so that the stone is not ground to powder, but cast off in flakes with very little injury to the drill.

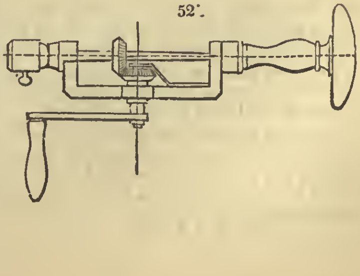
Another screw-auger, which is perhaps the most general after the double-lipped screw-auger, Fig 515, is known as the *American screw-auger*, and is shown in Fig. 518; this has a cylindrical shaft, around which is brazed a single fin or rib; the end is filed into a worm as usual, and immediately behind the worm a small diametrical mortise is formed for the reception of a detached cutter, which exactly resembles the nicking-point and chisel-edge of the centre-bit; it may be called a centre-bit for deep holes. The parts are shown detached in Fig. 519. The loose cutter is kept central by its square notch, embracing the central shaft of the auger; it is fixed by a wedge driven in behind, and the chisel-edge rests against the spiral worm. Spare cutters are added in case of accident, and should the screw be broken off, a new screw and mortise may be made by depriving the instrument of so much of its length. This instrument will be found on trial extremely effective; and on account of the great space allowed for the shavings, they are delivered perfectly, until the worm is buried a small distance beneath the surface of the hole.

The Americans have also invented an auger, thoroughly applicable to producing square holes, and those of other forms: the tool consists of a steel tube, of the width of the hole, the end of the tube is sharpened from within, with the corners in advance, or with four hollowed edges. In the centre of the square tube works a screw-auger, the thread of which projects a little beyond the end of the tube, so as first to penetrate the wood, and then to drag after it the sheath, and thus complete the hole at one process; the removed shavings making their escape up the worm and through the tube. For boring long mortises, two or more square augers are to be placed side by side, but they must necessarily be worked one at a time. The tools Figs. 513 to 520 are American.

The screw-auger acts as a hollow taper-bit or rimmer, and the screw-form point and shaft assist in drawing it into the wood; but the instrument must pass entirely through for making cylindrical holes.

The most usual of the modes of giving motion to the various kinds of boring bits, is by the ordinary carpenter's brace with a crank-formed shaft. The instrument is made in wood or metal, and at the one extremity has a metal socket called the *pad*, with a taper square hole, and a spring catch used for retaining the drills in the brace when they are withdrawn from the work; and at the other it has a swivelled head or shield, which is pressed forward horizontally by the chest of the workman; or when used vertically, by the left hand, which is then commonly placed against the forehead.

521.



The ordinary carpenter's brace is too familiarly known to require further description, but it sometimes happens, that in corners and other places there is not room to swing round the handle; the *angle brace*, Fig. 521, is then convenient. It is made entirely of metal, with a pair of bevel pinions, and a winch-handle that is placed on the axis of one of these, at various distances from the centre, according to the power or velocity required. Sometimes the bevel-wheel attached to the winch handle is three or four times the diameter of the pinion on the drill; this gives greater speed, but less power.

The augers, which from their increased size require more power, are moved by transverse handles some augers are made with *shanks*, and are riveted into the handles just like the gimlet; occasionally the handle has a socket or pad, for receiving several augers, but the most common mode is to form the end of the shaft into a ring or eye, through which the transverse handle is tightly driven. The brad-awls, and occasionally the other tools requiring but slight force, are fitted in straight handles; many of the smaller tools are attached to the lathe-mandrel by means of chucks, and the work is pressed against them, either by the hand, or by a screw, a slide, or other contrivance; Figs. 510 and 511 are always thus applied.

Drills for metal, used by hand.—The frequent necessity in metal works, for the operation of drilling holes, which are required of all sizes and various degrees of accuracy, has led to so very great a variety of modes of performing the process, that it is difficult to arrange with much order the more important of these methods and apparatus.

The ordinary piercing drills for metal do not present quite so much variety as the wood drills recently described. The drills for metal are mostly pointed; they consequently make conical holes, which cause the point of the drill to pursue the original line, and eventually to produce the cylindrical hole. The comparative feebleness of the drill-bow limits the size of the drills employed with it to about one-quarter of an inch in diameter; but as some of the tools used with the bow, agree in kind with those of much larger dimensions, it will be convenient to consider as one group, the forms of the edges of those drills which cut when moved in *either* direction.

Figs. 522, 523, and 524, represent, of their largest sizes, the usual forms of drills proper for the reciprocating motion of the drill-bow, because their cutting edges being situated on the line of the axis, and chamfered on each side, they cut, or rather *scrape*, with equal facility in both directions of motion.

522. 523. 524. 525. 526. 527.

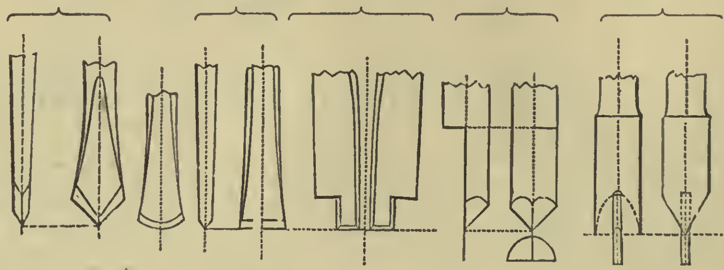


Fig. 522 is the ordinary double-cutting drill; the two facets forming each edge meet at an angle of about 50 to 70 degrees, and the two edges forming the point meet at about 80 to 100; but the watch-makers, who constantly employ this kind of drill, sometimes make the end as obtuse as an angle of about 120 degrees; the point does not then protrude through their thin works, long before the completion of the hole. Fig. 523, with two circular chamfers, bores cast-iron more rapidly than any other reciprocating drill, but it requires an entry to be first made with a pointed drill; by some, this kind is also preferred for wrought-iron and steel. The flat-ended drill, Fig. 524, is used for flattening the bottoms of holes. Fig. 525 is a duplex expanding drill, used by the cutlers for inlaying the little plates of metal in knife-handles; the ends are drawn full size.

Fig. 526 is also a double-cutting drill; the cylindrical wire is filed to the diametrical line, and the end is formed with two facets. This tool has the advantage of retaining the same diameter when it is sharpened; it is sometimes called the Swiss drill, and was employed by M. Le Rivière, for making the numerous small holes in the delicate punching machinery for manufacturing perforated sheets of metal and pasteboard; these drills are sometimes made either semicircular or flat at the extremity, and as they are commonly employed in the lathe, they will be hereafter further noticed.

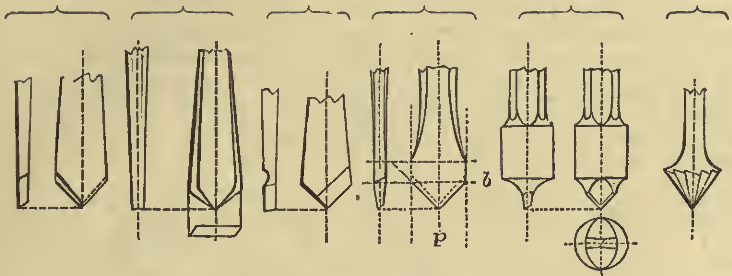
The square countersink, Fig. 527, is also used with the drill-bow; it is made cylindrical, and pierced for the reception of a small central pin, after which it is sharpened to a chisel-edge, as shown. This countersink is in some measure a diminutive of the pin-drills, Figs. 534 to 537, and occasionally circular collars are fitted on the pin for its temporary enlargement, or around the larger part to serve as a stop, and limit the depth to which the countersink is allowed to penetrate, for inlaying the heads of screws. The pin is removed when the instrument is sharpened.

By way of comparison with the double-cutting drills, the ordinary forms of those which only cut in *one* direction, are shown in Figs. 528, 529, and 530. Fig. 528 is the common single-cutting drill, for the drill-bow, brace, and lathe; the point, as usual, is nearly a rectangle, but is formed by only two facets, which meet the sides at about 80° to 85°; and therefore lie very nearly in contact with the extremity of the hole operated upon, thus strictly agreeing with the form of the turning tools for brass. Fig. 529 is a similar drill, particularly suitable for horn, tortoise-shell, and substances liable to agglutinate and clog the drill; the chamfers are rather more acute, and are continued around the edge behind its largest diameter, so that if needful, the drill may also cut its way *out* of the hole.

Fig. 530, although never used with the drill-bow, nor of so small a size as in the wood-cut, is added to show how completely the drill proper for iron, follows the character of the turning tools for that metal; the flute or hollow filed behind the edge, gives the hook-formed acute edge required in this tool, which is in other respects like Fig. 528; the form proper for the cutting edge is shown more distinctly in the diagram *a*, Fig. 534.

Care should always be taken to have a proportional degree of strength in the shafts of the drills, otherwise they tremble and chatter when at work, or they occasionally twist off in the neck; the point should be also ground exactly central, so that both edges may be cut. As a guide for the proportional thickness of the point, it may measure at *b*, Fig. 531, the base of the cone, about one-fifth the diameter of the hole; and at *p*, the point, about one-eighth, for easier penetration: but the fluted drills are made nearly of the same thickness at the point and base.

528. 529. 530. 531. 532. 533.

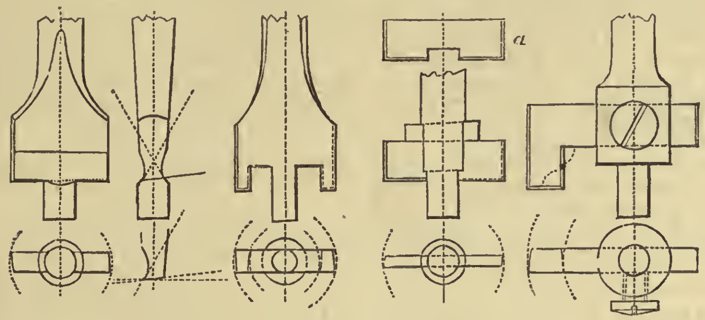


In all the drills previously described, except Fig. 526, the size of the point is lessened each time of sharpening; but to avoid this loss of size, a small part is often made parallel, as shown in Fig. 531 In Fig. 532, this mode is extended by making the drill with a cylindrical lump, so as to fill the hole; this is called the *recentering-drill.* It is used for commencing a small hole in a flat-bottomed cylindrical cavity; or else, in rotation with the common piercing-drill, and the half-round bit, in drilling small and very deep holes in the lathe. Fig. 532 may be also considered to resemble the *stop-drill*, upon which a solid lump or shoulder is formed, or a collar is temporarily attached by a side-screw, for limiting the depth to which the tool can penetrate the work.

Fig. 533, the *cone-countersink*, may be viewed as a multiplication of the common single-cutting drill Sometimes, however, the tool is filed with four equidistant radial furrows, directly upon the axis, and with several intermediate parallel furrows sweeping at an angle around the cone. This makes a more even distribution of the teeth than when all are radial as in the figure, and it is always used in the spherical cutters or countersinks known as *cherries*, which are used in making bullet-moulds.

On comparison, it may be said, the single-chamfered drill, Fig. 528, cuts more quickly than the double-chamfered, Fig. 522, but that the former is also more disposed of the two to swerve or *run* from its intended position. In using the double-cutting drills, it is also necessary to drill the holes at once to their full sizes, as otherwise the thin edges of these tools stick abruptly into the metal, and are liable

534. 535. 536. 537.



to produce jagged or groovy surfaces, which destroy the circularity of the holes; the necessity for drilling the entire hole at once, joined to the feebleness of the drill-bow, limits the size of these drills.

In using the single-chamfered drills it is customary, and on several accounts desirable, to make large holes by a series of two or more drills; first the run of the drill is in a measure proportioned to its diameter, therefore the small tool departs less from its intended path, and a central hole once obtained, it is followed, with little after-risk, by the single-cutting drill, which is less penetrative. This mode likewise throws out of action the less favorable part of the drill near the point, and which in large drills is necessarily thick and obtuse; the subdivision of the work enables a comparatively small power to be used for drilling large holes, and also presents the choice of the velocity best suited to each progressive diameter operated upon. But where sufficient power can be obtained, it is generally more judicious to enlarge the holes previously made with the pointed-drills, by some of the group of pin-drills, Figs. 534 to 537, in which the guide-principle is very perfectly employed: they present a close analogy to the plug centre-bit and the expanding centre-bit used in carpentry.

The ordinary *pin-drill*, Fig. 534, is employed for making countersinks for the heads of screw-bolts in laid flush with the surface, and also for enlarging holes commenced with pointed drills, by a cut parallel with the surface; the pin-drill is also particularly suited to thin materials, as the point of the ordinary

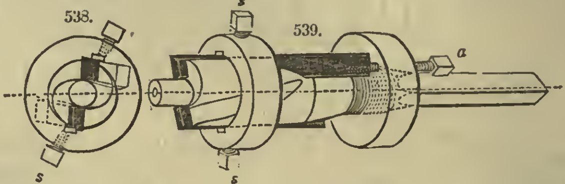
drill would soon pierce through, and leave the guidance less certain. When this tool is used for iron it is fluted as usual, and *a* represents the form of the one edge separately.

Fig. 535 is a pin-drill, principally used for cutting out large holes in cast-iron and other plates. In this case the narrow cutter removes a ring of metal, which is, of course, a less laborious process than cutting the hole into shavings. When this drill is applied from both sides it may be used for plates half an inch and upwards in thickness; as, should not the tool penetrate the whole of the way through, the piece may be broken out, and the rough edges cleaned with a file or a broach.

Fig. 536 is a tool commonly used for drilling the *tube-plates* for receiving the tubes of locomotive-boilers: the material is about $\frac{3}{4}$ inch thick, and the holes $1\frac{3}{4}$ diameter. The loose cutter *a* is fitted in a transverse mortise, and secured by a wedge; it admits of being several times ground before the notch which guides the blade for centrality is obliterated. Fig. 537 is somewhat similar to the last two, but is principally intended for sinking grooves; and when the tool is figured, as shown by the dotted line, it may be used for cutting bosses and mouldings on parts of work not otherwise accessible.

Many ingenious contrivances have been made to insure the dimensions and angles of tools being exactly retained. In this class may be placed Mr. Roberts' pin-drill, Figs. 538 and 539; in action it resembles the fluted pin-drill, Fig. 534, but the iron stock is much heavier, and is attached to the drilling-machine by the square tang; the stock has two grooves at an angle of about 10 degrees with the axis, and rather deeper behind than in front. Two steel cutters, or nearly parallel blades, represented black, are laid in the groves; they are fixed by the ring and two set-screws *s s*, and are advanced, as they become worn away, by two adjusting-screws *a a*, (only one seen,) placed at the angle of 10 degrees through the second ring; which, for the convenience of construction, is screwed upon the drill-shaft just beyond the square tang whereby it is attached to the drilling-machine. The cutters are ground at the extreme ends, but they also require an occasional touch on the oilstone to restore the keenness of the outer angles, which become somewhat rounded by the friction. The diminution from the trifling exterior sharpening, is allowed for by the slightly taper form of the blades.

538. 539.

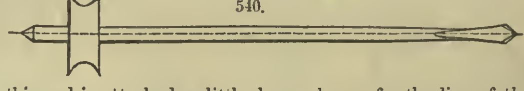


The process of drilling generally gives rise to more friction than that of turning, and the same methods of lubrication are used, but rather more commonly and plentifully; thus oil is used for the generality of metals—or from economy, soap and water; milk is the most proper for copper, gold, and silver; and cast-iron and brass are usually drilled without lubrication. For all the above-named metals, and for alloys of similar degrees of hardness, the common-pointed steel drills are generally used; but for lead and very soft alloys, the carpenters' spoon-bits and nose-bits are usually employed, with water. For hardened steel, and hard crystalline substances, copper or soft-iron drills, such as Figs. 529 or 530, supplied with emery-powder and oil, are needed; or the diamond drill-points, Figs. 531, 532, and 533, are used for hardened steel, with oil alone.

Having considered the most general forms of the cutting parts of drills, we will proceed to explain the modes in which they are put in action by hand-power, beginning with those for the smallest diameters, and proceeding gradually to the largest.

Methods of Working Drills by Hand-power.—The smallest holes are those required in watch-work, and the general form of the drill is shown on a large scale in Fig. 540; it is made of a piece of steel wire, which is tapered off at the one end, flattened with the hammer, and then filed up in the form shown at large in Fig. 522; lastly, it is hardened in the candle. The reverse end of the instrument is made into a conical point, and is also hardened; near this end is attached a little brass sheave for the line of the drill-bow, which, in watchmaking, is sometimes a fine horsehair, stretched by a piece of whalebone of about the size of a goose's quill stripped of its feather.

540.



The watchmaker holds most of his works in the fingers, both for fear of crushing them with the table-vice, and also that he may the more sensibly feel his operations; drilling is likewise performed by him in the same manner. Having passed the bowstring around the pulley in a single loop, (or with a *round turn*,) the centre of the drill is inserted in one of the small centre-holes in the sides of the table-vice, and the point of the drill is placed in the mark or cavity made in the work by the centre-punch; the object is then pressed forward with the right hand, whilst the bow is moved with the left.

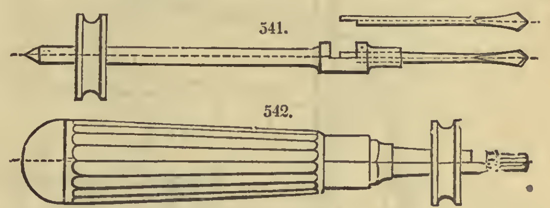
Clockmakers, and artisans in works of similar scale, fix the object in the tail-vice, and use drills, such as Fig. 540, but often larger and longer; they are pressed forward by the chest, which is defended from injury by the breastplate, namely, a piece of wood or metal about the size of the hand, in the middle of which is a plate of steel, with centre-holes for the drill. The breastplate is sometimes strapped round the waist, but is more usually supported with the left hand, the fingers of which are ready to catch the drill should it accidentally slip out of the centre.

As the drill gets larger the bow is proportionably increased in stiffness, and eventually becomes the half of a solid cone, about one inch in diameter at the larger end, and 30 inches long; the catgut string is sometimes nearly an eighth of an inch in diameter, or is replaced by a leather thong. The string is attached to the smaller end of the bow by a loop and notch, much the same as in the archery-bow, and is passed through a hole at the larger end, and made fast with a knot; the surplus length is wound round the cane, and the cord finally passes through a notch at the end, which prevents it from uncoiling.

Steel bows are also occasionally used; these are made something like a fencing-foil, but with a hook at the end for the knot or loop of the cord, and with a ferrule or a ratchet, around which the spare cord is wound. Some variations also are made in the sheaves of the large drills; sometimes they are cylindrical with a fillet at each end; this is desirable, as the cord necessarily lies on the sheave at an angle, in fact in the path of a screw; it pursues that path, and with the reciprocation of the drill-bow the cord traverses, or screws backwards and forwards upon the sheave, but is prevented from sliding off by the fillet. Occasionally, indeed, the cylindrical sheave is cut with a screw coarse enough to receive the cord, which may then make three or four coils for increased purchase, and have its natural screw-like run without any fretting whatever; but this is only desirable when the holes are large and the drill is almost constantly used, as it is tedious to wind on the cord for each individual hole. The structure of the bows, breastplates, and pulleys, although often varied, is sufficiently familiar to be understood without figures.

When the shaft of the drill is moderately long, the workman can readily observe if the drill is square with the work as regards the horizontal plane; and to remove the necessity for the observation of an assistant as to the vertical plane, a trifling weight is sometimes suspended from the drill-shaft by a metal ring or hook; the joggling motion shifts the weight to the lower extremity: the tool is only horizontal when the weight remains central.

In many cases, the necessity for repeating the shaft and pulley of the drill is avoided, by the employment of holders of various kinds, or *drill-stocks*, which serve to carry any required number of drill-points. The most simple of the drill-stocks is shown in Fig. 541; it has the centre and pulley of the ordinary drill, but the opposite end is pierced with a nearly cylindrical hole, just at the inner extremity of which a diametrical notch is filed. The drill is shown separately at *a*; its shank is made cylindrical, or exactly to fit the hole, and a short portion is nicked down also to the diametrical line, so as to slide into the gap in the drill-stock, by which the drill is prevented from revolving; the end serves also as an abutment whereby it may be thrust out with a lever. Sometimes a diametrical transverse mortise, narrower than the hole, is made through the drill-stock, and the drill is nicked in on both sides; the cylindrical hole of 541, should be continued to the bottom of the notch, the end of the drill should be filed off obliquely, and it should be prevented from rotating, by a pin inserted through the cylindrical hole parallel with the notch; the taper end of the drill would then wedge fast beneath the pin.



Drills are also frequently used in the *drilling-lathe;* this is a miniature lathe-head, the frame of which is fixed in the table-vice; the mandrel is pierced for the drills, and has a pulley for the bow, therein resembling Fig. 542, except that it is used as a fixture.

The Fig. 542 just referred to, represents one variety of another common form of the drill-stock, in which the revolving spindle is fitted in a handle, so that it may be held in any position, without the necessity for the breastplate; the handle is hollowed out to serve for containing the drills, and is fluted to assist the grasp.

Fig. 543 represents the socket of a "*universal drill-stock*," invented by Sir John Robinson; it is pierced with a hole as large as the largest of the wires of which the drills are formed, and the hole terminates in an acute hollow cone. The end of the drill-stock is tapped with two holes, placed on a diameter; the one screw, *a*, is of a very fine thread, and has at the end two shallow diametrical notches; the other, *b*, is of a coarser thread and quite flat at the extremity. The wire-drill is placed against the bottom of the hole, and allowed to lean against the adjusting-screw *a*, and if the drill be not central, this screw is moved one or several quarter-turns, until it is adjusted for centrality; after which the tool is strongly fixed by the plain set-screw *b*.

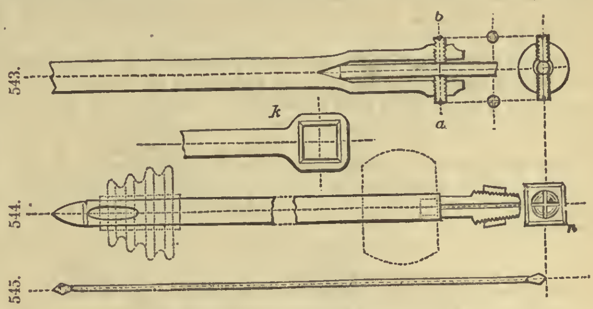


Fig. 544 is a drill-stock, contrived by Mr. William Allen: it consists of a tube, the one end of which has a fixed centre and pulley much the same as usual; the opposite end of the tube has a piece of steel fixed into it, which is first drilled with a central hole, and then turned as a conical screw, to which is fitted a corresponding screw-nut *n;* the socket is then sawn down with two diametrical notches, to make four internal angles, and lastly, the socket is hardened. When the four sections are compressed by the nut, their edges stick into the drill and retain it fast, and provided the instrument is itself concentric, and the four parts are of equal strength, the centrality of the drill is at once ensured. The outside of the nut, and the square hole in the key *k*, are each taper, for more ready application; and the drills are of the most simple kind, namely, lengths of wire pointed at each end, as in Fig. 545.

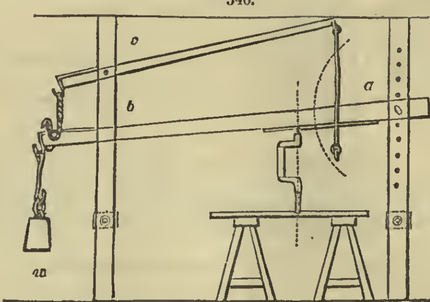
The sketch, Fig. 544, is also intended to explain another useful application of this drill-stock, as an *upright* or *pump drill*, a tool little employed in this country, (except in drilling the rivet-holes for mending china and glass, with diamond drill,) but as well known among the oriental nations as the breast-drill.

Holes that are too large to be drilled *solely* by the breast-drill and drill-bow, are frequently commenced with those useful instruments, and are then enlarged by means of the hand-brace, which is very similar to that used in carpentry, except that it is more commonly made of iron instead of wood, is somewhat larger, and generally made without the spring-catch.

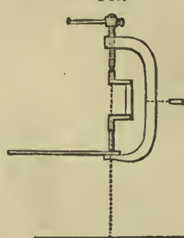
Holes may be extended to about half an inch diameter, with the hand-brace; but it is much more expeditious to employ still larger and stronger braces, and to press them into the work in various ways by weights, levers, and screws, instead of by the muscular effort alone.

Fig. 546 represents the old smith's press-drill, which although cumbrous, and much less used than formerly, is nevertheless simple and effective. It consists of two pairs of wooden standards, between which works the beam *a b;* the pin near *a* is placed at any height, but the weight *w* is not usually changed, as the greater or less pressure for large and small drills, is obtained by placing the brace more or less near to the fulcrum *a;* and this part of the beam is shod with an iron plate, full of small centre-holes for the brace. The weight is raised by the second lever *c d*, the two being united by a chain, and a light chain or rope is also suspended from *d*, to be within reach of the one or two men engaged in moving the brace. It is necessary to relieve the weight when the drill is nearly through the hole, otherwise it might suddenly break through, and the drill becoming fixed, might be twisted off in the neck.

546.



547.



The inconveniences in this machine are, that the upper point of the brace moves in an arc instead of a right line; the limited path when strong pressures are used, which makes it necessary to shift the fulcrum *a;* and also the necessity for readjusting the work under the drill for each different hole, which in awkwardly-shaped pieces is often troublesome.

A portable contrivance of similar date, is an iron bow-frame or clamp, shown in Fig. 547; the pressure is applied by a screw, but in almost all cases, whilst the one individual drills the hole, the assistance of another is required to hold the frame; Fig. 547 only applies to comparatively thin parallel works, and does not present the necessary choice of position. Another tool of this kind, used for boring the side-holes in cast-iron pipes for water and gas, is doubtless familiarly known; the cramp or frame divides into two branches about two feet apart, and these terminate like hooks, which loosely embrace the pipe, so that the tool retains its position without constraint, and it may be used with great facility by one individual.

548.

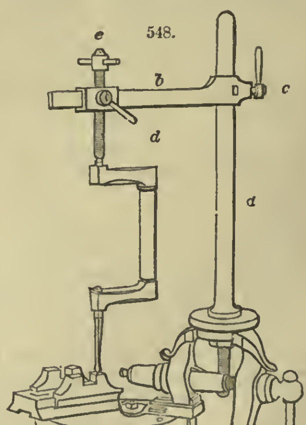


Fig. 548 will serve to show the general character of various constructions of more modern apparatus, to be used for supplying the pressure in drilling holes with hand-braces. It consists of a cylindrical bar *a*, upon which the horizontal rectangular rod *b* is fitted with a socket, so that it may be fixed at any height, or in any angular position, by the set-screw *c*. Upon *b* slides a socket, which is fixed at all distances from *a*, by its set-screw *d;* and lastly, this socket has a long vertical screw *e*, by which the brace is thrust into the work.

The object to be drilled having been placed level, either upon the ground, on trestles, on the work-bench, or in the vice, according to circumstances, the screws *c* and *d* are loosened, and the brace is put in position for work. The perpendicularity of the brace is then examined with a plumb-line, applied in two positions, (the eye being first directed as it were along the north and south line, and then along the east and west,) after which the whole is made fast by the screws *c* and *d*. The one hole having been drilled, the socket and screws present great facility in readjusting the instrument for subsequent holes, without the necessity for shifting the work, which would generally be attended with more trouble than altering the drill-frame by its screws.

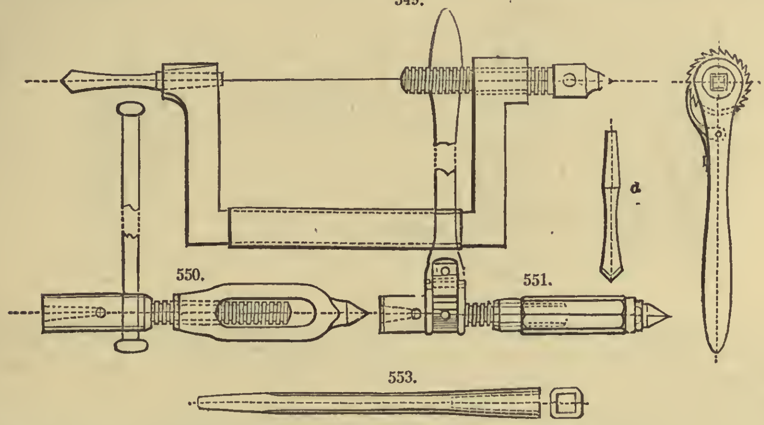
Sometimes the rod *a* is rectangular, and extends from the floor to the ceiling; it then traverses in fixed sockets, the lower of which has a set-screw for retaining any required position. In the tool represented, the rod *a* terminates in a cast-iron base, by which it may be grasped in the tail-vice, or when required it may be fixed upon the bench. In this case the nut on *a* is unscrewed; the cast-iron plate, when reversed and placed on the bench, serves as a pedestal; the stem is passed through a hole in the bench, and the nut and

washer, when screwed on the stem beneath, secure all very strongly together. Even in establishments where the most complete drilling machines driven by power are at hand, modifications of the press-drill are among the indispensable tools: many are contrived with screws and clamps, by which they are attached directly to such works as are sufficiently large and massive to serve as a foundation.

Various useful drilling tools for engineering works, are fitted with left-hand screws, the unwinding of which elongate the tools; so that for these instruments which supply their own pressure, it is only necessary to find a solid support for the centre. They apply very readily in drilling holes within boxes and panels, and the abutment is often similarly provided by projecting parts of the castings; or otherwise the fixed support is derived from the wall or ceiling, by aid of props arranged in the most convenient manner that presents itself.

Fig. 549 is the common brace, which only differs from that in Fig. 548 in the left-hand screw; a right-hand screw would be unwound in the act of drilling a hole when the brace is moved round in the usual direction, which agrees with the path of a left-hand screw. The cutting motion produces no change in the length of the instrument, and the screw being held at rest for a moment during the revolution, sets in the cut; but towards the last, the feed is discontinued, as the elasticity of the brace and work suffice for the reduced pressure required when the drill is nearly through, and sometimes the screw is unwound still more to reduce it.

549. 550. 551. 553.



The *lever-drill*, Fig. 550, differs from the latter figure in many respects; it is much stronger, and applicable to larger holes; the drill-socket is sufficiently long to be cut into the left-hand screw, and the piece serving as the screwed nut, is a loop terminating in the centre point. The increased length of the lever gives much greater purchase than in the crank-form brace, and in addition the lever-brace may be applied close against a surface where the crank-brace cannot be turned round; in this case the lever is only moved a half circle at a time, and is then slid through for a new purchase, or sometimes a spanner or wrench is applied directly upon the square drill-socket.

The same end is more conveniently fulfilled by the *ratchet-drill*, Fig. 551, apparently derived from the last; it is made by cutting ratchet-teeth in the drill-shaft, or putting on the ratchet as a separate piece, and fixing a pall or detent to the handle; the latter may then be moved backward to gather up the teeth, and forward to thrust round the tool, with less delay than the lever in Fig. 550, and with the same power, the two being of equal length. This tool is also peculiarly applicable to reaching into angles and places in which neither the crank-form brace nor the lever-drill will apply. Fig. 552, the *ratchet-lever*, in part resembles the ratchet-drill, but the pressure-screw of the latter instrument must be sought in some of the other contrivances referred to, as the ratchet-lever has simply a square aperture to fit on the tang of the drill *d*, which latter must be pressed forward by some independent means.

554. 555.

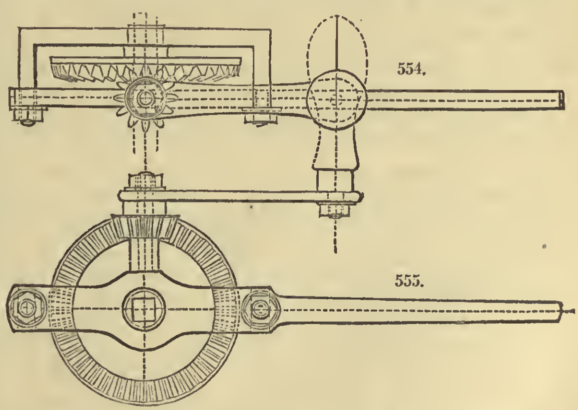


Fig. 553, which is a simple but necessary addition to the braces and drill tools, is a socket having at the one end a square hole to receive the drills, and at the opposite, a square tang to fit the brace; by this contrivance the length of the drill can be temporarily extended for reaching deeply-seated holes. The sockets are made of various lengths, and sometimes two or three are used together, to extend the length of the brace to suit the position of the prop; but it must be remembered, that with the additional length the tortion becomes much increased,

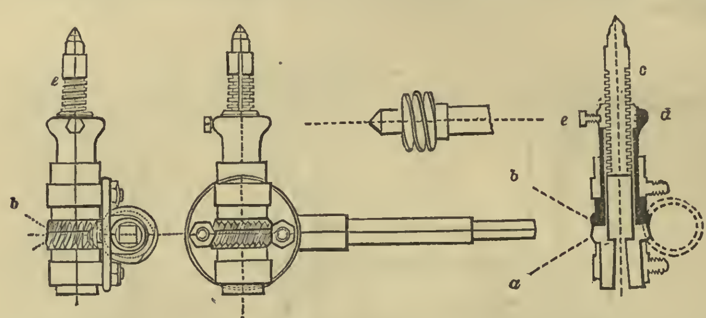
and the resistance to end-long pressure much diminished, therefore the sockets should have a bulk proportionate to their length.

The French brace, Fig. 521, is also constructed in iron, with a pair of equal bevel-pinions, and a left-hand centre-screw like the tools, Figs. 549, 550, and 551; it is then called the *corner-drill.* Sometimes, also, as in the succeeding Figs. 554 and 555, the bevel-wheels are made with a hollow square or axis, as in the ratchet-lever, Fig. 552; the driver then hangs loosely on the square shank of the drill-tool, or cutter-bar, and when the pinion on the handle is only one-third or fourth of the size of the bevel-wheel with the square hole, it is an effective driver for various uses; the long tail or lever serves to prevent the rotation of the driver, by resting against some part of the work or of the work-bench.

All the before-mentioned tools are commonly found in a variety of shapes in the hands of the engineer, but it will be observed they are all driven by hand-power, and are carried to the work. I shall conclude this section with the description of a more recent drill-tool of the same kind.

This instrument is represented of one-eighth size, in the side view, Fig. 556, in the front view, 557, and in the section, 558; it is about twice as powerful as Fig. 555, and has the advantage of feeding the

556. 557 558.



cut by a differential motion. The tangent-screw moves at the same time the two worm-wheels *a* and *b;* the former has fifteen teeth, and serves to revolve the drill; the latter has 16 teeth, and by the difference between the two, or the *odd tooth,* advances the drill slowly and continually, which may be thus explained.

The lower wheel *a*, of 15 teeth, is fixed on the drill-shaft, and this is tapped to receive the centre-screw *c*, of four threads per inch. The upper wheel of 16 teeth is at the end of a socket *d*, (which is represented black in the section Fig. 558,) and is connected with the centre-screw *c*, by a collar and internal key, which last fits a longitudinal groove cut up the side of the screw *c;* now therefore the internal and external screws travel constantly round, and nearly at the same rate, the *difference* of one tooth in the wheels serving continually and slowly to project the screw *c*, for feeding the cut. To shorten or lengthen the instrument rapidly, the side-screw *e* is loosened; this sets the collar and key free from the 16 wheel, and the centre-screw may for the time be moved independently by a spanner.

The *differential screw-drill,* having a double thread in the large worm, shown detached at *f*, requires 7½ turns of the handle to move the drill once round, and the feed is one 64th of an inch for each turn of the drill; that being the sum of 16 by 4.

Drilling and Boring Machines.—The motion of the lathe-mandrel is particularly proper for giving action to the various single-cutting drills referred to; they are then fixed in square or round hole drill-chucks which screw upon the lathe-mandrel. The motion of the lathe is more uniform than that of the hand-tools, and the popit-head, with its flat boring-flange and pressure-screw, form a most convenient arrangement, as the works are then carried to the drill exactly at right angles to the face. But in drilling very small holes in the lathe, there is some risk of unconsciously employing a greater pressure with the screw, than the slender drills will bear. Sometimes the cylinder is pressed forward by a horizontal lever fixed on a fulcrum; at other times the cylinder is pressed forward by a spring, by a rack and pinion motion, or by a simple lever, and the best arrangement of this latter kind is that next to be described.

In the manufacture of harps there is a vast quantity of small drilling, and the pressure of the cylinder popit-head is given by means of a long, straight, double-ended lever, which moves horizontally, (at about one-third from the back extremity,) upon a fixed post or fulcrum erected upon the backboard of the lathe. The front of the lever is connected with the sliding cylinder by a link or connecting-rod, and the back of the lever is pulled towards the right extremity of the lathe, by a cord which passes over a pulley at the edge of the backboard, and then supports a weight of about twenty pounds.

Both the weight and the connecting-rod may be attached at various distances from the fixed fulcrum between them. When they are fixed at equal distances from the axis of the lever, the weight, if twenty pounds, presses forward the drill with twenty pounds, less a little friction; if the weight be two inches from the fulcrum and the connecting-rod eight inches, the effect of the weight is reduced to five pounds; if, on the other hand, the weight be at eight and the connecting-rod at two inches, the pressure is fourfold, or eighty pounds.

The connecting-rod is full of holes, so that the lever may be adjusted exactly to reach the body of the workman, who, standing with his face to the mandrel, moves the lever with his back, and has therefore both hands at liberty for managing the work. Sometimes a stop is fixed on the cylinder, for drilling holes to one fixed depth; gages are attached to the flange for drilling numbers of similar pieces

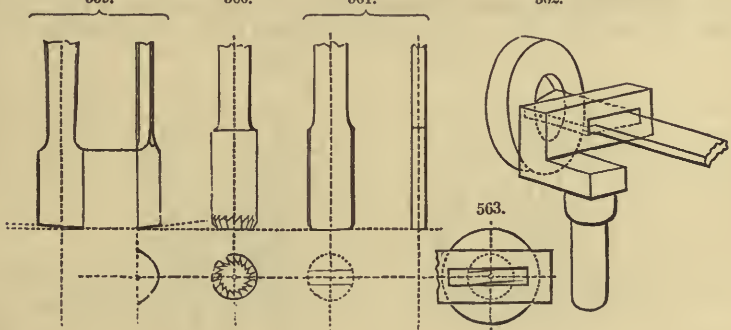
at any fixed distance from the edge: in fact, this very useful apparatus admits of many little additions to facilitate the use of drills and revolving cutters.

Great numbers of circular objects, such as wheels and pulleys, are chucked to revolve truly upon the lathe-mandrel, whilst a stationary drill is thrust forward against them, by which means the concentricity between the hole and the edge is ensured.

The drills employed for boring works chucked on the lathe, have mostly long shafts, some parts of which are rectangular or parallel, so that they may be prevented from revolving by a hook-wrench, a spanner, or a hand-vice, applied as a radius, or by other means. The ends of the drill-shafts are pierced with small centre-holes, in order that they may be thrust forward by the screw of the popit-head, either by hand or by self-acting motion; namely, a connection between either the mandrel or the prime mover of the lathe, and the screw of the popit-head, by cords and pulleys, by wheels and pinions, or other contrivances.

The drills, Figs. 528 and 530, are used for boring ordinary holes; but for those requiring greater accuracy, or a more exact repetition of the same diameter, the lathe-drills, Figs. 559 to 562, are commonly selected. Fig. 559, which is drawn in three views and to the same scale as the former examples, is called the *half-round bit*, or the *cylinder-bit*. The extremity is ground a little inclined to the right angle, both horizontally and vertically, to about the extent of three to five degrees. It is necessary to turn out a shallow recess exactly to the diameter of the end of the bit as a commencement, the circular part of the bit fills the hole, and is thereby retained central, whilst the left angle removes the shaving. This tool should never be sharpened on its diametrical face, or it would soon cease to deserve its appellation of *half-round* bit: some indeed give it about one-thirtieth more of the circumference. It is generally made very slightly smaller behind, to lessen the friction; and the angle, not intended to cut, is a little blunted half-way round the curve, that it may not scratch the hole from the pressure of the cutting edge. It is lubricated with oil for the metals generally, but is used dry for hard woods and ivory, and sometimes for brass.

559. 560. 561. 562.



563.

The rose-bit, Fig. 560, is also very much used for light finishing cuts, in brass, iron, and steel; the extremity is cylindrical, or in the smallest degree less behind, and the end is cut into teeth like a countersink; the rose-bit, when it has plenty of oil, and but very little to remove, will be found to act beautifully, but this tool is less fit for cast-iron than the bit next to be described. The rose-bit may be used without oil for the hard woods and ivory, in which it makes a very clean hole; but as the end of the tool is chamfered, it does not leave a flat-bottomed recess the same as the half-round bit, and is therefore only used for thoroughfare holes.

The drill, Fig. 561, is much employed, but especially for cast-iron work; the end of the blade is made very nearly parallel; the two front corners are ground slightly rounding, and are chamfered; the chamfer is continued at a reduced angle along the two sides, to the extent of about two diameters in length; this portion is not strictly parallel, but is very slightly largest in the middle, or barrel-shaped: this drill is used dry for cast-iron.

Fig. 561, in common with all drills that cut on the side, may, by improper direction, cut sidewise, making the hole above the intended diameter; but when the hole has been roughly bored with a common fluted drill, the end of the latter is used as a turning tool, to make an accurate chamfer; the bit 561 is then placed through the stay as shown in Fig. 562, and is lightly supported between the chamfer upon the work and the centre of the popit-head: the moment any pressure comes on the drill, its opposite edges stick into the inner sides of the loop, which thus restrains its position; much the same as the point and edges of the turning tools for iron dig into the rest, and secure the position of those tools.

It is requisite the drill and the loop should be exactly central. Fig. 562 shows the common form of the stay when fitted to the lathe-rest, but it is sometimes made as a swing-gate, to turn aside, whilst the piece which has been drilled is removed, and the next piece to be operated upon is fixed in the lathe. Sometimes also the drill 561, has blocks of hard wood attached above and below it, to complete the circle; this is usual for wrought-iron and steel, and oil is then employed.

These three varieties are exclusively lathe-drills, and are intended for the exact repetition of a number of holes of the particular sizes of the bits, and which, on that account, should remove only a thin shaving to save the tools from wear.

The cylinder bits, however, may be used for enlarging holes below half an inch, to the extent of about one-third their diameter at one cut; and for holes from half an inch to one inch, about one-fourth their

diameter or less; and as the bits increase in size, the proportion of the cut to the diameter should decrease.

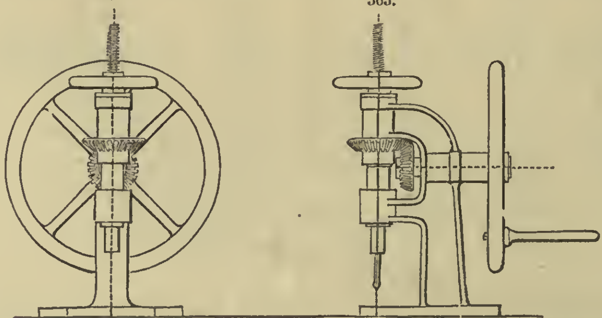
The cylinder bit is not intended to be used for drilling holes in the solid material, and as the piercing drills are apt to swerve in drilling small and very deep holes, the following rotation in the tools is sometimes resorted to. A drill, Fig. 531, say three-sixteenths diameter, is first sent in to the depth of an inch or upwards, and the hole is enlarged by a cylinder bit of one-quarter inch diameter. The centre at the end of the hole is then restored to exact truth, by Fig. 532, a recentering drill, the plug of which exactly fits the hole made by the cylinder bit; the extremity of the recentering drill then acts as a fixed turning-tool; and should the first drill have run out of its position, 532 corrects the centre at the end of the hole. Another short portion is then drilled with 528, enlarged with the half-round bit, and the conical extremity is again corrected with the recentering drill; the three tools are thus used in rotation until the hole is completed, and which may be then cleaned out with one continued cut, made with a half-round bit a little larger than that previously used.

Some of the large half-round bits are so made, that the one stock will serve for several cutters of different diameters. In the bit used for boring out ordnance, the parallel shaft of the boring-bar slides accurately in a groove, exactly parallel with the bore of the gun; the cutting blade is a small piece of steel affixed to the end of the half-round block, which is either entirely of iron, or partly of wood; and the cut is advanced by a rack and pinion movement, actuated either by the descent of a constant weight, or by a self-acting motion derived from the prime mover. For making the spherical, parabolical, or other termination to the bore, cutters of corresponding forms are fixed to the bar.*

There are very many works which, from their weight or size, cannot be drilled in the lathe in its ordinary position, as it is scarcely possible to support them steadily against the drill; but these works are readily pierced in the drilling-machine, which may be viewed as a lathe with a vertical mandrel, and with the flange of the popit-head enlarged into a table for the work, which then lies in the horizontal position simply by gravity, or is occasionally fixed on the table by screws and clamps. The structure of these important machines admits of almost endless diversity, and in nearly every manufactory some peculiarity of construction may be observed.

Figs. 564 and 565 exhibit Nasmyth's Portable Hand-drill, which is introduced as a simple and efficient example, that may serve to convey the general characters of the drilling-machines. The spindle

564. 565.



is driven by a pair of bevel-pinions; the one is attached to the axis of the vertical fly-wheel, the other to the drill-shaft, which is depressed by a screw moved by a small hand-wheel.

Sometimes, as in the lathe, the drilling-spindle revolves without endlong motion, and the table is raised by a treadle or by a hand-lever; but more generally the drill-shaft is cylindrical and revolves in, and also slides through, fixed cylindrical bearings. The drill-spindle is then depressed in a variety of ways; sometimes by a simple lever, at other times, by a treadle which either lowers the shaft only one single sweep, or by a ratchet that brings it down by several small successive steps, through a greater distance; and mostly a counterpoise weight restores the parts to their first position when the hand or foot is removed. Friction-clutches, trains of differential wheels, and other modes, are also used in depressing the drill-spindle, or in elevating the table by self-acting motion. Frequently also the platform admits of an adjustment independent of that of the spindle, for the sake of admitting larger pieces; the horizontal position of the platform is then retained by a slide, to which a rack and pinion movement, or an elevating screw, is added.

Drilling-machines of these kinds are generally used with the ordinary piercing-drills, and occasionally with pin-drills; the latter instrument appears to be the type of another class of boring tools, namely, *cutter-bars*, which are used for works requiring holes of greater dimensions, or of superior accuracy, than can be attained by the ordinary pointed drills.

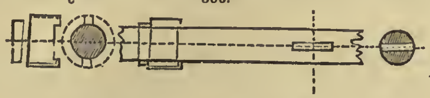
The small application of this principle, or of cutter-bars, is shown on the same scale as the former drills, in Fig. 566; the cutter *c*, is placed in a diametrical mortise in a cylindrical boring-bar, and is fixed by a wedge; the cutter *c* extends equally on both sides, as the two projections or ears embrace the sides of the bar, which is slightly flattened near the mortises.

Cutter-bars of the same kind, are occasionally employed with cutters of a variety of forms, for

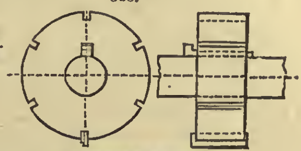
* The outside of the gun is usually turned, whilst the boring is going on, by the hand-tools. A plug of copper is screwed into the brass guns to be perforated for the touch-hole, copper being less injured by repeated discharges than the alloy of 9 parts copper and 1 part tin, used for the general substance of the gun; the curved bit smooths off the end of the plug.

making grooves, recesses, mouldings, and even screws, upon parts of heavy works, and those which cannot be conveniently fixed in the ordinary lathe. Fig. 567 represents one of these.

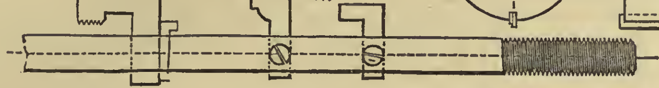
566.



568.



567.



The larger application of this principle is shown in Fig. 568, in which a cast-iron cutter-block is keyed fast upon a cylindrical bar; the block has four, six, or more grooves in its periphery. Sometimes the work is done with only one cutter, and should the bar vibrate, the remainder of the grooves are filled with pieces of hard wood, so as to complete the bearing at so many points of the circle; occasionally cutters are placed in all the grooves, and carefully adjusted to act in succession—that is, the first stands a little nearer to the axis than the second, and so on throughout, in order that each may do its share of the work; but the last of the series takes only a light finishing cut, that its keen edge may be the longer preserved. In all these cutters the one face is radial, the other differs only four or five degrees from the right angle, and the corners of the tools are slightly rounded.

These cutter-bars, like the rest of the drilling and boring machinery, are employed in a great variety of ways, but which resolve themselves into three principal modes:

First. The cutter-bar revolves without endlong motion, in fixed centres or bearings—in fact, as a spindle in the lathe; the work is traversed, or made to pass the revolving cutter in a right line, for which end the work is often fixed to a traversing slide-rest. This mode requires the bar to measure, between the supports, twice the length of the work to be bored, and the cutter to be in the middle of the bar; it is therefore unfit for long objects.

Secondly. The cutter-bar revolves, and also slides with endlong motion, the work being at rest; the bearings of the bar are then frequently attached in some temporary manner to the work to be bored, and are often of wood.*

In another common arrangement, the boring-bar is mounted in headstocks, much the same as a traversing mandrel, the work is fixed to the bearers carrying the headstocks, and the cutter-bar is advanced by a screw. The screw is then moved either by the hand of the workman, by a star-wheel, or a ratchet-wheel, one tooth only in each revolution, or else by a system of differential wheels, in which the external screw has a wheel, say of 50 teeth, the internal screw a wheel of 51 teeth, and a pair of equal wheels or pinions drives these two screws continually, so that the advance of the one-fiftieth of a turn of the screw, or their difference, is equally divided over each revolution of the cutter-bar, much the same as in the differential motion of the screw-drill, Fig. 556.

This second method only requires the interval between the fixed bearings of the cutter-bar to be as much longer than the work, as the length of the cutter-block; but the bar itself must have more than twice the length of the work, and requires to slide through the supports.

Cutter-bars of this kind are likewise used in the lathe; in the act of boring, the end of the bar then slides like a piston into the mandrel. Such bars are commonly applied to the vertical boring-machines of the larger kinds, which are usually fitted with a differential apparatus, for determining the progress of the cut; the bar then slides through a collar fixed in the bed of the machine.

In some of the large boring-machines either one or two horizontal slides are added, and by their aid, series of holes may be bored in any required arrangement. For instance, the several holes in the beams, or *side-levers*, and cranks of steam-engines are bored exactly perpendicular, in a line, and at any precise distances, by shifting the work beneath the revolving spindle upon the guide or railway; in pieces of other kinds, the work is moved laterally during the revolution of the cutters, for the formation of elongated countersinks and grooves.

Thirdly. In the largest applications of this principle, the boring-bar revolves upon fixed bearings without traversing; and it is only needful that the boring-bar should exceed the length of the work, by the thickness of the cutter-block, of which it has commonly several of different diameters. The cutter-block, now sometimes ten feet diameter, traverses as a slide down a huge boring-bar, whose diameter is about thirty inches. There is a groove and key to couple them together, and the traverse of the cutter-block down the bar is caused by a side-screw, upon the end of which is a large wheel, that engages in a small pinion, *fixed* to the stationary centre or pedestal of the machine. With every revolution of the cutter-bar, the great wheel is *carried around the fixed pinion*, and supposing these be as 10 to 1, the great wheel is moved one-tenth of a turn, and therefore moves the screw one-tenth of a turn also, and slowly traverses the cutter-block.

The contrivance may be viewed as a huge, self-acting, and revolving sliding-rest; the cutter-bars are equally applicable to portions of circles, such as the D-valves of steam-engines, as well as to the enormous interior of the cylinder itself.

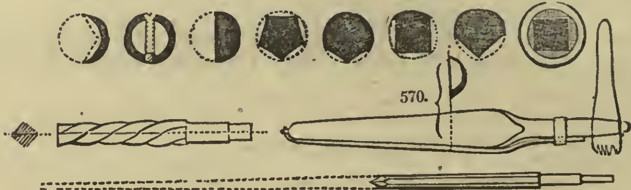
All the preceding boring tools cut almost exclusively upon the end alone.. They are passed entirely through the objects, and leave each part of their own particular diameter, and therefore cylindrical; but I now proceed to describe other boring tools, that cut only on their sides, go but partly through the

* Cylinders of 40 inches diameter for steam-engines have been thus bored by attaching a cast-iron cross to each end of the cylinder; the crosses are bored exactly to fit the boring-bar, one of them carries the driving-gear, and the bar is thrust endlong by means of a screw, moved by a ratchet or star wheel.

work, and leave its section a counterpart of the instrument. These tools are generally conical, and serve for the enlargement of holes to sizes intermediate between the gradations of the drills, and also for the formation of conical holes, as for valves, stopcocks, and other works. The common pointed drill, or its multiplication in the rose countersink, is the type of the series: but in general the broaches have sides which are much more nearly parallel.

Broaches for making taper holes.—The tools for making taper holes, are much less varied than the drills and boring tools for cylindrical holes. Thus the carpenter employs only the rimer, which is a fluted tool like the generality of his bits; it is sharpened from within, as shown in Fig. 569, so as to act like a paring tool. Flutes and clarionets are first perforated with the nose-bit, and then broached with taper holes, by means of tools of this kind, which are very carefully graduated as to their dimensions. Fig. 570 represents a German rimer, used by wheelwrights for inlaying the boxes of axletrees; the loose blade is separated from the shell of the instrument, by introducing slips of leather or wood between the two; the detached cutter fits on a pin at the front, and is fixed by a ring or collar against the shaft.

569. 571. 572. 573. 574. 575. 576. 577.



570.

578.

A curious rimer for the use of wine-coopers, by which the holes were made more truly circular, and the shavings were prevented from dropping into the cask. The stock of the instrument consists of a hollow brass cone, seen in section in Fig. 571; down one side there was a slit for containing a narrow blade or cutter, fixed by three or four screws placed diametrically. The tube was thus converted into a conical plane; the shavings entered within the tube, and were removed by taking out a cork from the small end of the cone.

The broaches for metal are made solid, and of various sections; as half-round, like Fig. 572; the edges are then rectangular. But more commonly the broaches are polygonal, as in Fig. 573, except that they have 3, 4, 5, 6, and 8 sides, and their edges measure respectively 60, 90, 108, 120, and 135 degrees. The four, five, and six-sided broaches are the most general, and the watchmakers employ a round broach in which no angle exists, and the tool is therefore only a burnisher, which compresses the metal and rounds the hole.

Ordinary broaches are very acute, and Fig. 574 may be considered to represent the general angle at which their sides meet—namely, less than one or two degrees; the end is usually chamfered off with as many facets as there are sides, to make a penetrating point, and the opposite extremity ends in a square *tang*, or shank, by which the instrument is worked.

Square broaches, after having been filed up, are sometimes twisted whilst red-hot. Fig. 577 shows one of these; the rectangular section is but little disturbed, although the faces become slightly concave. The advantage of the tool appears to exist in its screw form: when it is turned in the direction of the spiral, it cuts with avidity and requires but little pressure, as it is almost disposed to dig too forcibly into the metal: when turned the reverse way, as in unscrewing, it requires as much or more pressure than similar broaches not twisted. This instrument, if bent in the direction of its length, either in the act of twisting or hardening, does not admit of correction by grinding, like those broaches having plane faces. It is not much used, and is almost restricted to wrought-iron and steel.

Large countersinks that do not terminate in a point, are sometimes made as solid cones; a groove is then formed up one side, and deepest towards the base of the cone, for the insertion of a cutter, (see Fig. 574.) As the blade is narrowed by sharpening, it is set a little forward in the direction of its length, to cause its edge to continue slightly in advance of the general surface, like the iron of a plane for cutting metal.

Fig. 579 represents Mr. Richard Roberts' broach, in which four detached blades are introduced, for the sake of retaining the cone or angle of the broach with greater facility The bar or stock has four

579.

shallow longitudinal grooves, which are nearly radial on the cutting face, and slightly undercut on the other The grooves are also rather deeper behind, and the blades are a little wedge-form both in section and in length, to constitute the cone, and the cutting edges. In restoring the edges of the blades, they are removed from the stock, and their angles are then more easily tested: when replaced, they are set nearer to the point, to compensate for their loss of thickness.

Broaches are also used for perfecting cylindrical holes, as well as for making those which are taper The broaches are then made almost parallel, or a very little the highest in the middle; they are filed with two or three planes at angles of 90 degrees, as in Fig. 575 or 576. The circular part not being able to cut, serves as a more certain base for foundation, than when the tool is a complete polygon; and the stems are commonly made small enough to pass entirely through the holes, which then agree very exactly as to size. Such tools are therefore rather entitled to the name of finishing drills, than broaches

The size of the parallel broaches is often slightly increased, by placing a piece or two of paper at the convex part; leather and thin metal are also used for the same purpose. Gun-barrels are broached with square broaches, the cutting parts of which are about eight to ten inches long; they are packed on the four sides with slips or spills of wood, to complete the circle, as in Fig. 577, in which the tool is supposed to be at work. The size of the bit is progressively enlarged by introducing slips of thin paper, piece by piece between two of the spills of wood and the broach; the paper throws the one angle more towards the centre of the hole, and causes a corresponding advance in the opposite or the cutting angle. Sometimes, however, only one spill of wood is employed.

A broach used by the philosophical instrument makers in finishing the barrels of air-pumps, consisted of a thin plate of steel inserted diametrically between two blocks of wood, the whole constituting a cylinder with a scraping edge slightly in advance of the wood; slips of paper were also added.

According to the size of the broaches, they are fixed in handles like brad-awls; they are used in the brace, or the tap-wrench—namely, a double-ended lever with square central holes. Sometimes also broaches are used in the lathe just like drills, and for large works, broaching machines are employed; these are little more than driving-gear terminating in a simple kind of universal joint, to lead the power of the steam-engine to the tool, which is generally left under the guidance of its own edges, according to the common principle of the instrument.

In drills and broaches, the penetrating angles are commonly more obtuse than in turning tools; thus in drills of limited dimensions, the hook-form of the turning tool for iron is inapplicable, and in the larger examples, the permanence of the tool is of more consequence than the increased friction. But on account of the additional friction excited by the nearly rectangular edges, it is commonly necessary to employ a smaller velocity in boring than in turning corresponding diameters, in order to avoid softening the tool by the heat generated; and in the ductile fibrous metals, as wrought-iron, steel, copper, and others, lubrication with oil, water, &c., becomes more necessary than in turning.

The drills and broaches form together a complete series. First the cylinder-bit, the pin-drills, and others with blunt sides, produce cylindrical holes by means of cutters at *right angles* to the axis; then the cutter becomes *inclined* at about 45 degrees, as in the common piercing-drill and cone countersink; the angle becomes much less in the common taper broaches; and finally disappears in the parallel broaches, by which we again produce the cylindrical hole, but with cutters *parallel* with the axis of the hole.

Still considering the drills and broaches as one group, the drills have comparatively thin edges, always less than 90 degrees, yet they require to be urged forward by a screw or otherwise, the resistance being sustained in the line of their axes. The broaches have much more obtuse edges, never less than 90, and sometimes extending to 135 degrees; and yet the greater force required to cause the penetration of their obtuse edges into the material, is supplied without any screw, because the pressure in all these varied tools is at right angles to the cutting edge.

Thus supposing the sides of the broach extended until they meet in a point, as in Fig. 578, we shall find the length will very many times exceed the diameter, and by that number will the force employed to thrust forward the tool be multiplied, the same as in the wedge, whether employed in splitting timber or otherwise; and the broach being confined in a hole, it cannot make its escape, but acts with great lateral pressure, directed radially from each cutting edge; and the broach under proper management leaves the holes very smooth and of true figure.

BRACKETS AND PILLOW-BLOCKS. See Geering.

BRAKE. The drag applied generally to the wheels of carriages to check their velocity in passing down hills, by means of friction. The brake attached to railway carriages consists of a piece of wood, which is pressed upon the rim of the wheels of the carriages by a hand-lever, worked by the brakeman. The brake of the tender alone affords a sufficient resistance to stop a train under ordinary circumstances. The term is also used in reference to the contrivance for arresting the motion of machinery.

On English railways brakes are applied to the wheels of a part only of the carriages attached to a train; these are termed guard vans. The number of these brake carriages depending upon the inclinations of the line and the speeds employed. The engine also is generally reversed to assist the brakes. It must be recollected, however, that by stopping a train too rapidly, great injury results both to the permanent way and the rolling stock.

The following considerations should determine the amount of brake power required.

The forces which act on the train after the steam has been shut off, are the axle friction and rolling friction of the train, and the pressure of the wind; the friction tends gradually to bring the train to rest, the pressure of the wind to accelerate or retard it, as the case may be, and this will therefore be omitted from the conclusions to be drawn.

To stop a train rapidly, brakes are applied to some of the wheels, and the engine is reversed. The application of brakes prevents the wheels from revolving, and introduces the friction due to the weights on the wheels to which brakes are applied. The act of reversing the engine does not immediately stop the forward motion of the driving wheel, but forces it to revolve at a somewhat slower rate than that due to the speed of the train, and thus causes a friction of surfaces to take place between the wheel and rail.

The axle and rolling friction may be assumed to be some proportion of the total weight of the train; the friction of the wheels to which brakes are applied may be taken as some proportion of the insistent weights: by experiment on English railways, it appears that the axle and rolling friction may be taken at $\frac{1}{334}$ part of the weight of the train, and the friction due to the brakes at about $\frac{1}{5}$ of the weight on them.

Hence, if l represent the gross load of the train,
w " the weight on the wheels to which brakes are applied,
R " the retardation in feet per second,
g " the force of gravity,
and, if the train be on an incline,
$\frac{1}{p}$ represent the slope of such incline,

$$R = \left\{ \frac{l-w}{334} + \frac{w}{8} \pm \frac{2}{p} \right\} \frac{g}{l},$$

the latter term being used with the negative sign when the train is descending, and the positive sign when ascending the gradient.

If $S =$ space traversed by the train in coming to rest,
$v =$ velocity in feet per second at the moment the steam is shut off and the brakes applied,

$$S = \frac{v^2}{2 R}$$

In estimating practically the space which would be required for a train to stop in, eight or ten seconds should be allowed for time lost in applying the brakes.

Since more than half the total number of fatal accidents which occur upon railroads arise from collision, it is important that the attention of railroad companies should be specially directed to precautions against this source of danger. The possibility of preventing collision will depend upon the proportion which the number of brakes and brakemen upon the train bears to its weight and speed. It is found by experience that the distance within which a train of given weight can be brought to rest by a given number of brakes, will be in proportion to the square of its speed, that is to say, with a double speed it will require four times the number of brakes; with a treble speed nine times the number of brakes, and so on.

The means of stopping a train are, the brake on the tender, the brakes on the cars, *and in fine, reversing the action of the engine.* This is a dangerous process. In this way the whole force of the steam is suddenly made to resist the progressive motion of the engine; the cars are consequently urged against the engine, and against each other, and the obvious tendency is to throw the cars from the rails by *doubling up the train.* Before reversing the engine, or even applying the brake to the tender, it is therefore advisable to warn the brakemen to apply the brakes to the cars composing the train; this being done, and the brake being then applied to the tender, there is less danger in reversing the steam on the engine, the whole train remaining elongated by the friction of the brakes applied to the rear cars.

The common form of car brake at present in use, is operated by a brakeman standing on the platform at either end of the car. A vertical rod turning in a step at the bottom is made to wind up by means of a hand wheel, a few links of chain connecting by an iron rod with a lever attached to the bottom of the car. This lever acts directly on a heavy wooden bar suspended from the car trucks by hooks and chains at either end. The ends of these bars support the friction blocks, which are of wood lined with metal, and are made to bear directly upon the periphery of the wheel. By means of a small ratchet wheel and detent on the platform, the vertical rod is held stationary when the brakes are put on, and is released when the motion of the train is stopped; the action of this form of brake is direct, simple and efficient.

Various forms of self-acting brakes have been devised, and much ingenuity has been displayed in the endeavour to obtain this object, and although none of them are as yet in general use, the importance of security from accident in railway travel, demands a careful investigation of the best methods of preventing collisions by this means.

In "Loughridge's Self-acting Car Brake," the cars are stopped by the friction of the ordinary brakes, but the power actuating them is derived directly from a drum shaft on the locomotive. This shaft, or rather pulley keyed thereon, is pressed into contact with the flange of the driving wheels, and is thus compelled to revolve and wind up a stout chain running the length of the train beneath the cars. This chain applies the brakes of all the cars. To prevent pulling too severely and fracturing some portion of the mechanism, provision is made for limiting the extent of its action by causing it to release its hold of the driving wheel so soon as a certain portion of the chain is taken up. The point at which this unshipping movement comes into play is previously arranged by the engineer, so that however excited in view of danger, or careless and bungling, he cannot endanger the integrity of any important part.

To cause one continuous chain to operate all the brakes, an ingenious arrangement is adopted. A stout lever, some three or four feet long, is hung under each car, and provided with sheaves or pulleys at each end, around which the chain makes a curve like the letter S, and continues on to the next. When the chain is pulled by the winding of the shaft, this lever is moved by the tension, and forces the brakes into contact with the wheels.

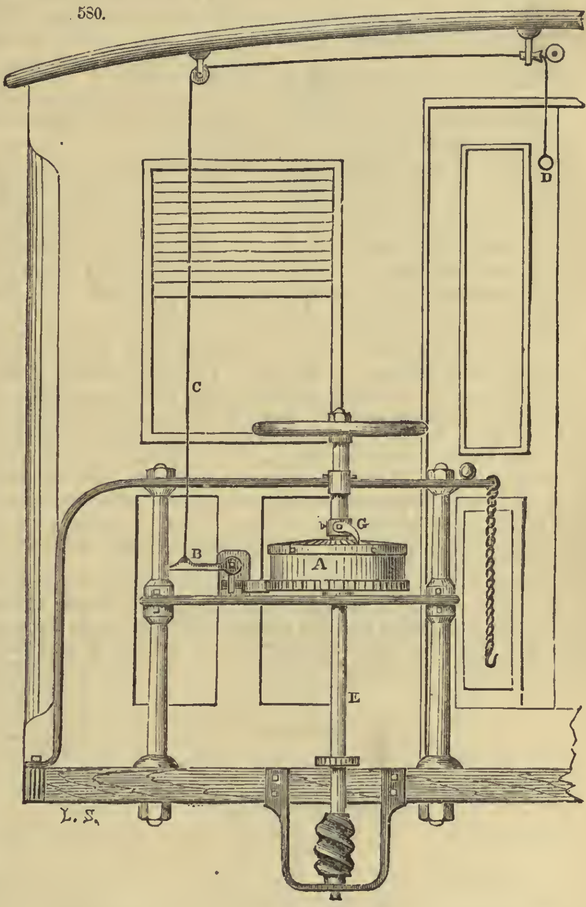
The United States Railroad Car Brake of Wm. G. Creamer, is an improved method of operating brakes, by bell or signal cords, as represented in fig. 580.

The principal features of this invention and its operation, are as follows:—To the ordinary hand wheel and brake-shaft, (for winding up the brakes,) is attached a drum A or loose pulley containing a strong spiral spring. This spring is wound up by a reverse motion of the brake-shaft, to which is attached an arm and pawl G, taking into a circle of ratchet teeth on the top of the drum A. When the spring is wound ready for use, it is held in check by a lever B, from the extremity of which passes a branch line to the top of the car at D, and connecting about three feet forward to the bell-cord. The branch line is attached to the lever B by a ring in such a way that when the lever is drawn up vertically the ring disconnects. This is rendered necessary to insure the working of the brakes by the bell-cord whether the train is extended on an up grade, or contracted on a down grade. The attachment

of the branch line of each car, some three feet forward, enables the engineer to apply the brakes of all the cars simultaneously, by pulling the bell-cord, and at the same time it does not interfere with the bell-cord as a means of enabling the conductor to signalise the engineer. When the conductor pulls the bell-cord it rings the bell, and simply makes slack on the several branch lines connected with the brake, but does not operate the brake. The conductor, brakeman, or even passengers however can, if an emergency arises in any part of the train, instantly close all the brakes, by pulling the bell-cord, or any accidental separation of the train produces the same effect, namely, bringing the retarding force on all the cars into instant action.

A train has been repeatedly stopped with this apparatus within 350 feet at 30 miles per hour; the brakes being shod with cast iron; with wooden shoes, a train may be stopped within 250 feet.

580.



The advantages claimed for this invention are as follows:

First.—It enables the Engineman in any sudden emergency or premonition of danger, instantly to apply the brakes of every car of the train, (without signals or brakemen,) with their utmost power, and hold each car by itself, independent of each other, even if the engine or a part of the cars are thrown from the track.

Second.—It also enables the conductor, brakeman, or even passengers of the train, whether moving forward or backward, in front or rear, in any emergency, to apply every brake of the entire train in an instant, without reference to its length.

Third.—It involves no alteration in the construction or method of working the present brakes, puts no additional machinery or apparatus under the cars, exposed to dust and friction, and where it cannot be seen when the train is in motion, but places the entire mechanism on the platform, where it is constantly under the eye of the brakeman and attendants of the train.

Fourth.—Each car having an independent arrangement of its own, a train can be made up with a part of the cars fitted with this apparatus and a part without. Those fitted with the apparatus can be connected with the bell-cord, and when required, the brakes can be worked as previously described. This will be a great advantage where passenger cars are behind freight or cattle trains.

Fifth.—No additional machinery or mechanism is required on the engine. No additional responsibility is put upon the engineer. In case of danger, instead of giving the usual signals, he would give the bell-cord a jerk, (which would apply every brake instantly,) and reverse his engine. He could then jump off if he chose.

Sixth.—This improvement does not interfere with the use of the signal-cord for transmitting signals to the engineer, nor does it interfere with the use of the brakes by hand, even when set, and ready for use by the bell-cord. While the brake is being applied by hand, the engineer can release the latch and finish the work in an instant. The connection of the brake operator with the hand-wheel can be maintained constantly without interrupting the operation of either plan.

Seventh.—This apparatus being connected to, and identified with the common brake-shaft under the hand-wheel, its position is such, that it is constantly seen by the brakeman or attendants of the train; and if out of order, the fact is immediately known, and the remedy applied. This would not be the case if it were placed on the top, or under the car, or anywhere out of constant sight.

Eighth.—Two brakemen are all that is really necessary in a train of any length, or (not exceeding eight cars) so far as the ordinary stoppages are concerned, while at the same time, the means are at hand for the instant and powerful application of every brake from any part of the train if required. In any such case it would be necessary for the brakeman to go to each car and release the brakes. Such emergencies would not of course be of daily occurrence, and the time required would not exceed

a minute, which is a matter of no consequence whatever. If brakemen are placed for every two cars, as ordinarily, the whole brakes could be released in a moment as now on signal.

The damage from breaking of a chain, or rail, or wheel, or axle, will be greatly mitigated on trains where this invention is used. In the first place, in sudden danger the engineer does not give the signals, or if given at all, they are given hurriedly, and perhaps not heard or understood, or if heard at unexpected places, the brakeman, if on the platform, cannot avoid the temptation to look out and see what is the matter; if there is an impending crash in view, he cannot resist the inclination to jump off, or at least to get inside the car; no man under the circumstances can deliberately exert his whole strength on the platform; the consequence is, that little or nothing can be done towards averting an accident by the present brakes as applied by hand. Trains never can, or never will, be run without brakemen or attendants; at least two men are wanted besides the conductor, for baggage and brakes on trains of four or five cars. They are called brakemen, but the application of the brakes, for all ordinary purposes, is a very small portion of their duties. They have to clean the cars, trim the lamps, examine the boxes, make the fires, wood up at stations, take back signals, &c., &c. Just as many men would be wanted, supposing they would not be wanted as brakemen.

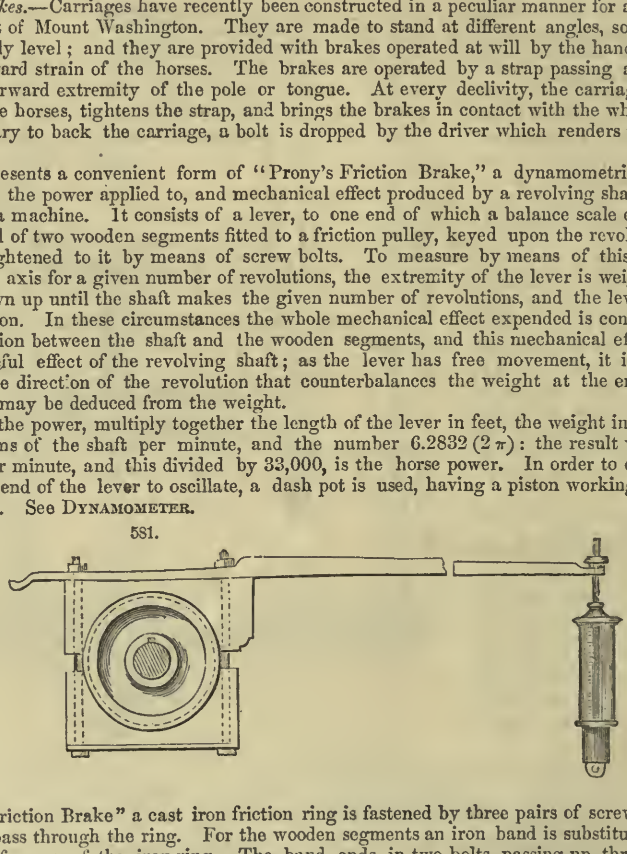
This apparatus may be described as a *mechanical connection of all the brakes of the train in one controlling power, and that furnishes the means of direct and instant application, perfectly accessible from the engine or any part of the train.*

Carriage Brakes.—Carriages have recently been constructed in a peculiar manner for a turnpike road over the summit of Mount Washington. They are made to stand at different angles, so that the floors are always nearly level; and they are provided with brakes operated at will by the hand of the driver, or by the backward strain of the horses. The brakes are operated by a strap passing around a pulley or ring in the forward extremity of the pole or tongue. At every declivity, the carriage in crowding forward upon the horses, tightens the strap, and brings the brakes in contact with the wheels. When it becomes necessary to back the carriage, a bolt is dropped by the driver which renders the brakes inoperative.

Fig. 581, represents a convenient form of "Prony's Friction Brake," a dynamometrical instrument used to measure the power applied to, and mechanical effect produced by a revolving shaft, or other revolving part of a machine. It consists of a lever, to one end of which a balance scale or weights may be attached, and of two wooden segments fitted to a friction pulley, keyed upon the revolving shaft, and which can be tightened to it by means of screw bolts. To measure by means of this arrangement, the power of the axis for a given number of revolutions, the extremity of the lever is weighted, and the screw bolts drawn up until the shaft makes the given number of revolutions, and the lever maintains a horizontal position. In these circumstances the whole mechanical effect expended is consumed in overcoming the friction between the shaft and the wooden segments, and this mechanical effect is *equal* to the work or useful effect of the revolving shaft; as the lever has free movement, it is only the friction acting in the direction of the revolution that counterbalances the weight at the end of the lever, and the friction may be deduced from the weight.

To calculate the power, multiply together the length of the lever in feet, the weight in lbs., the number of revolutions of the shaft per minute, and the number 6.2832 (2π): the result will be the lbs. raised 1 foot per minute, and this divided by 33,000, is the horse power. In order to counteract the tendency of the end of the lever to oscillate, a dash pot is used, having a piston working in a cylinder filled with water. See DYNAMOMETER.

581.



In "Eger's Friction Brake" a cast iron friction ring is fastened by three pairs of screws on any sized shaft that will pass through the ring. For the wooden segments an iron band is substituted, embracing half the circumference of the iron ring. The band ends in two bolts passing up through a wooden beam, and may be tightened at will by means of screw nuts. To prevent the firing of the wood, or excessive heating of the iron, water is constantly supplied through a small hole in the beam.

Example. To determine the mechanical effect produced by a water wheel, a friction brake was placed in the shaft, and when the water let on had been perfectly regulated for six revolutions per minute, the weight G, including the reduced weight of the instrument, was 530 lbs.; the leverage of this weight was $a = 10.5$ feet. From these quantities the effect given off by the water wheel is deduced.

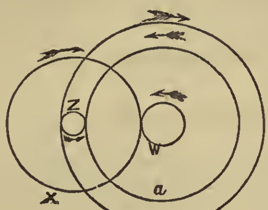
$$L = \frac{\pi.\ 6.\ 10.5.}{30}\ 530 = 3497 \text{ feet. lbs.} = 6.3 \text{ horse power.}$$

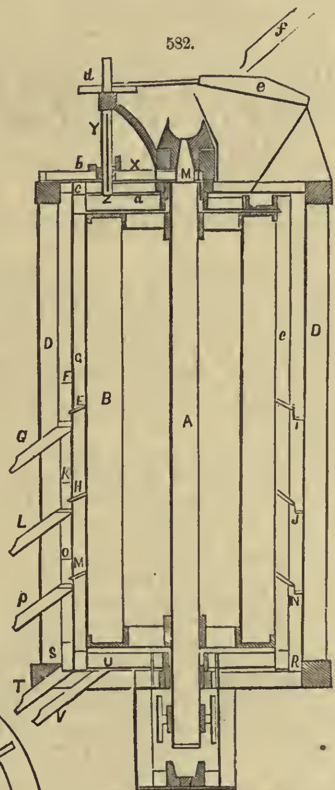
BRAN SEPARATOR. This is the invention of E. R. Benton, of Milwaukie, Wisconsin, and it has been deemed one of no minor importance. The following description of its construction and operation in connection with the accompanying engravings, will enable our readers fully to understand it.

Fig. 581 is a sectional view, and Fig. 583 a sectional plan, with the top parts removed in order more plainly to show the parts represented in Fig. 582. A, is the shaft. B, the cylinder. C, the inner re-

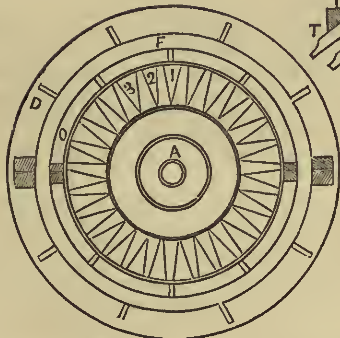
volving shell; and D, the outer or stationary shell. The cylinder is made by framing staves of the form, and in the position represented at 1, 2, 3, &c., Fig. 583, into corresponding cast heads. The staves thus forming the longitudinal and working surface, and which may be covered with any kind of material that will make it rough and durable. Air is let into the cylinder, the best at the lower end, through equidistant holes around the centre, and the quantity gaged by a circular revolving slide, and spaces between the staves emit it to carry the flour and other stuffs through the several qualities of wire-cloth with which the inner surface of the revolving shell is covered. The cylinder is driven by a belt and

582.





583.



pulleys, as is represented at the bottom of Fig. 582; and the bridge and oilpot for the point and step, and the fixture for supporting the upper journal-box of the shaft, are cast in a piece with their respective heads of the outer shell, thus rendering this part of the machine perfect. The inner surface of the revolving shell is covered with the above-named wire-cloth. Thus, the space between the top and the bevelled dividing ring E, Fig. 582, is covered with a quality that will let through little else but pure flour, which falls, and by the dividing ring is conducted into an endless trough I, attached to the inner and sheet-iron or zinc-lined surface of the stationary shell, and by the sweepers F, attached to the revolving shell, is brought around and discharged at the spout G. The space between the dividing rings E and H is covered with a quality that will discharge an inferior quality to the above, which falls, as above into the endless trough J, and by the sweepers K, is brought around and discharged at the spout L. The space between the dividing rings H and M is covered with a quality that will take out the fine particles of the bran, called dusting, which falls, as above, into the endless trough N, and by the sweepers O, is discharged at the spout P. The space between the dividing ring M and the bottom, is covered with a quality that will separate the shorts from the bran, the shorts falling to the bottom, or into the endless trough R, and by the sweepers S is discharged at the spout T, the bran passing down inside of the revolving shell, and by the arms U, of its cast head, is swept around to, and discharged

at the spout V. The revolving shell is driven by a combination of gear-wheels, thus: The pinion above, on the principal shaft A, Fig. 582, drives the wheel X, on the small or centre shaft Y, and the pinion Z, on the last-named shaft, drives the projecting cogged-wheel rim *a*, cast in a piece with the top head, which will turn it the same way with the cylinder; and to turn it the contrary way, the projecting rim *a* must be so large as to circumscribe and be driven by the pinion Z, working into cogs upon its inner periphery, as seen by the figures W, of pitch circles, the figures denoting the corresponding pitch circles of the wheels and pinions in Fig. 582. *b*, is a circular inclined plane, so calculated as to lift a mallet or hammer to strike upon the end of the revolving shell to keep the cloth from clogging, the blow to be struck upon a block resting upon its upper rim, and projecting up through a corresponding hole in the stationary head, as at C. *d*, is a set of cams on the shaft Y, which shake a wire sieve *e*, that receives the uncleaned and unseparated bran, shorts, and dustings from the bolts, as through the spout *f*, the sieve carrying off all coarse extraneous stuff that might injure the machine, the bran falling through the sieve and entering the machine passing between the arms of the upper head of the revolving shell on to the head of the cylinder.

BRASS. See METALS AND ALLOYS.

BRASSES. A term applied by mechanics to boxes or bushings of brass.

BRAZILETTO. See WOODS, *varieties of.*

BRAZIL-WOOD. See WOODS, *varieties of.*

BRAZING, the soldering together of edges of iron, copper, brass, &c., with an alloy of brass and zinc, called spelter solder.

BREAD. The only substance adapted to the making of good fermented bread is the flour of wheat. The essential constituents of wheat flour are starch, also called farina or fecula, gluten, and a little albumen. According to Vogel, 100 parts of wheat flour contain, of starch 68 parts, gluten 24, gummy sugar 5, and albumen 1-5; but these proportions vary with the goodness of the wheat.

The starch of wheat flour is very nutritive. Gluten is a mixture of vegetable fibrine, and a small quantity of a peculiar matter containing nitrogen, called *gliadine*, to which its adhesive properties are due. The small proportion of sugar in wheat flour enables it to ferment on being mixed with water, without the addition of yeast. Thus the dough of wheat flour, by spontaneous fermentation, becomes converted into leaven.

During the rising of the dough, carbonic acid is formed at every part, and is prevented from escaping by the gluten, which forms a kind of adhesive web. The formation of this gas causes the dough to swell in every direction, and the particles of starch to separate, in which condition the process is arrested by the heat of the oven, so that when the bread is cut open, it is piled full of cavities, each of which in the dough contained a globule of carbonic acid.

In the preparation of wheat for the manufacture of bread, the ground grain is usually separated into three parts, the *flour*, the *pollard*, and the *bran;* the flour forms, on an average, about three-fourths of the wheat ground. The white flour is pleasing both to the eye and taste, and there is a strong prejudice in favor of white bread; hence various methods of bleaching are resorted to, but it is doubtful if the whitest bread, even supposing it to be pure, is conducive to health and economy. By rejecting the *bran*, as we do when using only the finest flour for bread, we actually lose a large amount of nourishment of the most important kind. According to Liebig, the separation of bran from the flour *is rather injurious than useful to nutrition.* By using unbolted flour for bread the product is increased at least one fifth. From the several varieties of flour obtained by *bolting*, three kinds or classes of bread are manufactured. 1. Wheaten bread, or *firsts*, which is made of the finest flour; 2. household bread, or *seconds*, which is somewhat coarser; 3. brown bread, *thirds*, which is made of flour of various degrees of coarseness. For making firsts, the flour is entirely separated from the bran or husks; in the other descriptions the bran is not entirely removed, but the coarse broad bran is separated from the coarsest flour.

The baker generally takes a portion only of the water which he intends to employ in making the required quantity of dough, at a temperature of from 70° to 100°, and containing a portion of salt necessary to give the bread its proper flavor. Yeast is next mixed with the water, and then a portion of flour is added, always less than the quantity intended for the finished dough. The mixture is covered up and left in a warm situation. In about an hour this mixture, termed the *sponge*, thus set apart, begins to ferment. It swells out and heaves up, evidently in consequence of the generation of some internal elastic fluid, which, in this instance, is carbonic acid gas. When no longer capable of retaining the pent-up air, it bursts and subsides. After the second or third rising and dropping of the sponge, the baker interferes, otherwise the bread formed from this dough would be sour. At this period he therefore adds to the sponge the remaining portions of flour and water and salt, necessary to form the dough into the required consistence and size, and next incorporates all these materials with the sponge, by long and laborious kneading. The dough is left to itself for a few hours, during which time it continues in an active state of fermentation throughout its whole extent. After a second kneading, to distribute the gas within it as equally as possible throughout the whole mass, the dough is weighed out into portions requisite to form the kinds of bread desired. These loaves are once more set aside for an hour or two in a warm place, and the continued fermentation soon expands each mass to about double its former volume. They are now considered fit for the fire, and are finally baked into loaves, which when they quit the oven, are nearly twice as large as when they entered it. The gas contained in the bread is expanded by the heat throughout every part of the loaf, and swells out its whole volume, giving it the piled vesicular structure. Thus a well-made and well-baked loaf is composed of an infinite number of cellules, each of which is filled with carbonic acid gas, and lined with, or composed of, a glutinous membrane; and it is this that communicates the light, elastic, porous texture to bread.

Various arrangements are in use for making bread by machinery. The usually laborious occupation of kneading and mixing the dough is now perfectly well performed by mechanical means, and automatic

ovens receive the dough and return it baked to the basket. Thus large quantities of perfect bread are made expeditiously and at a low price.

The following is a description of Berdan's Automatic Oven, in Brooklyn, N. Y.:

"The oven is of brick, eighteen feet long, nine feet broad, and thirty-two feet high, having a lower and upper story. Underneath the oven is a furnace, from which the heat is conducted to, and through the oven, by means of fire-brick tubes; and the furnace is so constructed and arranged that, by means of a self-acting damper attached to a piece of metal, which opens and shuts as the metal contracts and expands, the heat in the oven can be regulated and kept constantly at the same temperature. The mercury stands at about 292 degrees. There are four doors or entrances to this oven; two in the lower, and two in the upper story. Within the oven is an endless chain, to which arms are attached, and upon which thirty-two forms are laid, about two feet apart. This chain can be moved either by hand or by steam power (the latter being used for convenience and economy in the present case, there being a steam engine on the premises), and revolves perpendicularly through the oven at just that rate of speed as is required to bake the bread with a single revolution; and by means of a conical cylinder, the time of the revolution can be regulated to the fraction of a minute. These thirty-two platforms support thirty-two large bread-pans. Outside, and by the doors of the oven, are two waiting or tender-cars, and all these cars and oven-doors are moved by the same power that moves the endless chain.

"When it is put in motion, one of the oven-doors rises of its own accord, an empty pan trundles out of the oven, and is placed upon the tender-car, by which it is carried to a door on the other side of the oven. A pan containing sixty loaves of dough is placed on this car. The door opposite to which the car is, opens, and the loaded pan at once moves into the oven; the door instantly closes after it, and the pan commences its revolution upon the endless chain. Immediately after the close of this door, the other door opens, and another empty pan moves out, is filled at once with its freight of dough, and then takes its station, like its predecessor at the first door, and follows after in the same manner until the thirty-two cars are filled—the pans always entering at one door and issuing at the other. From the time that all the pans are loaded, a pan of baked bread comes out and dumps itself at one door of the oven as fast as the dough is put in at the other door."

At present the ships of the English navy are supplied with ship-bread, or biscuit, made by machinery, before the introduction of which they were made by hand. In 1833 an apparatus was constructed for this purpose by Mr. Grant, of Gosport. The first process is the preparation of the dough for baking. The meal is conveyed into a cylinder 4½ feet long, 3 feet 2 inches in diameter, and water is let in from a cistern at the back of the cylinder, regulated by a gauge to the exact quantity required for mixing the meal. Through the centre of the cylinder is fitted a shaft armed with knives, and working horizontally. The shaft being set in motion, the knives revolve through the meal and water. During the first half minute the meal and water do not appear to unite; but after this the dough begins to assume a consistency, and in two minutes 5 cwt. of well-mixed dough is produced. The cylinder is formed so that its lower half is easily separated by means of a wheel and pinion from the upper sides, thereby forming a trough containing the dough, from which it is removed, and placed under the breaking-rollers to be kneaded. These rollers, two in number, weigh 1500 pounds each, and are propelled from off a two-throw crank-shaft by means of connecting rods and pendulums; they pass backwards and forwards over the dough during five minutes, when the 5 cwt. of dough is brought into a solid, perfect, and equal consistency. From the breaking-rollers the dough is cut into pieces 18 inches square, and placed on boards 6 feet long by 3 feet wide, which are conveyed, by means of a line of friction-rollers connected by an endless chain, under a second set of rollers, to be rolled to the required thickness of the biscuit. The square of dough being thus pressed out, so as to cover the surface of the board on which it is transferred under the cutting and stamping-plate, is at the same moment cut and stamped, *or docked*, into 42 hexagonal biscuits, which, being now complete, are at once conveyed to the oven on carriages constructed for the purpose. The hexagonal shape is preferred in order that there may be no waste, the sides of each biscuit fitting accurately into those adjoining. The hexagonal cutters do not completely separate the biscuits, so that a whole sheet of them can be put into the oven at once, and, after being withdrawn, they are broken asunder by hand. The grain for the biscuits is prepared at the Government mills; it is a mixture of fine flour and middlings. The ovens are of wrought iron, with an area of 160 square feet. About 112 lbs. weight of biscuits is put into the oven at one time; this is called a suit, and is reduced to about 100 lbs. by the baking.

The bake-house at Gosport was provided with one mixing machine, two breaking-rollers, four sheet-rollers, and four stampers; and it was calculated that this machinery would require eight men and eight boys to supply the nine ovens; that the produce per hour would be 10,000 biscuits, or one ton of bread, at a cost for labor and other incidental expences of 5¼d. per cwt. It was found, however, in practice that the machinery could easily supply eighteen ovens, should it be advisable to enlarge the works to that extent. With the exception of the men employed in heating and managing the ovens, no professional bakers are required, ordinary laborers and boys being fully competent to every other part of the work.

M. Lecompte De Fontainemoreau, of Finsbury, has patented certain improvements in apparatus for kneading and baking bread, &c. The "apparatus for kneading" dough consists of a semi-cylindrical trough, within which is placed longitudinally an axis or shaft, to which are attached on the opposite sides two rows of radial arms, the arms on one side of the shaft being placed opposite the spaces between those on the other side. The ends of the arms of each set are connected together by rods parallel to the shaft which carry short arms projecting inwards, and placed between the long arms. The shaft is driven by a winch handle, and the action of the arms when it is in motion, effectually kneads the dough contained in the trough. The "apparatus for baking" consists of a circular oven provided internally with a revolving table, on which are placed the articles to be baked; and which table is made to rise or fail, as may be required, to change the temperature. The bottom of the oven is heated by

tubular flues, under the movable table; the sides by vertical flues, which lead from the fire-place to the top of the oven, where space is left for the heat to circulate over the whole of it. Above the top flue, which is formed by two plates of metal, the oven is covered with earth, except at one part, where is fixed a receptacle to contain water for the service of the kneading apparatus; such water being heated by the flames, &c., passing through the flue on the top of the oven. A thermometer applied to the exterior shows the degree of heat, and dampers are provided for its regulation.

The following improvements in bread and biscuit machinery are patented by Mr. Exall, of Reading. For kneading flour into dough he uses a hollow screw, or spiral bar of iron, revolving in a cylinder or tube. The materials to be kneaded are supplied by a hopper at one end of the cylinder, which is horizontal, and forced out at the opposite end through a mouth-piece of any suitable form of orifice. The kneaded dough, previously passed through a pair of roughing rolls, is placed on a feed-table, and supplied in a sheet of any desired thickness by a pair of rollers to a travelling web, which carries it successively under the operation of marking or stamping dies, and cutters, having a reciprocating vertical motion, by which the dough is stamped and cut into the form of biscuits, which are then transferred to the oven. When the biscuits are round and cut to waste from the sheet of dough, the apparatus is so arranged as to separate the detached fragments, and prevent their going into the oven with the rest.

A new form of oven is used, in which the baking is effected in the interior of a series of horizontal tubes, set like gas retorts above a fire, or in a flue, and open at either one or both ends, but provided with suitable doors for keeping the same closed during the operation of baking.

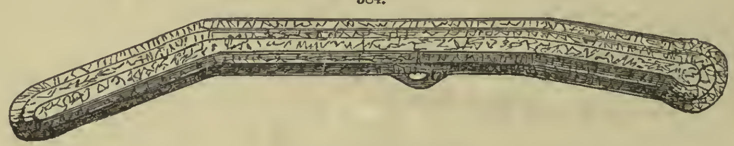
BREAKWATER. A kind of artificial embankment, dike, or rampart, formed of large stones, and erected for the purpose of protecting the entrances of harbors, also roadsteads, from the effects of violent winds, by breaking the force of the waves of the sea; the shipping, moored behind them, lying perfectly secure.

The most celebrated works of this description are those of Cherbourg, in France, and Plymouth, in England.

That of Cherbourg was the first executed, having been begun in the year 1783: the building of the wall was commenced upon upright cones of timber, and each cone was intended to have been about 150 feet diameter at the base, 60 feet at the top, and about 60 or 70 feet high, the depth of water at spring-tides, in the line in which they were sunk, varying from 56 to 70 feet; they were also intended to have been filled with stones to the top, and after allowing some time for settling, the masonry was intended to have been commenced upon them; but a few of these cones only were constructed, when, in consequence of the difficulty of the undertaking, the whole was covered with large stones, thrown in at random. This breakwater is 10 feet above the highest tides, and has a roadway or platform 20 feet wide on the side next the shore, a parapet-wall being built upon it on that next the sea.

The Plymouth breakwater was commenced in 1812. It is composed of blocks of stone, 1½ to 2 and 3 tons weight, and consists of a central part, 1000 yards long; and two wings, each 350 yards long,

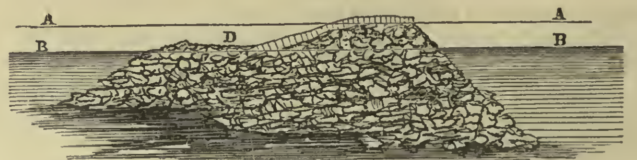
584.



Plan of Plymouth Breakwater.

directed towards the sea, and forming angles of 158° with the centre portion. A transverse section taken through the breakwater shows an average base of 290 feet, and the breadth at the top is 48 feet, with an average depth of water, at low spring-tides, of 36 feet; the side next the sea is sloped in the

585.



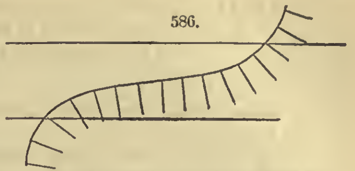
Section of Plymouth Breakwater.—A A, high-water spring tides. B B, low-water spring tides. D, the fore-shore.

proportion of 1 perpendicular to 7 horizontal, and the side next the land is 1 to 5; these sides were not intended, originally, to have had so great a slope, but, in consequence of the violence of the waves during its construction, it was thought proper to increase them, as executed.

The stone was raised in large blocks, some of which contained 10 tons, and were thrown into the sea, in the direction set out for the breakwater, care being taken that the greater number were deposited upon the outer slope. After a number of these large masses had been lowered, a smaller class of stones, quarry rubbish, rubble, and lime-screenings, were thrown in to fill up the interstices, and close all the cavities; these found their position, by the action of the sea, and the great mass became, as it advanced, perfectly wedged together.

BREAKWATER. Fig. 586 represents a form often given to the pavement of the glacis or sea slope of a breakwater. The stones should be of sufficient size to resist the action of the sea.

586.



Section showing the Breakwater Glacis.

BREAST. In mining, the face of coal-workings.

BREASTS. The name given to the bushes connected with small shafts or spindles.

BREAST WALL. A wall built up breast-high, as a parapet-wall, or a retaining-wall, placed at the foot only of a slope.

BREAST WHEEL. A water-wheel which receives its motion from a stream of water flowing on to the breast or side of it, and then descending, bears by its weight upon the lower part of the wheel. See Water-Wheel.

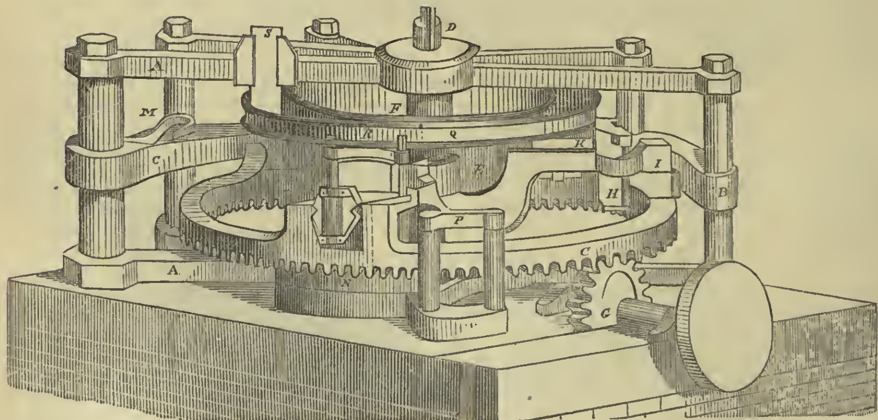
BRICK. An artificial preparation of clay, sand, and ashes, burnt in a kiln, or clamp, and used for building, and for other purposes; good brick earth is also sometimes found in a natural state. A good brick is about 8¾ inches long, 4¼ inches wide, and 2½ inches thick, when burnt.

Bricks appear to have been used for architectural purposes at a very remote period, as we learn from the Scriptures that the Israelites were employed to make bricks in Egypt; and some of the most durable of the Greek and Roman monuments which have come down to us, are wholly, or in great part, constructed of this material. In the East they bake their bricks in the sun; the Romans used them crude, only leaving them a long time in the air to dry, about four or five years. In modern times, brick-making is nowhere carried to greater perfection than in Holland, where most of the floors of the houses, and frequently the streets, are paved with excellent and very durable bricks. Loam and marl are in England considered the best materials for bricks. The former is a natural mixture of sand and clay, which may be converted at once into bricks; marl is a mixture of limestone and clay in various proportions. The neighborhood of London is remarkably adapted for the making of bricks, the soil of the whole surrounding country being clay at a certain depth, generally below a bed of gravel, and the bottom of the Thames yielding the sand which is used in this manufacture; but great practical carelessness seems to pervade the whole business as conducted there. The following is a description of the process as it is usually conducted around the metropolis: The earth is dug up in the autumn, and suffered to remain in a heap until the next spring, that it may be well penetrated by the air, and particularly by the winter frosts, which, by pulverizing the more tenacious particles, greatly assists the operations of mixing and tempering. In making up this heap for the season, the soil and ashes, or sand, are laid in alternate layers or strata, each stratum containing such a thickness as the stiffness of the soil may admit or require. In tempering the earth, much judgment is required as to the quantity of sand to be thrown into the mass, for too much renders the bricks heavy and brittle, and too little leaves them liable to shrink and crack in the burning. The addition of sea-coal ashes, as practised about London, not only makes it work easy, but saves fuel, as when the mixture is afterwards sufficiently heated these bricks are chiefly burned by the fuel contained in the clay. When the brick-making season arrives, the heap is dug up, the stony particles carefully removed, and the mass properly tempered by a thorough incorporation and intermixture of the materials, with the addition of as little water as possible, so as to form a tough viscous paste. If, in this operation, too much water be used, the paste will become almost as dry and brittle as the soil of which it is composed. In order more effectually and regularly to mix the loam and ashes, it is now generally performed in a sort of mill, named a pug-mill. This consists of a large tub or tun, fixed perpendicularly in the ground, and having an upright bar, fitted with knives, placed obliquely. The upright bar is turned by a horizontal lever, to which a horse is attached, and the soil being put in at top, is, by the revolution of the knives, forced through a hole in the side of the tub near the bottom, whence it is removed to the mould-table, which is placed under a moveable shed, and is strewed with dry sand. A girl rolls out a lump somewhat larger than the mould will contain. The moulder receives this lump from the girl, throws it into his mould previously dipped in dry sand, and with a flat smooth stick about 8 inches long, kept for the purpose in a pan of water, he strikes off the overplus of the soil; he then turns the brick out of the mould upon a thin board rather larger than the brick, upon which it is removed by a boy, who places it on a light barrow of a particular construction, which being loaded with a certain number of bricks, they are sprinkled with sand, and wheeled to the hacks. The hacks for drying are each wide enough for two bricks to be placed edgewise across, with a passage between the heads for the admission of the air, to facilitate the circulation of which the bricks are usually laid in an angular direction. The hacks are usually carried eight bricks high; the bottom bricks at the ends are usually old ones. In showery weather the hacks must be carefully covered with wheat or rye straw, unless sheds or roofs be built over the hacks, as is done in some parts of the country, but in London this is impracticable, from the very great extent of the grounds. In fine weather the bricks will be ready for turning in a few days, in doing which they are reset more open than at first, and in six or eight days more they will be ready for burning. In the vicinity of London bricks are commonly burned in clamps. In building the clamps, the bricks are laid after the manner of arches in the kilns, with a vacancy between every two bricks for the fire to play through. The flue is about the width of a brick, carried straight up on both sides for about three feet; it is then nearly filled with dry bavins or wood, on which is laid a covering of sea-coal and cinders, (or, as they are termed, *breeze;*) the arch is then overspanned, and layers of breeze are strewed over the clamp, as well as between the rows of bricks. When the clamp is about six feet wide, another flue is made in every respect similar to the first. This is repeated at every distance of six feet throughout the clamp, which, when completed, is surrounded with old bricks, if there be any on the grounds, if not, with some of the driest of the unbaked ones reserved for the purpose; on the top of all, a thick layer of breeze is laid. The wood is then kindled which sets

fire to the coal; and when all is consumed, which will be in about twenty or thirty days if the weather be tolerable, the bricks are concluded to be sufficiently burned. To prevent the fire burning too furiously, the mouths of the flues are stopped with old bricks, and the outside of the whole clamp plastered with clay; and against any side particularly exposed to the rain, &c., screens are laid, made of reeds worked into frames about six feet high, and of a width to admit of being moved about with ease. This is the mode of manufacturing the ordinary descriptions of bricks; but the superior sort, termed *washed malms* or *marls*, are tempered with greater care and attention. For this purpose a circular recess is built about four feet high, and from ten to twelve feet diameter, paved at bottom, with a horse-wheel placed in its centre, from which a beam extends to the outside for the horse to turn it by. The earth is then raised to a level with the top of the recess, and forms a platform for the horse to walk upon. Contiguous to the recess a well is formed for supplying the recess with water, which is raised by a pump worked by the horse-wheel. A harrow made to fit the interior of the recess, thick set with long iron teeth, and well loaded, is chained to the beam of the wheel to which the horse is harnessed. The soil prepared in the heap in the usual manner is brought in barrows, and distributed regularly round the recess, and a quantity of chalk is added, and a certain portion of water; and the horse being set in motion, drags the harrow, which forces its way into the soil, admits the water into it, and by tearing and separating the particles, not only mixes the ingredients, but also affords an opportunity for stones and other heavy matters to fall to the bottom. Fresh clay, chalk, and water, continue to be added until the recess is full. On one side of the recess, and as near it as possible, several hollow square pits are prepared about 18 inches or 2 feet deep. The soil, reduced to a kind of liquid paste, is discharged from the recess by a sluice, and conveyed by wooden troughs to the pits. In these pits the fluid soil diffuses itself, settling of an equal thickness, and remains until wanted for use, the superfluous moisture being drained or evaporated away by exposure to the atmosphere. The remainder of the process is the same as for the common sort of bricks. In the country, bricks are always burned in kilns, whereby much waste is prevented, less fuel is consumed, and the bricks are more expeditiously burned. A kiln is usually 13 feet long by 10 feet 6 inches wide, about 12 feet in height, and will burn 20,000 bricks at a time. The walls are about 14 inches square, and incline inwards towards the top. The bricks are set on flat arches, having holes left between them resembling lattice-work. The bricks being set in the kiln, and covered with pieces of broken bricks or tiles, some wood is put in and kindled to dry them gradually; this is continued till the bricks are pretty dry, which is known by the smoke turning from a darkish to a transparent color. The burning then takes place, and is effected by putting in brushwood, furze, heath, faggots, &c.; but before these are put in, the mouths of the kiln are stopped with pieces of brick called *shinlog*, piled one upon another, and closed over with wet brick-earth. This shinlog is carried just high enough to leave room sufficient to thrust in a faggot at a time; the fire is then made up, and continued till the arches assume a whitish appearance, and the flames appear through the top of the kiln, upon which the fire is slackened, and the kiln cooled by degrees. This process is continued, alternately heating and slackening, till the bricks are thoroughly burned, which is usually in the space of forty-eight hours.. Many attempts have been made of late years to supersede, by the aid of machinery, a portion of the manual labor now employed in the manufacture of bricks.

BRICK-MACHINE. Fig. 587 is a representation of Stephen Ustick's, for *Moulding aud Pressing Bricks* from untempered clay

587.



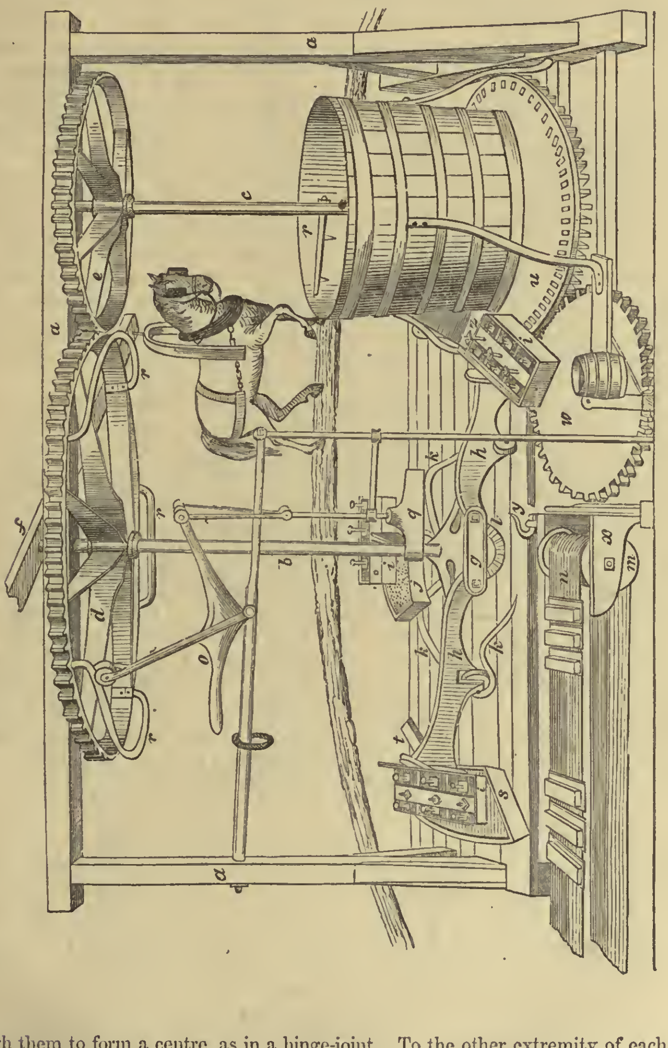
A A, frames, between which the cams B C and the centre shaft D are firmly bolted.
B C, cams which give the pressure to the outer pistons.
D, centre shaft on which the wheel of moulds revolves.
E, cam-wheel on the centre shaft D, which gives the pressure to the inner pistons.
F, cam-wheel on side shaft, above the cam-wheel E, which gives motion to the fillers. The view of this cam-wheel is obstructed by the receiver.
G, the pinion on the driving-shaft.
G, revolving wheel on the shaft D, having pairs of parallel arms to which the moulds are bolted, and between which the pistons slide.
H, the moulds.
I I, pistons which condense the clay.
K, the fillers which supply the moulds with clay.
L, the hoppers above the fillers.
M, a light cam, which brings the outer piston out of the mould after the brick is pressed, while the inner one is thrust through the mould, carrying the brick with it, by a projection of the cam-wheel E.
N, a perpendicular cam which operates the plunger O, to discharge the bricks from the pistons.
P P, cams which bring the pistons into the moulds.
Q, annular receiver, into which the clay falls from the pulverizer.
R, openings in the bottom of the receiver communicating with the hoppers L.
S, scraper which fills the hoppers

After the first pressure is given to the clay, which commences when the outer piston is at the front end of the cam B, the air is let off of the brick by the filer, (the front end of which is a false top to the mould,) moving inwards, leaving the upper part of the brick bare for the condensed air to escape; it then moves back to its place before the piston reaches the back end of the cam C, and then the second pressure is given to the brick, without any loss of time, as a brick is made in each mould in every revolution of the wheel.

From the full explanation of the different parts of the machine, and their functions, and by reference to the figure, it will readily be seen that it is simple in its construction, as all the motions to the pistons and fillers are given by *stationary cams* as the wheel of the mould rotates. The pressing cams give a powerful progressive pressure—the same in effect as that given by toggle-joint levers.

Fig. 588 is a representation of Messrs. Choice and Gibson's brick-making machine, *a a a a* is an upright frame, with cross beams at top and bottom; *b c* are two vertical shafts, carrying two horizontal spur-wheels *d* and *e*, the teeth of which take into one another; these are put in motion by the horse-shaft *f*, or any other convenient power. Near the bottom of the shaft *b*, is fixed a large cast-iron collar *g*, having three deep mortises; into each of these the end of an iron arm *h* is fitted, with a bolt

588.



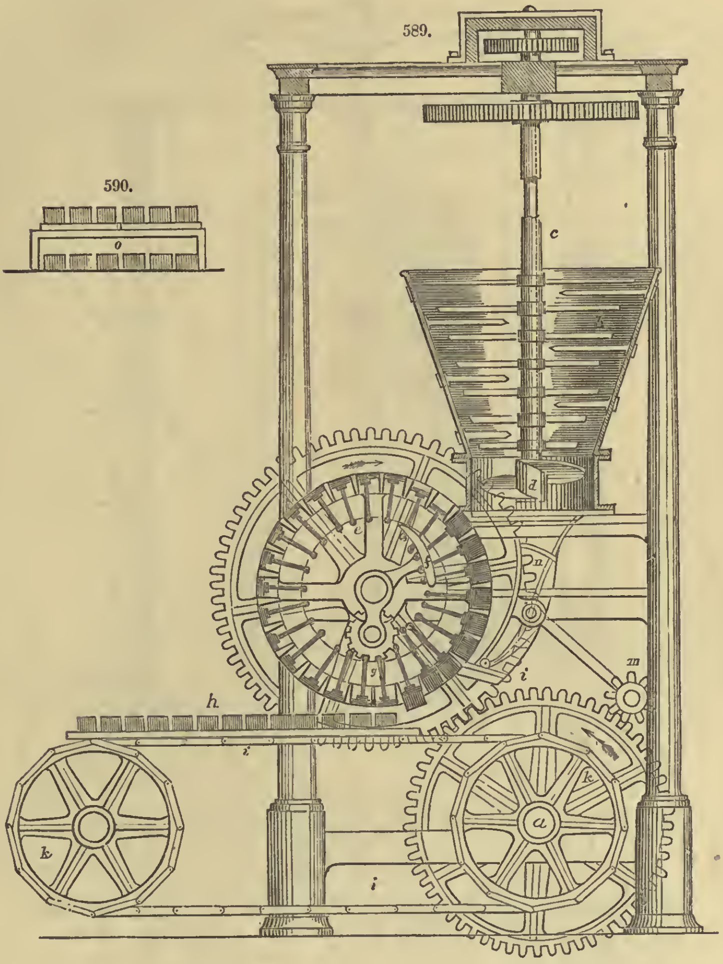
passing through them to form a centre, as in a hinge-joint. To the other extremity of each of the arms *h* is firmly fixed, by screw-bolts, a cast-iron mould-box *i*, having three divisions for three bricks, in which work three stocks or false bottoms, having upright bolts passing through holes in the top. By the revolution of the shaft, these mould-boxes, with their arms, are successively carried up and over the risers *k k k*, which form circular curves in the plan, and appear so in the perspective, but are in reality

inclined planes. At l, near the bottom of the shaft, is a small bevelled wheel, which actuates a pinion fixed on the spindle of the drum-wheel m that passes under the floor of the machine; an endless strap passing round the drum m, and another placed at the required distance, continually carries the bricks forward to their destination as fast as they are made, and deposited upon it. o is a crank or lever, attached by a joint to the framing, as shown, at the upper end of which is fixed a roller; by the revolution of the wheel above the three circular bars or cams, $r\,r\,r$, attached to the wheel, successively act upon the roller, and depress the crank o, which first raises the rod and weight q, and afterwards, as soon as the crank is relieved of the pressure, allows it to drop and strike the mould-boxes, by which the bricks are discharged out of them. s is a box of cast-iron, containing water, into which the mould-boxes dip; t is a cushion, upon which they next fall in succession, by which the superfluous water is taken off; and j is a box of dry sand, into which the mould-boxes afterwards fall, their surfaces becoming in consequence slightly coated with sand previous to becoming charged with clay. The horizontal wheel e worked by d actuates the shaft c bearing the knives in the pug-mill. At the lower end of the shaft c is fixed the large circular revolving bottom-plate u, the periphery of which being furnished with teeth or cogs, as shown, take into the teeth of a circular revolving plate v, over which, as the mould-box passes, the lower surface of the bricks becomes smoothed. At x is a small frame, working up and down in a casing, with a pulley and counterbalance weight, like a sash window; it is raised by the crank y as each mould-box passes, when three little boards are placed across the frame by a boy, for the reception of the bricks. When these are deposited by the means described, the frame drops below the level of the endless strap n; the latter then receives them, and carries them off to their destination. At z is fixed a flat box, which acts as a gage to regulate the thickness of the stratum of clay revolving upon the bottom plate u of the pug-mill. The operation of this machine is as follows: the clay being worked in the ordinary manner through the pug-mill, it passes out at the mouth, (not shown, being on the opposite side,) from thence under a flap which partly regulates the quantity on the bottom plate, and next under the gage, which determines it precisely. A mould-box having passed over the highest inclined plane or riser k, first falls on the stratum of clay, and chops out three bricks, filling the moulds therewith by the false bottoms rising up to the determined point from the pressure of the clay against them; the moulds, with the bricks in them, then slide over the polishing plate r, (which is kept wet by water constantly dripping upon it from a tub;) from thence the moulds pass on to the frame x, when the weight q strikes against the protruded bolts of the false bottoms, and pushes out the bricks upon the boards on the frame; the frame then descends two or three inches by their weight, and delivers the boards upon the endless strap, which, being constantly in motion, carries the bricks away to be deposited on the hacks. The mould-box being discharged, is then carried upon its roller up the first riser k, drops into the water, thence rises again, falls upon the cushion, next into the sand-box, whence ascending again, the highest inclined plane being duly prepared, it falls again upon the bottom plate of the pug-mill, and chops out three more bricks, during which period each mould-box has operated in a similar manner.

We shall now proceed to describe the brick-making machinery invented by Mr. Leahy, and erected by him for the Patent Brick Company; it is represented in the succeeding figure. a is the main horizontal shaft in direct communication with the steam-engine or other first mover; b is a hopper-formed vessel, technically termed the pug-mill, in which the clay and other materials are tempered and mixed up: it is for this purpose furnished with cross iron bars, or blades of steel; part of these are firmly fixed to the *hollow* vertical shaft c, and the remainder bolted to the sides of the pug-mill, and they are so arranged, that those fixed to the shaft cut in as they revolve between the others. The clay is delivered into the hopper or pug-mill by an endless chain of buckets, (in the same manner as ballast is raised;) it is then cut up and tempered by the knives and bars in the pug-mill, and gradually descending, it falls, or rather is forced by the superincumbent pressure upon the circular inclined plane d, which consists of a single thread or spiral turn of a very large screw, occupying the whole internal space of the lower cylindrical end of the mill, where it is exhibited in section. This screw or circular inclined plane is fixed to the central shaft passing longitudinally the hollow shaft, and a slow reversed motion is given to it, by means of an intermediate wheel acting upon pinions in the upper part of the frame. The blades on the hollow shaft revolve in the pug-mill at the rate of fifteen turns in a minute, grinding and dividing the materials much more completely than in the ordinary mode of brick-making. In this attenuated state the materials are forced upon the circular inclined plane of the screw, and as this slowly revolves in a contrary direction at the rate of five turns in a minute, it takes hold of the clay, (by a peculiar adaptation not easily described,) and forces it out of the mill in a very compact state, into a receptacle below: of this, one side is always in immediate contact with the moulds, and those two sides which are at right angles to the former side are closed by iron cheeks, between which the lever or forcing flap n acts by pressure, and fitting closely, prevents the escape of the clay, so that it can only pass into the moulds. These moulds are placed round the periphery of a circular frame e, made of flat iron rings, fixed upon bars or spokes, and turning upon a *fixed* shaft. There are twenty-five of these moulding-boxes in one circle; but as the frame e may be of any breadth, it may contain twice twenty-five or thrice twenty-five on the circumference of the cylinder, provided that the engine is capable of affording sufficient power or force to cut or mould so many bricks at each revolution. Each moulding-box is furnished with a false or moveable bottom, to which rods are attached, for the purpose of pushing out the brick when moulded, and drawing back the bottom to its place to receive a fresh portion of the clay. The manner in which these operations are performed is extremely simple and ingenious. The ends of each of the moulding-box rods are bent at right angles, and an eccentric piece f is so fixed, that, as the moulds revolve, and at the moment that the surface of each is covered by being in contact with the clay, it gradually draws back the false bottom, and with it the clay, which is also urged on by the circular inclined plane d; and to render the bricks solid and compact, a powerful pressure is applied to them by means of the flap forcer n, to which a backward and forward motion is given by the *thrusting* of a rod attached to a revolving crank. The moulding-boxes, immediately they are thus filled, are subjected alternately to the action of a steel scraper, which

levels and smooths their surface, and is made to operate by the pressure of springs. The bricks, now completely formed and fast in their moulds, pass downwards in their revolution, which brings the ends of the rods under the operation of a cylindrical roller, with grooves made round it at equal distances; into these grooves the ends of the rods successively pass, which, in their revolution, force out the rods, and thereby push out the bricks from the moulds on to boards placed underneath to receive them. The bricks thus made are carried forward to the hacks or drying-house, upon an endless web or chain *i i*, to which a continued motion is communicated by the revolution of the two polygonal drums or wheels *k k*, placed at the requisite distance asunder. The upper part of the engraving shows a side elevation of the machine, and the lower part a section of it; and although these views serve to give a general idea of the construction of the apparatus, it has been impracticable to show the gearing by which the

589.



590.

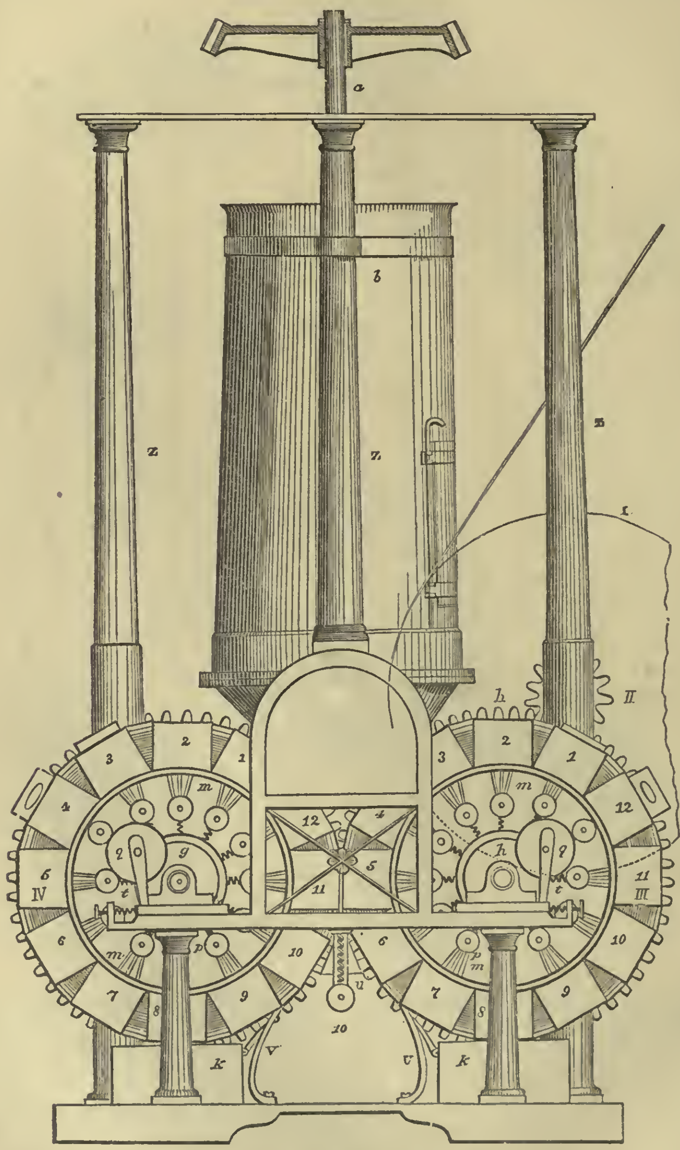
several motions are produced; we will therefore attempt to describe it as follows:—Upon the horizontal shaft *a*, (which makes 2½ revolutions per minute,) is fixed a toothed, bevelled wheel, which drives a bevelled pinion on an upright shaft, (not shown;) nearly at the top of this a spur-wheel is fixed, which works into a pinion fixed upon the upper end of the hollow shaft *c*, which carries the knives or blades in the pug-mill. Upon the upper end of this upright shaft is also fixed a pinion, which works into an intermediate pinion turning upon an axis. This intermediate pinion acts upon another pinion affixed to the internal shaft, communicating a slow and reversed motion to it, and also the circular inclined plane affixed to it; at the lower end, on the main horizontal shaft, is fixed a spur-wheel *m*, which gives motion to the crank and to the flap forcer connected to it. *o*, in the separate figure, gives the form of the shelves comprising the drying apparatus,—Mr. Leahy proposing to dry bricks either by flues or by steam, instead of ranging them in hacks exposed to the variations and inclemencies of the weather,—by which means it is presumed that the bricks will be rendered dry enough for burning, either in kilns or clamps, in a much shorter time than in the common method, and the process may be carried on in winter as well as in summer. If drying by flues be resorted to, a drying-house must be furnished with proper stages, and shelves must be provided. Around and across the lower part of these, flues framed

either of bricks or cast-iron are to be placed, through which flame or heated air is to be conveyed. In drying by steam, the vapor is conveyed from the boiler through cast-iron pipes throughout the drying-house, and boards are arranged upon stages, (similar to those in Fig. 590.) so as to leave intervals between the rows of bricks, and to prevent their touching one another.

Nash's Patent Brick-making Machinery.

This invention, which we have now to describe, is not the only one, we believe, that has been brought into successful operation. The leading features of Mr. Nash's mechanism consist in the application o

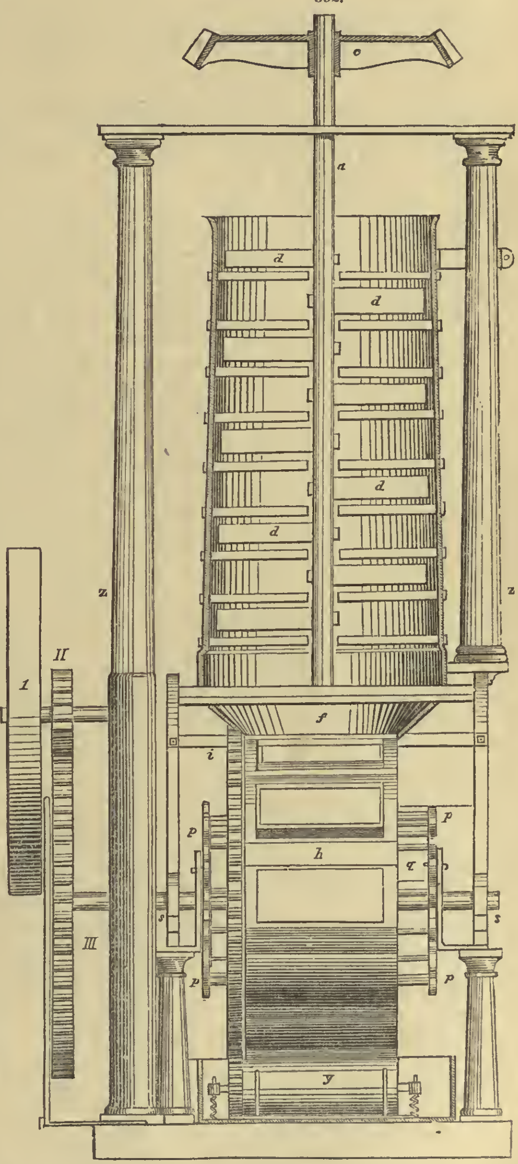
591.



separate or detached moulds of a particular construction to a series of mould-boxes, which are consecutively brought into action; in the employment of heaters, placed in contact with, or contiguous to, the fresh bricks, during the process of their being moulded; and in lieu of sand, which is generally used to prevent the adhesion of the bricks to the moulds, employing elastic absorbent substances, such as cloth saturated with water. In the subjoined engravings, Fig. 591 represents a front elevation, and Fig. 592 an end elevation of the principal parts of the machine. A vertical shaft *a* is made to revolve in the cylinder or pug-mill *b*, by any adequate force acting upon the bevelled wheel *c*. A number of broad

steel or iron blades *d d d* are attached to the shaft *a*, their surfaces being set at such an angle as will cause them, during their revolution, to pass nearly in contact with the edges of two other sets of knives *e e e*, fixed on opposite sides of the cylinder, by which means the clay and other materials with which the mill is charged are tempered and amalgamated, and then forced into the hopper *f*, fixed to the lower extremity of the pug-mill. This hopper is divided into two equal chambers by a vertical blade or knife, which separates the materials into equal portions, which are supplied to the moulds in a compact state. The moulds are lodged in rectangular cavities at equal distances in the periphery of two polygonal drums *g h;* these cavities are marked 1 to 12. To one face or side of the drums are attached two toothed wheels, gearing into each other so as to revolve in opposite directions when motion is communicated to one of them. These wheels lying at the back of Fig. 591 cannot be seen, but one of them is shown at *i* in Fig. 592. The moulds, after being filled with the plastic material, are pushed out from their recesses by means of pistons at *m m*, easily fitting the recesses, and sliding upon parallel rods fixed to the rims of each drum. To each piston is attached, by a short rod, a cross-head, sliding upon the parallel rods, and having at each end small anti-friction wheels *p p*, which, by the motion given to the machinery, come in contact with a larger wheel *q*, placed eccentrically, which thus raises the pistons, and the moulds which lie upon them are then removed by hand and emptied. During this latter process the emptied mould-receiver will have passed over the centre of the eccentric wheel *q*, and the piston will be descending when the attendant places the emptied mould in its former situation, to be filled again from the hopper as it passes under it. Between each of the rectangular mould-boxes are formed a series of wedge-shaped boxes, termed by the patentees "hollow sectors," into each of which is placed a red-hot iron, the object of which is to expel the superfluous moisture from the newly-formed brick, &c., in order that the manufacture may be conducted in the winter as well as the summer. These irons are heated in the kiln-fires. The axis of the polygonal drums revolve in plummer-blocks, supported upon a strong frame *s;* but as the polygonal drums revolve in close contact, the plummer-blocks are free to slide in grooves in the frame, and the wheels are kept in contact by the action of strong helical springs *t*, which press against the plummer-blocks, the other end of the springs abutting against a regulating screw. In the middle of, and underneath the horizontal frame *s*, is fixed a knife *u*, (supported in its place by a spiral spring,) which separates the whole or a portion of the superfluous materials from each mould, as the latter passes over the edge of the former. As some redundancy of material may still be left after the operation of the knife *u*, the exposed surface of the moulds in motion undergoes a similar treatment from two other knives *v v*, fixed to the foundation plate *w* of the machine. A trough or cistern *k k*, containing water, is placed under each of the drums, the lowest sides of which come in contact with a cylinder *y*, covered with strong coarse cloth or other suitable absorbent substance, which, as it revolves, takes up the water and delivers it to the moulds as before mentioned. These cylinders are mounted on elastic bearings, and derive their motion from pinions on their axes, actuated by the toothed wheels on the drums. In the centre of the foundation plate there is a cavity, or pit, for the reception of the superfluous clay or other materials, which are removed at pleasure. The pug-mill has a door in it, for the convenience of cleaning it out when requisite; and the whole of the upper part of the machine is supported by three columns

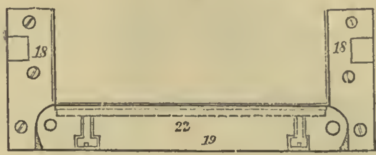
592.



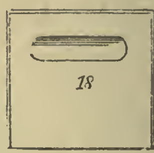
zzz. The polygonal drums are driven by a set of wheels lying at the back of Fig. 591, and therefore in that figure shown by dotted circles. No. I. is a band-wheel, which drives, by a pinion II, the two wheels III and IV, on the axes of the driving gearing, into each other, and turning in opposite directions. Those two wheels must have involute teeth, as their point of contact becomes variable by the movement of the axes of the drums. In case of negligence on the part of the boys, or other attendants of the machine, in not removing the bricks or tiles after the moulds containing them have passed the centre of the eccentric wheel, they fall back into their former position, and pass round to the place of delivery, as before, without any damage whatever being done to the machine.

Having explained the general arrangement and operation of the machine, there remains to be described the construction of the detached moulds. Fig. 593 represents a side view, and Fig. 594 an end view of one of these. The ends of the mould 18, 18, are made of wood, plated at the edges with iron, and fastened on by screws, as seen in Fig. 593. The bottom 19, is also of wood, but cased in a strong frame of cast-iron, and its two extremities are jointed to the ends 18, 18, so as to open only a little way, for allowing the brick to separate freely from it upon inverting the mould.

593.

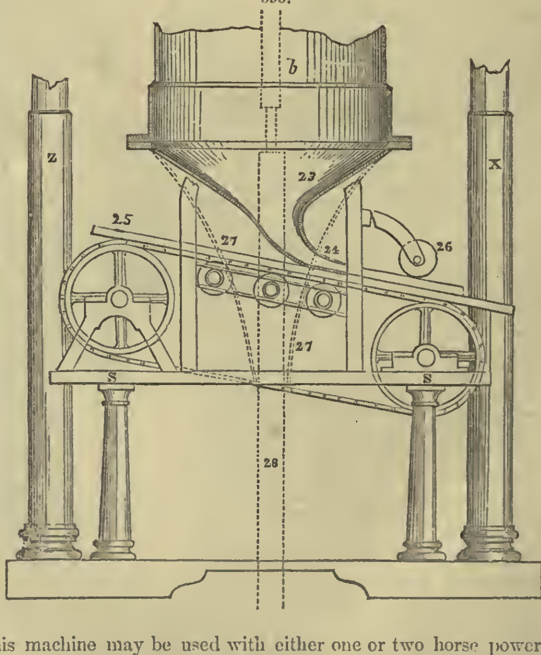


594.



This effect is facilitated by lining the interior of the mould with cloth, which, although constantly in a wet state, admits air to pass through its interstices when the clay is forced into the mould, so that when the brick is afterwards forced out, the moisture of the cloth, and the spring of the confined air, delivers the brick uniformly clean, without the adhesion of any clay. It will be observed that the two ends 18 of the mould have each a cavity; these cavities receive the fingers of the workman when he takes hold of the mould, which he afterwards inverts, drawing back the ends 18 at the instant, and pressing with his thumb upon the screw-heads 21, 21, the other ends of which are attached to a plate 22 underneath the cloth lining of the bottom, as shown by dots, causing the brick to be immediately disengaged. The two sides of the brick not included in the detached mould are formed by the partition between the mould-boxes and the hollow sectors. The forms and dimensions of the detached moulds are varied according to the nature of the articles to be produced therefrom. For adapting the machine to make tiles, or other articles of a greater length than a brick, two moveable blocks, which usually lie inside the hopper, to contract its lower dimensions, are taken out. In the making of drain tiles, and other articles having cavities within them, jointed horses or cores are employed; the plastic matter is forced around them by the action of the machine in the same manner as in forming a brick, and the subsequent operations are also the same, except that in the removal or delivery of such tiles from their moulds, suitable adaptations are made to prevent their being pressed or even touched by the hand. The annexed Fig. 595 exhibits another arrangement employed by Mr. Nash for making flat tiles, flooring tiles, &c., of any required breadth and thickness. This cut only represents the lower part of the machine, the upper being the same as in the previously-described apparatus. To the bottom of the pug-mill is fixed a funnel-shaped hopper 23, the materials in which, after being forced through a mouth 24, formed of the required shape, are received upon boards 25, and when cut to the proper length, are removed to sheds for drying. In order to equalize the surface of the clay after it has come out of the hopper, a roller 26, turning in bearings on a curved arm, which is fixed to a hinge-joint, gives to the material any pressure that may be required, by loading it accordingly. The dotted lines 27, 27, in the same figure, exhibit another funnel-shaped hopper, for the purpose of making pipes or tubes, by means of a centre core 28, between which and the cylindrical continuation of the hopper, the material is forced by the action of the pug-mill, and produces a tube, which, after having made a certain length of, is cut off, the tube being turned round, to render the inside smooth previously to its being removed. The patentee states that this machine may be used with either one or two horse power; that when used with one horse power, the product is about 700 per hour, or 8000 per day; to do which requires the services of two men and eight boys, occasioning an expense not exceeding two shillings and

595.



sixpence per 1000. With two horse power employed, the production is double, or 16,000 per day; but the quality of the bricks, which the editor has seen, is equal to those which are usually finished by grinding the surfaces by hand. The saving of labor in the production is about two shillings per 1000; but the quality rendering them worth five shillings per 1000 more in the market, the advantage of making by the machine, where good bricks are required, is equal to seven shillings per 1000.

BRICKS AND TILES, *Machinery for the manufacture of.* The application of machinery to the fabrication of bricks has met with considerable opposition in the diversity of physical and chemical conditions of the earths used. Thus, in some localities the clay has more tenacity and aluminous properties than in others; the mechanical powers sufficient for the last would be useless in the first.

As early as 1835, M. Terrasson had constructed a machine surpassing all previous ones in simplicity A frame, having wires stretched across, cuts into bricks the earth which has been compressed between a roller and planks.

M. Carville has invented a machine which simultaneously bruises and divides the earth, moulds and throws off the bricks; it may be applied to the fabrication of tiles and other earthen ware.

Description of M. Carville's Machine, Figs. 596 to 604.

Division and kneading of the Earths.—The earths used are clays, requiring sometimes sand or aluminous compounds. The mixture is the most difficult part in all the process of brick-making. To this end M. Carville uses a cylindrical barrel A, with a flat bottom; its upper part is opened in order to introduce the material. An axis B, also vertical, to which a rotary motion is imparted by a horse harnessed to the beam C, through the medium of the cast-iron socket *a*, (see Fig. 596, which is a vertical section through the middle of the machine.) This axis rests against two pillows, one adapted to a beam *b*, which unites the opposite sides of the machine, and the other upon an inferior cross-beam. This axis is provided with several flat iron branches *d*, which being fixed perpendicularly to the axis, their faces have an inclination of 45°. On these there are sharp-edged knives, to divide and knead the clay during their rotation; thus the earth is well divided before reaching the inferior part of the barrel. The branches *e f*, stouter than the former, but without knives, are attached at the very extremity of the axis, and receive from it a rotary motion, during which they press against the earth, forcing it out through the orifice *g*. The size of this orifice depends on the quantity needed to fill the moulds; the iron sliding-door *h* regulates this orifice.

This method for dividing and kneading is applied to the fabrication of earthen ware, porcelains, etc.

Moulding and casting off the Bricks.—It is specially in these functions that M. Carville's machine excels all others. He uses a series of moulds in cast-iron, forming an endless chain D, constantly moving; these moulds successively pass beneath the aperture through which the moistened earth is pressed, in order to receive it. Each link forms a rectangular frame, composed of four moulds, which have the precise dimensions of the bricks. Figs. 597, 598, 599, show a plan and transverse section of this chain.

Two wheels, with each four arms E, are situated on either side at the extremity of the apparatus. The iron bars *i* support the limbs and impart to them the movement of rotation communicated by the spur-wheel F; the arrows indicate the direction in which they are to move Fig. 596, so that the moulds are carried under the roller G after they are filled with earth.

This roller is of cast-iron, turning round a horizontal iron axis, set in motion by the beam C. Its office is to compress the earth in the moulds as it is received from the barrel. But as these moulds have no bottom, a moveable flooring is adapted to them to serve as such; it is made of strong sheet-iron *j*, the pieces approaching each other at distances proportional to the length of the bricks, and hooked to an endless chain passing over the rollers *k*; one of these rotates, giving to the chain a motion equal to the speed of the moulds. These must be nearly horizontal, when they pass beneath the barrel; to give them this direction, a number of wooden rollers H support the iron plates. The axes of these rollers are of iron, freely turning on pillows, Fig. 600.

The clay being thus moulded and pressed, soon meets the blades *l*, made of steel or cast-iron, which shave the two horizontal and parallel faces of the moulds, levelling and polishing the bricks.

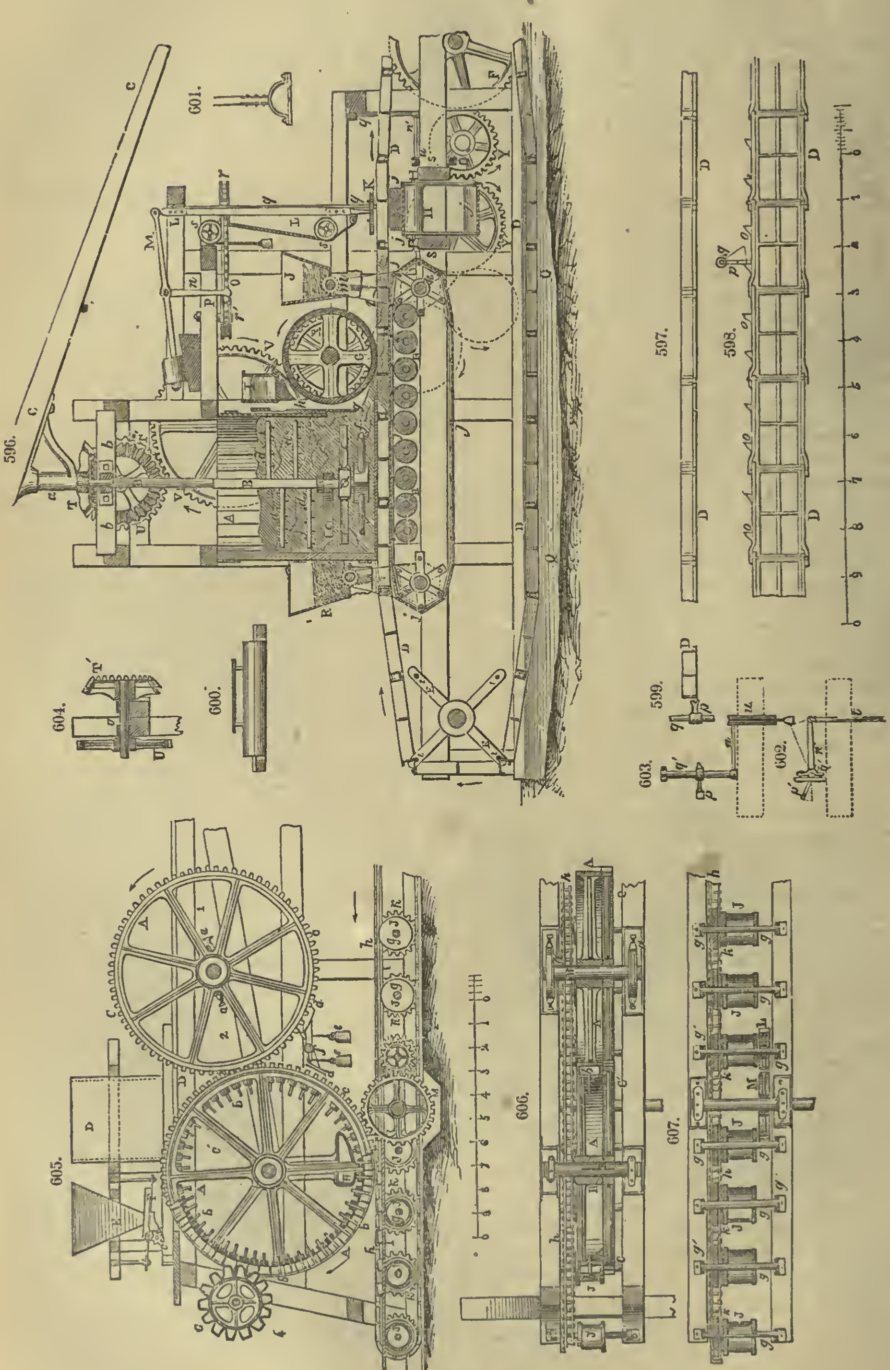
The clay is prevented from adhering to the surface of the rollers by the water slowly falling from the vessel I.

A wooden hopper J, containing fine and dry sand, sprinkles the bricks as they pass beneath *l*; a small fluted cylinder *m*, is adapted to the base of the hopper to allow the sand to come out—but in small quantity; this cylinder is rotated by means of a pulley and strap, or a small endless chain.

As soon as the bricks have passed the polishing blades, they are taken out of the moulds. This is ingeniously done by the simple process of M. Carville. Two pieces of cast-iron K, having a superficial dimension equal to that of the section of the mould, which they completely fill, are attached to a single vertical beam L, which is suspended to another beam M, the other extremity of which being balanced by a counterpoise, this is prevented from falling by a board N.

To the axis of the beam M a vertical branch *n* is adapted; this receives a movement of oscillation, depending on the speed of the endless chain of moulds. To this end, this last is provided with little knobs *o*, Fig. 598, which meet and push successively a horizontal lever *r*, Fig. 599, fixed to the vertical axis *g*. To the superior part of this axis is attached the pulley *r*, Fig. 596, to the circumference of which is hooked the small chain O, whose other extremity is fastened to the pulley *r'*, freely rotating round the iron pin P.

Thus when one of the knobs *o* is in contact with the inferior lever *p*, it pushes it in the direction of the chain, causing the vertical axis *q* to turn; the pulley attached to *q* turns also, carrying along the chain O, and since the extremity of the vertical branch *n* is engaged in one of its links, it is drawn by it: therefore the axis carrying it oscillates, and also the beam M; L descends, pushing the lumps K into the two corresponding moulds, thrusting the bricks on a moveable floor *j'*. The weight attached to the beam M causes L to rise, as soon as the lever is no longer acted on by the eminence *o*.



596. 597. 598. 599. 600. 601. 602. 603. 604. 605. 606. 607.

To bring back to its original position the beam L, a cord is attached to its lower extremity, passing through the pulleys $s\,s'$, and having a small counterpoise fastened to its other end.

The chain, going all the time, plunges into a reservoir of water Q, which extends its whole length, to wash the moulds. Following the direction indicated by the arrows, it passes under the hopper R, where the moulds are sprinkled with sand before reaching the barrel.

The second moveable flooring j', which receives the bricks, is composed of small plates forming an endless chain; parallel rollers, such as H', placed in a different direction from the first, support this chain. Their iron axes are moveable in pillows resting against oak beams S.

This flooring moves only when the beam L rises. The teeth o raise successively a short lever p', which is attached about the middle of the short vertical axis q'; to this is adapted a second lever n', fixed to a small horizontal beam t, which communicates through a rope with the pulley u. Thus, as soon as a tooth acts on p', its axis oscillates, and its inferior lever n forces the flooring j' to advance a distance equal to the breadth of the two bricks. The small rope passing through u has a counterpoise to bring back the levers to their original position.

The bricks being taken off without any handling, are put up to dry. The plates are set back to the chain j', on the side opposite to that on which the bricks were.

Description of the Machine of M. Capouillet, Figs. 605, 606, 607.

This machine consists of two cast-iron cylinders, performing the office of rollers; one is perfectly smooth, the other is pierced over all its surface with cavities, the dimension of which depends on the size of the bricks to be made: pistons are made to fit into these cavities. These pistons receive an alternative movement equal to the thickness of a brick.

Construction of the Cylinders.—The first cylinder A is solid and smooth; its diameter is 7·31 feet, and its breadth is 7·47 feet. It has an axis of wrought-iron B, turning in pillows with screws a. It receives its motion from the second cylinder, through a straight-toothed wheel C, whose inner diameter is precisely that of the external cylinder.

The second cylinder A' is of the same dimensions with the first, but whose circumference contains a great number of rectangular cavities, having only 0·039 feet between each, and of sufficient depth to contain each the thickness of a brick and of a metallic piston b. It has also a horizontal axis of wrought-iron B', of equal length with the preceding. It also is provided with an axis C' of equal diameter with C, with which it is engaged; the pinion M communicates motion to it.

The pistons b are rectangular, their dimensions in length and breadth being equal to the bricks; they are free in the cavities, but closely fitting: a cylindrical rod is attached to them.

Moulding the Bricks.—The clay being prepared, is brought into a rectangular box D, extending as far as the two cylinders, between which the earth falls and is carried away by them. The quantity is regulated by a slide adapted to the box, whose height must not be less than 6·50 feet. By its side is placed a hopper E, containing dry fine sand to be sprinkled on the cylinder A' before the earth enters its cavities. The spout F regulates the direction of the sand; to it an oscillating motion is imparted by the spokes c.

The clay, falling between the two cylinders from the box D, is pressed into the cavities of A', filling them in succession with so much more ease as the pistons are pushed in. These pistons had previously been forced in by the cog, which is furnished with the circumference of a strong cast-iron disk G, situated at the right of the cylinder, and having an iron axis. These cogs are disposed as in a cog-wheel, and engaging into the cavities of the cylinder, they push the pistons within the cylinder.

An eccentric of cast-iron H is contained within A', freely turning round on its axis, in order to force the pistons from within out, thus forcing the bricks away. The curve of this eccentric must be calculated to give the pistons play only the thickness of a brick. Fig. 605 gives an external elevation of the apparatus, and also a part of the vertical section, showing the disposition of the pistons.

Two scrapers $d\,d'$, adapted to iron levers, which oscillate round the common axis f, and which have counterpoise $e\,e'$, serve to keep the surface of the cylinders smooth and clean.

Transportation of the Bricks.—The horizontal boards I, receive the bricks as they are forced out of the moulding cylinder; they are moved with a speed somewhat greater than the cylinders, in order to leave a small space between the bricks. Their direction is from left to right.

These boards are carried by small cylindrical rollers J of cast-iron, the axes of which rest on collars g', pinned on the sleepers, as seen in the horizontal section, Fig. 607. The toothed-wheel k, in which an endless chain h is engaged, transmits to them the motion communicated to it by the wheel which is placed on one of the rollers, to which the small pinion L is adapted. This last is engaged in the principal pinion M, whose axis is turned by the prime mover which may be a hydraulic wheel, a steam-engine, or a horizontal beam turned by a horse.

Two brick-making machines much in favor in England, are Ainslie's and Hunt's. The latter has been extensively used in the execution of large contracts: it consists of two cylinders, each covered with an endless web, which are so placed that they form a sort of hopper on their two upper cylindrical surfaces, the ends being enclosed by two iron plates. The tempered clay is thrown into this hopper, and at the lower part it acquires the form and dimensions of a brick. Beneath is worked an endless chain, by the movement of the cylinders, and at various marked intervals are laid the pallet-boards under the hopper; the clay is brought down by a slight pressure, and enters a frame, which has a wire stretched across it, which projects through the mass, and cuts off the requisite thickness; this is immediately removed by the forward motion of the endless chain, and this operation is renewed as often as a new pallet-board is advanced under the hopper. This machine produces about 1,200 bricks per hour, and is worked by two men and three boys. By this plan less pressure is given than in most machines, consequently the bricks are less difficult to dry equally.

Machine-made bricks are smoother, heavier, and stronger than other bricks, but they do not adhere so well to the mortar, and are more difficult to dry well than those made by hand.

BRICK-MAKING MACHINE, ROTARY AND LOCOMOTIVE—By JOSEPH GRANT. Fig. 608 is a plan of the machine.

Fig. 609 is a side elevation, with one of the propelling wheels removed.

Fig. 610 is an end view of the mould-cylinder.

Fig. 611 is a transverse vertical section of the machine, seen from the back, showing the mould-cylinder in longitudinal section.

Fig. 612 is a transverse sectional elevation of the mould and pressing cylinders in part, with hopper attached, appearing as in operation.

608.

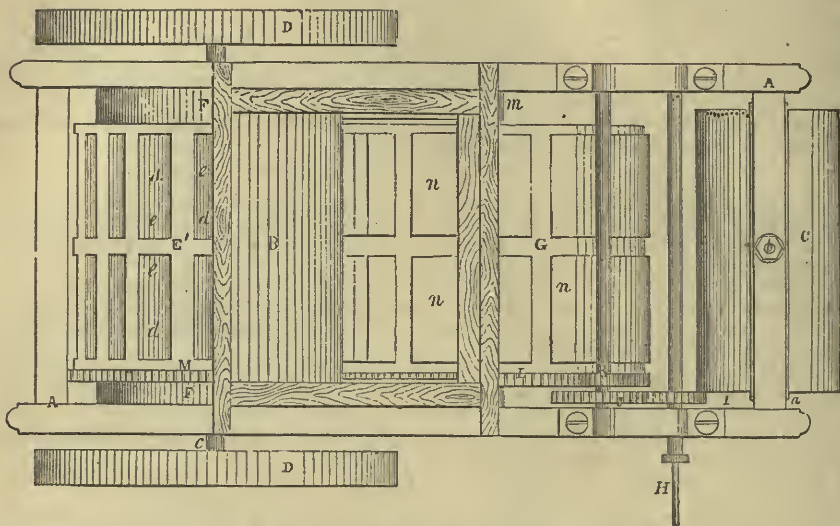


Fig. 613 is a view in detail of a grooved channel and cam, used in working the followers.

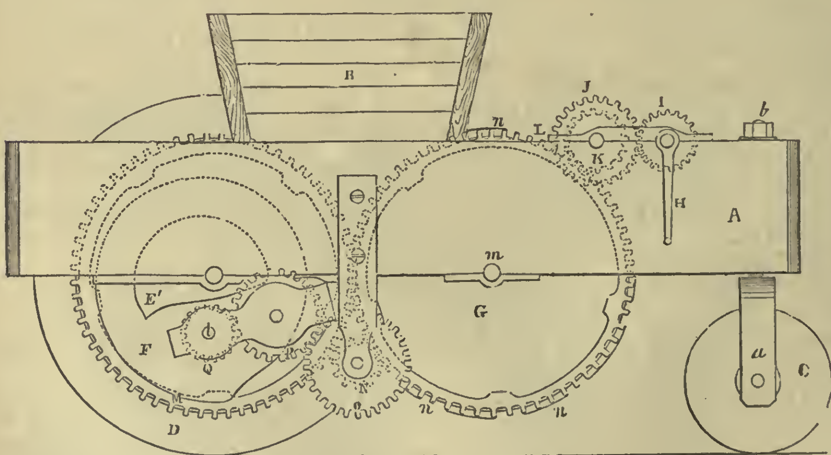
The same letters of reference denote similar parts throughout the several figures.

The nature of this invention consists in the use of two cylinders set horizontally in a suitable framing and revolving in opposite directions, being driven by geering, which also propels the machine forward as the brick is being made.

609.



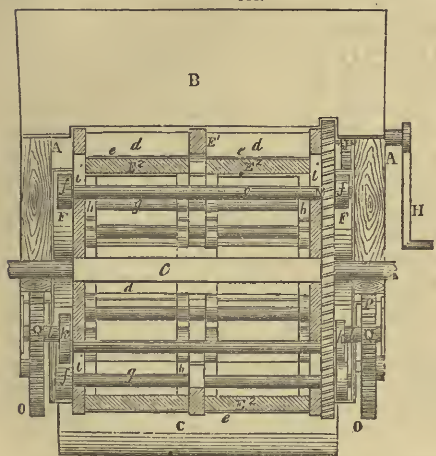
One of these cylinders is fitted with moulds, working in which are followers, forming the bottom of the moulds, and operated by rollers moving in fixed grooved channels, and by cams producing the drop-motion. The second or pressing cylinder is provided with plates working and fitting into the moulds of the other cylinder, pressing the clay, which is fed from a hopper above and between the two cylinders, the clay being drawn into the several moulds by its own weight and the revolving motion of the cylinders, and the bricks deposited on the ground or surface prepared for them, in regular layers or line as the machine moves forwards; a roller in front clears or prepares the ground or surface on which the bricks are to lay. The followers in the moulds are covered with cloth or similar material to prevent the clay or soft bricks from adhering to them—the machine being worked by hand or other power

To enable others skilled in the art to make and use this invention, the inventor describes its construction and operation as follows:

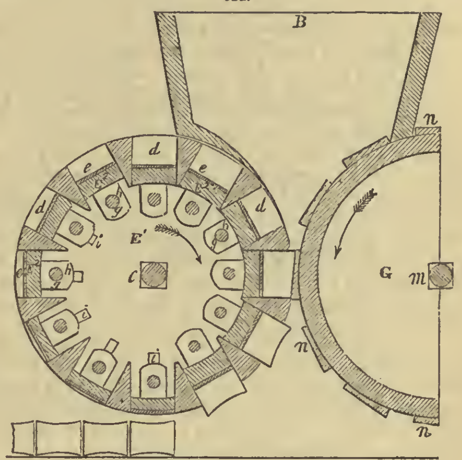
A A is the frame of the machine; B, the hopper through which the clay is fed; C, a levelling-roller, serving to carry the machine, and to clear or prepare the yard for deposit of the bricks; it works in a strap *a*, having a swivel-spindle *b*, to admit of the machine being moved about in any direction.

D D are travelling or propelling wheels fitted on the mould-cylinder shaft *c* and turning with it; E′ is the mould-cylinder keyed fast to the shaft *c*; it is made of iron, or other suitable material, and has on its circumference or surface spaces *d d d* forming the moulds. The number of moulds is not limited to two rows, as shown in the drawing, but will be dependent upon the length of the cylinders as well as the diameter; each mould or space *d d d* being only of the length of the brick, so that the machine may, if required, be constructed to form three or more layers.

611.

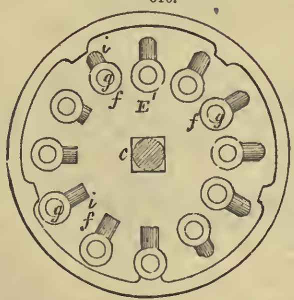


612.

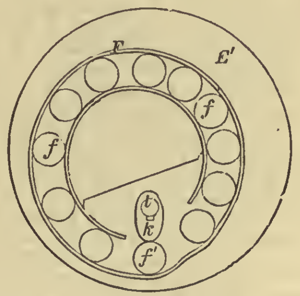


E^2 E^2 E^2 are followers, or plungers, working in and forming the bottom of the mould; they are covered on their top with fine cloth *e e e*, and are of length and breadth so as to fit loose in the moulds *d d d* in which they move, motion being given to them by rollers *f f f*, which turn on spindles *g g g* running through the cylinder E′ lengthways, passing through slots *i i i* at both ends; the spindles *g g g* are connected to the followers E^2 E^2 E^2 by pieces *h h h* attached to them, through which the spindles *g g g* pass, the rollers *f f f*, as the cylinder E′ is caused to revolve, moving in fixed grooved channels F F secured to the framing A A, the interior of one of which is seen in Fig. 3994, being positioned with relation to the cylinder E′ in the manner of an eccentric, one at either end, but differing from an eccentric in their being made of a scroll or irregular curve formation. The rollers *f f f*, travelling in the grooved channels F F, cause the followers E^2 E^2 E^2 to move in the moulds *d d d*, the followers at their bottom stroke leaving a space in the mould equal to or rather exceeding the thickness of a brick, and when forced out, working nearly to the outer edge of the moulds *k k*.

610.



613.



In fig. 613, are represented cams attached to shafts *l l*, and so positioned and set as to form as many revolutions for one revolution of the cylinder E′ as there are moulds in a single row, causing the cams *k k*, one at either end, to strike the rollers *f f f*, two together, that is, one at either end, and so on for all the rollers successively as they assume the position of *f*′, Fig. 613, causing the formed bricks to be shaken from their moulds when arriving at a perpendicular position. The bottom of the mould-cylinder E′ is situated rather more than the thickness of a brick from the ground or yard surface.

G is the pressing cylinder revolving in the opposite direction to the cylinder E′; it is keyed on the shaft *m*. *n n n* are pressing-plates fitted on the circumference or surface of the cylinder G, correspond

ing to the spaces or moulds *d d d* in the cylinder E′, into which they fit or press the clay; they are made thicker at the edge first entering the mould than the finishing or after edge, as shown more particularly in Fig. 612.

H is a handle for giving motion to the machine, (but the arrangement may be such that steam or other power may be applied.) I is a pinion turned by handle H; it operates a wheel J, on the shaft of which is a pinion K working into a wheel L fitted fast to the side of the cylinder G; the wheel L is in geer with a corresponding wheel M attached to the cylinder E′; the wheel L also drives a pinion N, on the shaft of which are wheels O O, one at either end, working into similar wheels P P that drive pinions Q Q fitted on the cam-shafts *l l*, which they operate. The relative proportions of these several wheels and pinions are such as not only to obtain additional power, but to operate the drop-motion formed by the cams *k k* at a proper time—that is, to strike the rollers when they assume the position of *f′*, Fig. 613, so as to release the brick, and likewise to operate the propelling or travelling wheels, which are of a suitable relative diameter, so that the machine will move at a speed proportioned to the discharge of brick, causing the bricks made to be deposited regularly, side by side, in layers.

The operation is as follows: clay being put into the hopper B, the handle H is made to turn, and by wheels and pinions I J K L and M the cylinders E′ G are made to revolve in opposite directions, as shown by arrows in Fig. 612, drawing the clay, partly forced by its own weight, into the moulds *d d d*; the pressing plates *n n n*, entering the moulds at their thick edge first, press, and together with the moulds form the brick; the plates *n n n* leaving the moulds at their thin edge, obviates the tendency which the soft brick has of being pressed thinner at the side or edge, receiving the last or latest impression. While the cylinders E′ G are performing this operation, the machine, through means of the propelling wheels D D, is moving forwards, and the several followers or plungers E^2 E^2 E^2 are being worked by means of the rollers *f f f* travelling in the fixed grooved channels F F, which causes the followers or plungers E^2 E^2 E^2 to draw in for receiving the clay, and when the brick is made to be forced out, and so drive out the brick, which is further released from the mould by the action of the cams *k k*, driven by the geering N O O P P Q Q, the cams *k k* striking the rollers *f f f* when arriving in the position of *f*, Fig. 613, and dropping or shaking the brick from the followers, which, being covered with fine cloth or other similar material, are not so liable to retain or cause the soft brick to adhere. The bricks are laid in the yard side by side and in perfect layers, in the manner shown in Fig 612, the number of layers being dependent upon the size of the machine or length of the cylinders E′ G, which may have one, two, three, or more rows of moulds or pressing-plates. This machine, therefore, not only makes bricks rapidly, but of an equal thickness, sound and perfect; and by being locomotive, can be moved about in any direction as convenience suggests, laying in the yard in regular order the bricks as made.

BRICK-MAKING MACHINE—Whipple's *Improvement, patented March* 25, 1851. Fig. 614 is a diagram illustrating the pulverizing or crushing action of the machine.

Fig. 615 is a side elevation of the machine.

Fig. 616 is a front or end elevation.

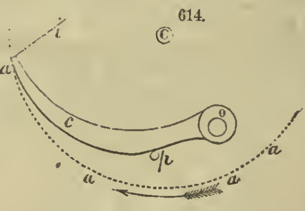
Fig. 617 is a longitudinal section.

Fig. 618 is a transverse section.

The same letters of reference denote similar parts throughout each of the several figures.

The nature of this machine consists in the use of a revolving screen working on a stationary axis set at a slight inclination from a horizontal position, and having attached to, or suspended from it, lugs or crushers, which, by their weight, serve to pulverize the clay; the stock or clay being fed in at one end of the screen, which by its revolving motion carries or drags the stock under the lugs or crushers, thereby breaking and pounding it; the pulverized clay falling through the apertures of the screen, and the waste or hard lumps and stones mixed up with the stock being expelled at the back or lower end of the screen.

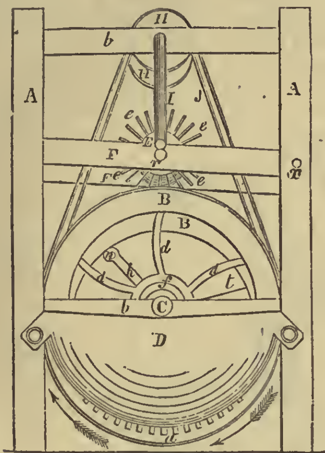
614.



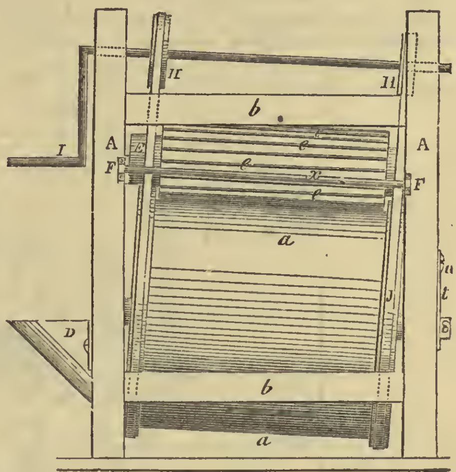
A A are uprights having cross or tie pieces *b b b*, which constitute the framing of the machine, or any similar suitable form of framing may be adopted; *a a a* are the bars forming the screen; they may be placed at any required distance apart, and are bound, or secured, in a cylindrical form, by hoops B B, into notches in which the ends of the bars *a a a* may fit, or be otherwise attached. To the hoops B B are arms *d d d*, connected with naves F F, which form the rotary bearings of the screen; the bars *a a a a* should be of such a shape in their cross section and so arranged as that any particles once entering the spaces, from within, between them, will readily pass off, that is, they should be broader on their interior than their exterior edges, thus making the outside width of the spaces greater than the inside, as is the case with many descriptions of fire-grates now in use; and for which purpose bars of a triangular, or any appropriate shape, may be used, their narrowest or curved face or sides being set outside: or the screen may be made of a cylinder having slots or openings corresponding to spaces formed by the bars *a a a a*. C is the stationary axis on which the naves F F of the screen rotate; it rests on the lower cross-pieces *b b*, and is kept or prevented from turning by its back end *s* being made square, and an arm *t* being fitted into it, the other end of the arm *t* being fastened to one of the uprights A by a screw *u*, Fig. 615, or any other simple and well-known arrangement may be used for keeping the axis C stationary; which is set, as will be seen by reference to the drawings, at a slight inclination from the horizontal position, for the purpose of giving the screen a corresponding position, or a dip at its back end. D is a feed-hopper or trough, which also is stationary. To the axis C are keyed, or otherwise secured, arms *h h l l m m*, seen more particularly in Figs. 617 and 618. *n* is a cross-bar connecting the arms *h h*. O is a bar connecting similar arms *l l*, and *p* a rod connecting the arms *m m*. *c c c c* are lugs or crushers having their fulcrum, or working as a hinge-joint, on the rod O, and at their other extremity

attached by cords or chains *i i i i* to the bar *n*, and resting on at their lower edge, or supported, by the rod *p*: either arrangement of the arms *h h*, cords or chains *i i i i*, or cross-bar *p* and arms *m m*, may be used for supporting or holding the lugs from touching or rubbing the screen; or both arrangements, as shown and described in combination, may be used. The lugs or crushers *c c c c c* may be made of any material, size, shape, and weight. *e e e e* are pickers arranged in a radial form round a small drum E, keyed to an axis *r*, working at either end in side-levers, or pieces F F. The pickers *e e e e* are of nearly the same length as the bars *a a a a* of the screen, and are of proper thickness and width apart to drop into the spaces between the bars *a a a a*. The side-levers F F are hung on a rod *x*, forming a joint on which to work, and their other end connected by a bar G, which is held by a catch or hook *g*, Fig. 618, H H are pulleys, being driven by a handle I, attached to their shaft or axis. The pulleys H H serve to drive the screen by straps J J, which pass round them and the hoops B B.

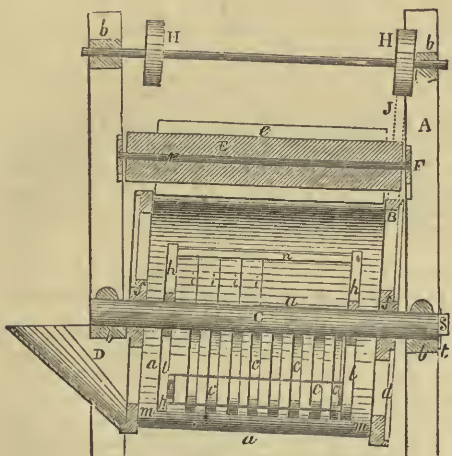
616.



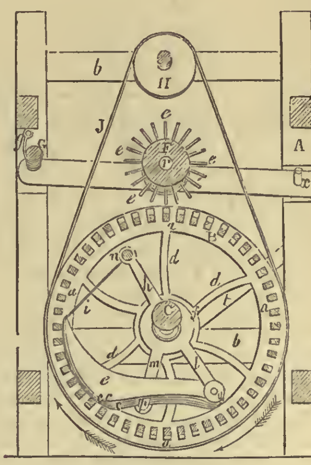
615.



617.



618.



I will now proceed further to describe the operation. The stock, or rough clay, is fed by the hopper D into the screen formed of bars *a a a a*, entering under the lugs *c c c c c*, and by the revolving motion of the screen in the direction shown by the arrows, Figs. 614, 616, and 618, the stock is carried under the lugs *c c c c c*, which yield or give, working on their joint *o*, and so produce a pressure by their weight on the clay, which serves to clear the stock, the fine and workable portion being pulverized and passing through the spaces between the bars *a a a a*, and the waste or hard lumps and stones mixed up in the stock, being worked out of the back end of the screen, the inclination of which downwards, and the revolving motion of the screen serving to expel the same. The object of the rod *p*, or cords *i i i i*, is to prevent the lugs from rubbing the screen, which would create unnecessary friction. The several lugs or crushers may be made of different sizes, shapes, or weights; those at the mouth of the screen, if desirable, made so as to merely break the stock, and the after-crushers

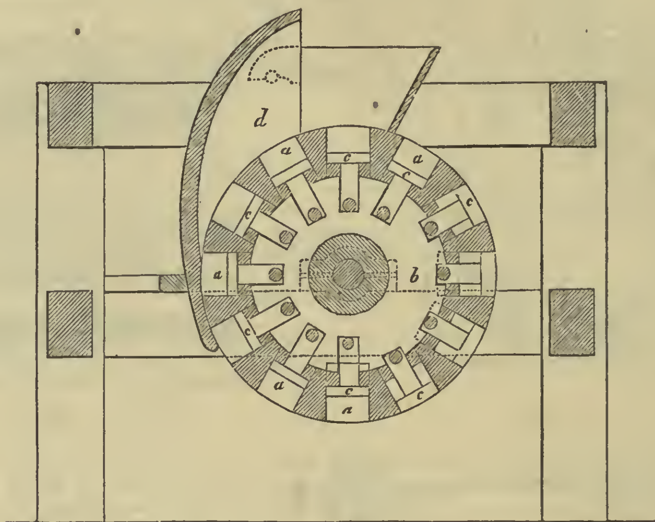
or lugs to pulverize the finer clay which is collected under the screen formed by the bars *a a a a*, and is thus tempered or prepared for making bricks.

The pickers *e e e e* may be thrown in or out of geer with the bars *a a a a*, by lowering or raising the side-levers F F, working as a hinge-joint on the rod *x*. By unfastening the hook *g*, Fig. 3999, the pickers *e e e e* are thrown in geer, entering the spaces of the bars *a a a a*, which, as the screen rotates, drives or causes to rotate also the pickers *e e e e*, which pick out or clear the screen of any soft clay or dirt which may clog the spaces between the bars *a a a a*. By the hook *g* the picker is thrown in or out of geer, and used only as required.

BRICK PRESS. *Patented by* John Riddle, Covington, Ky., April, 1851. In order to the formation by simple pressure, from untempered clay, of bricks possessing the requisite unity and coherency of structure, it is absolutely essential that the pressure should be uniform throughout their entire mass.

This result has never, to our knowledge, been attained, except by the application of pistons on opposite sides of the brick; but this mode, although (while the machinery remains in working order) adequate to the formation of a good article, is particularly ineligible, on account of its liability to clog and become deranged. The fact is, a brick-machine should have as few working joints as possible, especially in those parts which are in immediate connection with the clay.

619.



Machines in which the bricks are formed either in the circumference of a large wheel or in a straight bed of moulds, in connection with a wheel, by a simple rolling motion, have the requisite simplicity, but the pressure not being applied to all parts of the clay at once, the mass, while being pressed down at one part, rises up at other parts, which have passed the point of pressure, and cracks and becomes unequal in consistence; and having once taken its set, no pressure afterwards is adequate to rectify the defect. These difficulties the inventor has entirely overcome by a working machine containing the following devices, to wit:

Fig. 619 is a longitudinal section through the mould-wheel and its appurtenances.

The moulds *a* are placed around the perimeter of a wheel *b*, and the pressed brick may be extruded by followers *e*, which may fall back against a solid shoulder in the wheel, as usual.

The distinguishing features, however, of this arrangement exist in the peculiar construction of the feed-trough *d*, and its appendages; the trough is made to gradually narrow downwards, until it comes closely in contact with the rim of the wheel, and is thence extended forward in the form of a lip or flange *o*, hugging closely the wheel, and made to bear hard up against it, so that the clay, after its introduction into the trough, is squeezed into a smaller and smaller compass, as it descends, and by this means is pressed forcibly into the mould, until, coming in contact with the lip, the entire mass receives its ultimate compression powerfully and equally applied in every part.

BRIDGES. Bridges are constructed of various materials, arranged in varied forms. Bridges of stone or brick are arched; of wrought iron, tubular and trussed; of cast iron, plain girders; of wood, trussed. Cast and wrought iron are often used together; wood and wrought iron, in trussed and suspension bridges.

The forms of arches are varied—the semicircular, the segmental, and the elliptic. The most common form in use in this country is the segmental (fig. 621), the arc subtended being about 45°. Without going into the theory of the arch, requiring considerable mathematical knowledge, we proceed to give certain rules from the best authors, and examples of construction, to enable the mechanic to proportion the parts of a structure.

That the voussoirs of an arch may resist crushing, they must have a certain depth proportioned to the pressure of the arch; and as this increases from the curve towards the springing, the depth of the voussoirs should likewise increase from the crown to the springing. Peronnet has given as a rule for

the depth at the crown the formula $d =$,07 $r + 1$ foot, in which formula r is the greatest radius of curvature of the intrados. This formula is applicable to arches less than fifty feet radius; but beyond this it gives greater dimensions than in ordinary practice. In order to facilitate investigations on the stability of arches of the more usual forms, M. Petit calculated a series of tables, of which we give the abstract for circular arches, as the class occurring most frequently in practice.

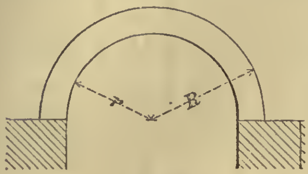


Fig. 620.

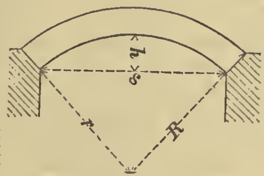

Fig. 621.

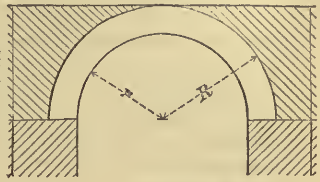

Fig. 622.

To find the thickness of abutment necessary to support the thrust of the arch, multiply the co-efficient found in the table for the particular case by 3.8, and the square root of the product multiplied by the radius, r, of the intrados, will give the extreme thickness of the abutment.

CO-EFFICIENT OF HORIZONTAL THRUST AT THE CROWN.

1.25	0.128	0.139	0.126	0.114	0.100	0.086	0.084	0.072
1.20	0.111	0.131	0.110	0.102	0.091	0.070	0.066	0.056
1.15	0.092	0.119	0.091	0.086	0.079	0.063	0.049	0.041
1.10	0.068	0.103	0.067	0.065	0.062	0.052	0.042	0.027
1.05	0.038	0.082	0.038	0.038	0.037	0.034	0.029	0.019

Example.—What is the horizontal thrust, and what the thickness of abutment necessary to support an arch of ten feet span and two feet rise?

$$\frac{s}{h} = \frac{10}{2}, \text{ therefore } s = 5h.$$

$$\frac{r}{h} = \frac{r}{2} = 3.625 \qquad r = 3.625 \times 2 = 7.25 \text{ ft.}$$

By Peronnet's formula, $d = 0.07 \times 7.25 + 1 = 1.50$.

$$R = 7.25 + 1.50 = 8.75$$

$$\frac{R}{r} = \frac{8.75}{7.25} = 1.20$$

By the table against 1.20, under the column $s = 5\ h$, we find 0.102 as the co-efficient of thrust, 150 lbs. being taken as the average weight of a cubic foot of masonry, the absolute thrust per square foot of surface is

$$0.102 \times 150 \times \overline{7.25}^2 = 804 \text{ lbs.}$$

$$\sqrt{0.102 \times 3.8} \times 7.25 = 4.50 \text{ feet, thickness of abutment.}$$

The formula gives the thickness of abutment, supposing the height infinite; for low abutments, the thickness may be reduced, for common spans, about ten per cent.

In the loading of a semicircular arch, especially, the tendency of a weight applied at the crown, is to rise the haunches. This is to be counteracted by backing with masonry at these points called the spandrel backing. When the arch is to be covered with earth, care should be taken in loading the arch evenly at both sides. The same remark applies to the setting of the arch-stones on the wooden centres whilst in process of construction.

The following table gives the dimensions of the arches of a selection of bridges of European construction.

LOCATION.	Material.	Form of Arch.	Span.	Rise.	Depth at crown.	Depth at spring.

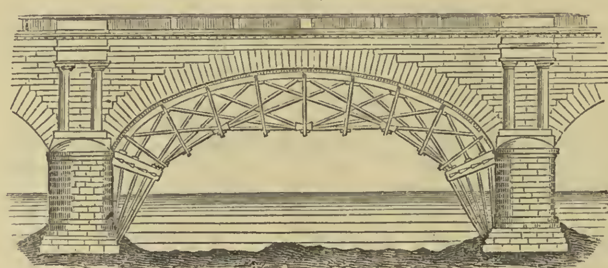
For smaller culverts of 15 to 30 feet span, the usual construction is to make the arch from 1 foot 6 inches to 2 feet deep. Arches in stone are seldom turned less than 1 foot deep, whatever may be the span; brick arches for less than 10 feet span are generally 8 inches, and this depth is required by building acts.

623.

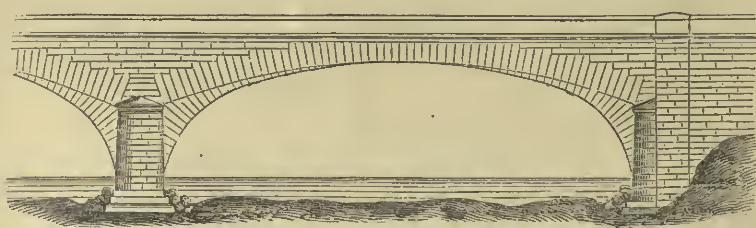


Details of one of the arches and centreing of Waterloo Bridge.

Waterloo Bridge, London, by Rennie, is considered a masterpiece. It was commenced in 1810, it is a level bridge, having nine arches, each 120 feet span, and 35 feet rise, and it is 42 feet 4 inches wide between the parapets.

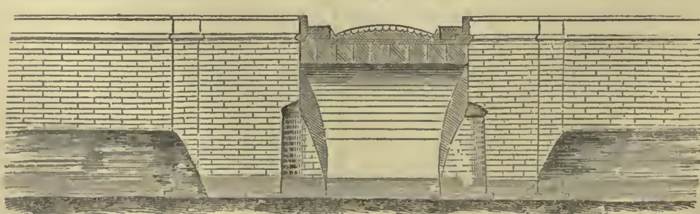
The bridge across the Seine, at Neuilly, built between the years 1768 and 1780, by Péronett, is a

624.



Elevation of one of the arches of Neuilly Bridge.

625.

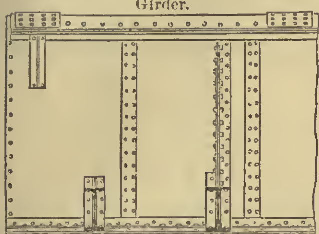


Transverse section of Neuilly Bridge.

very celebrated structure; it is also a level bridge, consisting of five elliptic arches, each of 128 feet span, and 32 feet rise.

Iron bridges.—The most popular form of wrought iron bridges in England is the tubular, applied on a large scale, the travel being in the interior, as at the Conway and Menai Bridge. See CONWAY TUBULAR BRIDGE. Or girders being constructed on this principle, over which the travel passes. See STRENGTH OF MATERIALS. The first bridge of this latter class, in this country at least, was built in 1846-7, on the Baltimore and Susquehanna Railroad, by James Milholland. Figs. 626, 627, 628, 629, represent still another form of plate-iron bridge, as designed by Mr. Martin, the engineer, to carry the railway from the London and North-Western Railway to the East and West India Docks. It carries the railway over Randolph street, Camden Town.

Fig. 626.—Side View of Longitudinal Girder.



The peculiarity consists in constructing the bridge with two side girders, each of a single web, of plates of iron, 71 feet long, 6 ft. 7½ inches high, and $\frac{5}{16}$ inches thick; put together with plates 5 inches wide, overlapping the vertical joints, and ¾-inch rivets placed 3 inches apart, and fixed to the top and bottom plates by angle-iron 3 inches wide, and ¾-inch rivets. The bottom plate is 2 ft. 8 in. wide, made with $\frac{5}{16}$-inch plates in lengths of 8 feet each, with plates overlapping the joints 6 in. wide. The outer flange is curved down 1 inch, to throw off the wet; the top plate is 2 ft. 8 in. girt, made with $\frac{5}{16}$-inch plates, excepting the three middle plates, which are ⅜-inch in thickness; the top is curved down 5 inches, and put together with inch rivets. The girders are stiffened by eight vertical plates on each side of the web, of $\frac{4}{16}$-inch iron, fixed by angle-iron 3 inches wide, and ¾-inch rivets placed 4 inches apart. There are also two similar stiffeners at each end, of ⅜-inch iron. The top plate is further stiffened by stays of T-iron, 5½ inches wide between each pair of stiffeners.

Fig. 627.—Enlarged Section of Girder, showing the Stiffeners,

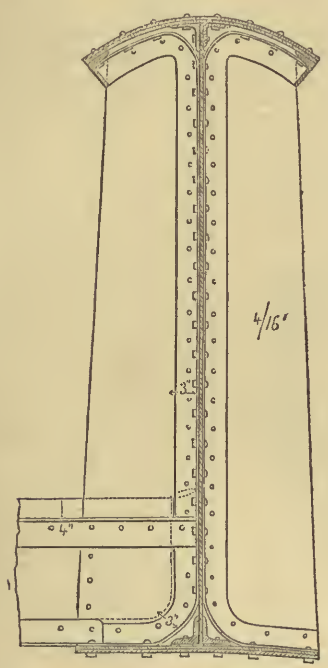


Fig. 628.—Section through Girder, showing the Stays to Stiffen the Top Plate.

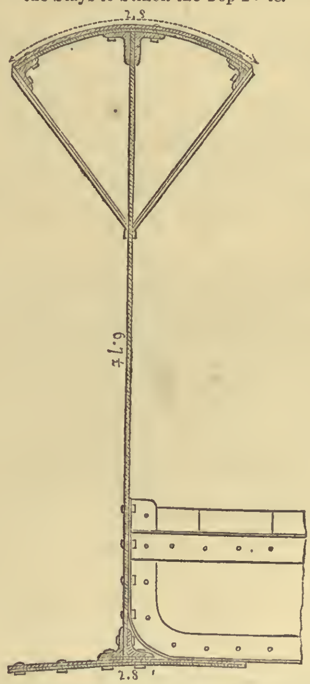

The cross girders are 24 ft. 6 in. long and 1 ft. 4 in. high, made with ⅜-inch plates in three lengths, and stiffened by angle-iron top and bottom, and on each side, 3½ inches wide, and fastened with ¾-inch rivets 4 inches apart. The ends of these cross girders rest upon the two girders first described.

Fig. 629.—Transverse Section.

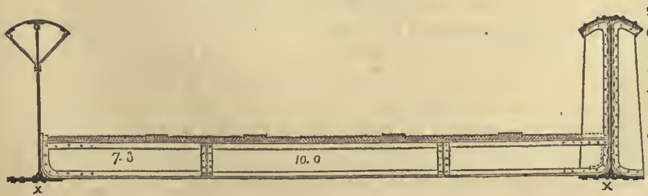

Fig. 629 is a cross section of the bridge. Fig. 626 is a side view of part of one of the longitudinal girders. Fig. 627 is an enlarged section of one of the girders, showing the stiffeners. Fig 628 is a section through the same girder, showing the tays to stiffen the top plate.

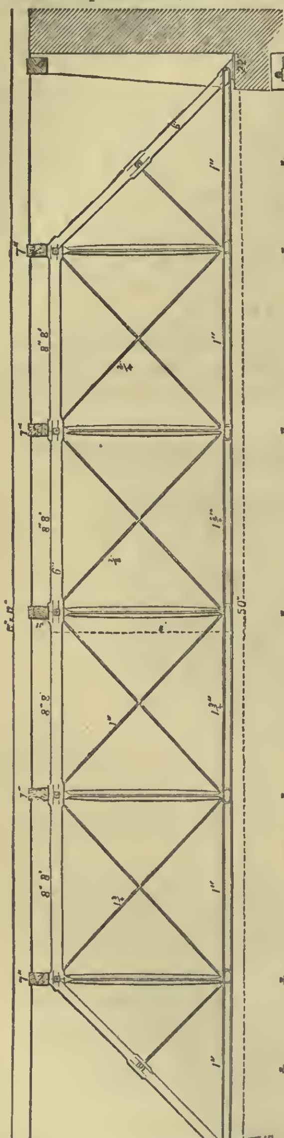
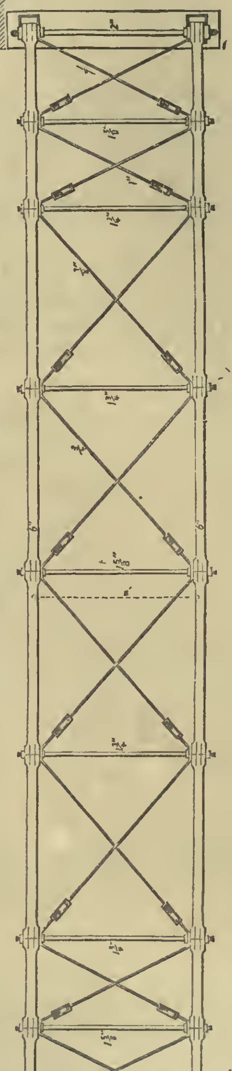
Cast-iron bridges.—Bridges constructed of this material alone are usually of short span and simple girders. See STRENGTH OF MATERIALS. Cast iron as a material is not considered as safe as wrought iron or wood; from some flaw, from frost, or from sudden jars, it gives way without notice; but as it is stronger per square inch than wrought iron in resisting a crushing force, it has been applied in connection with wrought iron where the strain is of this description. Whipple's bridge, figs. 630, 1, 2, 3, 4, is a bridge of this description.

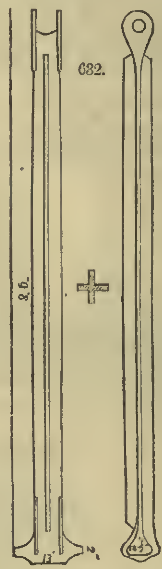
630.



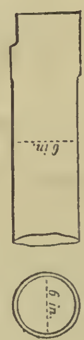
631.



632.



633.



634.

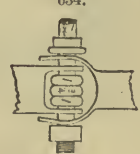


Fig. 630 represents the elevation, fig. 631 the plan, and figs. 632, 3 and 4, the details of framing. This bridge consists of two iron trusses of 50 feet span, and 9 feet high. What would be called the upper chord consists of cast-iron pipe, 6 inches in diameter, and $\frac{1}{2}$ inch thick, equal to 9 square inches—cast-iron uprights of + section, and 8 feet 4 inches apart from centre to centre, connect the upper chord on which the track rests, with the bottom or tie. This latter is of $1\frac{1}{4}$ round iron, in loops, two of which, side by side, constitute the tie between each pair of uprights. These loops pass over shoulders at the foot of the uprights, through which shoulders pass the diagonal $1\frac{1}{4}$ inch wrought-iron rods, secured and adjustable by nuts. The dimensions of all parts of this bridge are proportioned to the strains they are to receive, and were calculated to withstand a rolling weight of 2,000 lbs. per running foot.

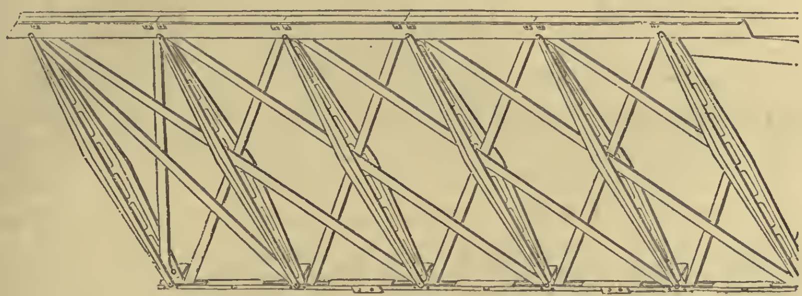
The weight of one truss with its proportion of track is less than three tons, or 6,720 lbs.. which is equivalent in its strain to 3,360 lbs. placed on the centre of each truss, to which add the weight at the centre to a load of 2,000 lbs. per foot run, viz., 25,000 lbs., and we have, as the weight on the centre of each truss, 28,360 lbs.

The Rider iron bridge, of which fig. 635 is an isometrical view of the method of framing, is also a combination of wrought and cast-iron in the form of a truss, but it is deficient in strength. The upper chord is of cast-iron, in two parts, bolted together, and "breaking joint," and forming a T section of about 12 square inches. The lower chord is of wrought-iron, composed of two plates, each 4 inches deep, by $\frac{1}{2}$ inch thick, placed side by side, with an interval of $\frac{5}{8}$ inch between them to receive the diagonal rods. These plates also "break joint," and at the joints have an additional plate of the same depth and thickness, and nearly two feet in length; the whole secured together by four bolts, two on

635.



each side of the joints. The uprights or posts connecting the chords, and to which they are bolted, are of cast-iron, about 3 feet 4 inches apart, of an H section, and of 8 square inches in area. Through a hole in the centre of these pass the diagonal rods, two in each pannel, of wrought-iron 2 by $\frac{5}{8}$ inches in the centre, and $2\frac{1}{4}$ by $5\frac{5}{8}$ inches at the ends; these are also bolted to the top and bottom chord.

Bollman's Bridge is still another combination of the same sort, but differs from the others in that there is no bottom chord necessary. The top chord and posts are of cast-iron, and the bottom of each post is supported by rods to either end of the upper chord. It may be considered a trussed cast-iron beam. The principles of the construction will be readily understood from the description. The largest of these bridges is at Harper's Ferry, and they are used considerably on the line of the Baltimore and Ohio Rail Road.

636.

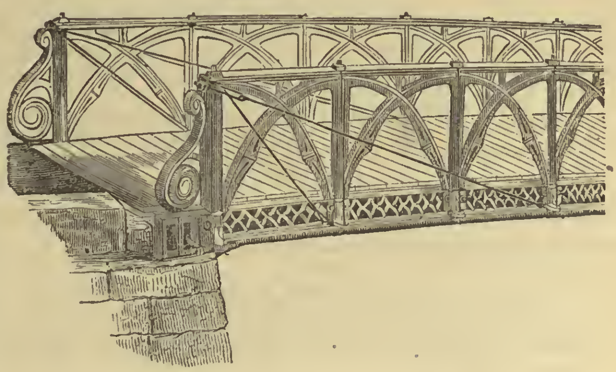


Fig. 636, is a perspective view of a part of Severson's Iron Bridge, near the abutment; it is cambered about 1 in 80 or 100—the whole combined forming a trussed girder. The sides or body of the truss, when made of cast-iron, will be composed of pieces, or voussoirs, corresponding in all parts with the arc of a circle, having a verse sine of 1 to a chord of 80 or 100. The ends and joints between the voussoirs being radii, the main ties made of wire cables, and the lower and upper parts of the voussoirs, will form three concentric arcs.

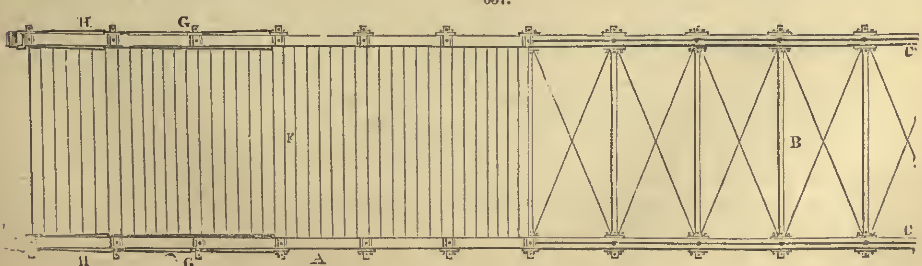
In fig. 637, at F is represented a portion of the floor as

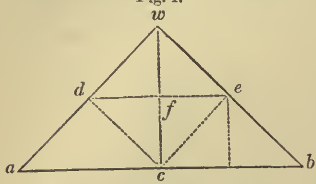
637.



seen from above; A, the upper rail, or arc; G G and H H the quarter braces; E, end pieces. At B is half the bridge as seen from below; D D, bottom of end pieces; C C, main cables, or ties. The sway-braces and under side of girders between C C at B.

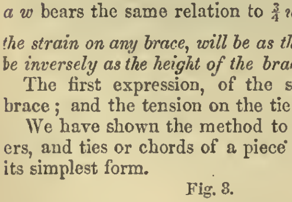
Wooden Bridges.—The simplest form of bridges is of course composed of single beams or string-pieces spanning the opening, on which are laid the floor-planks. For the strength of such beams, see STRENGTH OF MATERIALS. But as such constructions are only applicable to small spans, framed structures become necessary. We proceed therefore to investigate the general principles of trussing, applicable as well to iron as wooden constructions.

Fig. 1.



Commencing with the simple truss, let $a\ w$, $b\ w$ be two equal braces connected at the foot by the tie $a\ b$, and neglecting its own weight for the present, suppose the truss to sustain a weight W at the point w. Draw $w\ c$ perpendicularly to the tie, and let it represent in magnitude the weight W, that is to say, so many pounds as there are in W; let there be inches or half-inches or any convenient unit of measure in $w\ c$. Draw $c\ d$, $c\ e$, respectively parallel to $w\ b$ and $a\ w$; now by the composition and resolution of forces, $w\ e$, measured by the same scale as $w\ c$, will represent the thrust in the direction of $w\ b$, caused by the weight $w\ c$ or W; and $w\ d$ likewise equals in direction and magnitude the strain or thrust in the direction of the brace $a\ w$. We suppose the framing to rest at the points a and b on immovable supports; of course, half the weight, $\frac{1}{2}$W, will bear on each support, a and b; and the action at these points will be compounded of a vertical pressure equal to $\frac{1}{2}$W, and a horizontal strain or tension in the direction $a\ b$, equivalent to $\frac{1}{2}\ \mathrm{W}\ \frac{a\ c}{w\ c}$ For drawing $d\ e$, parallel to $a\ b$, bisecting in $f\ d\ f$ represents the tension on the tie $a\ b$. For *when three forces are in equilibrio about a point, if two of them are represented in direction and magnitude by the two sides of a triangle, the third side of this triangle must represent in direction and magnitude the third force.* Now, the point a is acted upon by three forces: an upward resistance equivalent to $\frac{1}{2}$ W, a pressure in the direction $w\ a$ equal to $d\ w$, and the tension of the tie $a\ b$ which will be the third side of the triangle of which the other two are $d\ w$ and $f\ w$, that is, $d\ f$; and in the similar triangles $w\ d\ f$, $w\ a\ c$, $d\ w : f\ w :: a\ w : c\ w$; and $d\ f : f\ w :: a\ c : c\ w$; or the strain in the direction of $a\ w$ bears the same relation to $\frac{1}{2}$ W that $a\ w$ bears to $c\ w$, and the tension on the tie bears the same relation to $\frac{1}{2}$ W that $a\ c$ bears to $c\ w$, or tension $= \frac{1}{2}\mathrm{W}\ \frac{a\ c}{c\ w}$ On the supposition that the braces are of different lengths, or the weight not immediately over the centre of the tie $a\ b$, we should still have the respective strains determined in the same manner. Thus $w\ c$ representing the weight w, sustained by the braces $a\ w$ and $b\ w$. Completing the parallelogram on this as a diagonal with the direction of the forces for the sides, and drawing $d\ f$ parallel to the tie $a\ b$, we have as the result of this arrangement an inequality in the action of the weight on the points a and b. $w\ f$ represents the weight on the point a, and $f\ c$ represents the weight on the point b; and the side of the triangle $w\ d\ f$, as in the first case, represents all the forces in operation on the point a—viz.: $w\ f$ (the weight on a) which bears the same relation to $w\ c$ (or the whole weight) that $c\ b$ bears to the whole tie $a\ b$. $d\ w$, the strain on the brace $a\ w$, and $d\ f$, the horizontal tension in the direction of the tie $a\ b$.

Fig. 2.

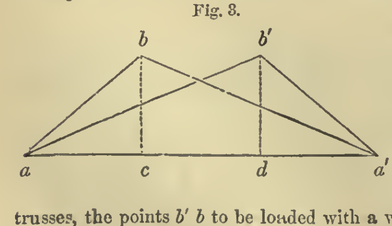


To determine these strains in terms of the given dimensions, as in the first example, we have (taking for convenience of calculation $a\ c$ as some multiple of $a\ b$, say $\frac{1}{4}$) by similar triangles, $d\ w : f\ w : a\ w : c\ w$, and $d\ f : f\ w :: a\ c : c\ w$; or the strain in the direction of $a\ w$ bears the same relation to $\frac{3}{4}\ w$ that $a\ w$ bears to $c\ w$; or $d\ w = \frac{3}{4}\ \mathrm{W}\ \frac{a\ w}{c\ w}$ and $d\ f = \frac{3}{4}\ \mathrm{W}\ \frac{a\ c}{c\ w}$ or *the strain on any brace, will be as the length of the brace, divided by its height, and the tensions on the tie will be inversely as the height of the braces.*

The first expression, of the strain on the brace, is the cosecant of the angle of inclination of the brace; and the tension on the tie is the cotangent of the same angle.

We have shown the method to be pursued in calculating the strains on the respective braces or rafters, and ties or chords of a piece of framing, which may be either a truss for a roof, or for a bridge in its simplest form.

Fig. 3.



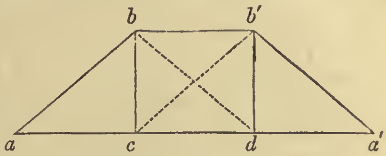
For short spans of either roof or bridge, say from thirty to forty feet, either of the two following forms may be used: The simplest is that shown in fig. , the truss resting on the points $a\ a'$, and the roadway bearing on those points, and on cross bearers at the points c and d. This form of truss is, however, less economical than that of fig. , and less rigid.

For the purpose of comparison, take $a\ a'$, in figs. , divided into three equal parts at the points c and d, and suppose, with the same height $b\ c$ to the two trusses, the points $b'\ b$ to be loaded with a weight, w.

Now it is clear that the weight on the points a and a' is the same in each truss, but the tension on

the tie is in the case of fig. 4, at a, $\frac{a\,c}{b\,c}$ w; but the tension on the tie of fig. 3 is, as before shown, $\frac{2\,a\,c}{3\,b\,c}\,\mathrm{w} + \frac{1\,a\,d}{3\,b'\,d}\,\mathrm{w}$. Substituting in this expression the value of $a\,d$, which $= 2\,a\,c$, and of $b'\,d$, which $= b\,c$, we have the tension $= \frac{4\,a\,c}{3\,b\,c}$ w, which is $\frac{1}{3}$ greater than in the case of fig. 4, of course requiring $\frac{1}{3}$ more material; which excess is not offsetted by the additional material required in the braces $b\,d$, $b'\,c$, of fig. 4, which is the preferable form, unless the abutments sustain the thrust; for in the latter case in fig. 4, the braces $b'\,c$, $b\,d$ cannot act directly on the abutments, as they may do in the case of fig. 3.

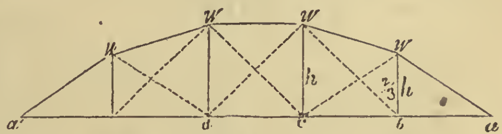
4.



Extending our investigation to longer spans, of say from 40 to 80 feet, the number of bearing points for the distribution of the weight being increased in the proportion of the length, a comparison analogous to the preceding, will show the most economical arrangement for the timber of such a bridge. The independent brace for each point of support, throwing their weight directly on the abutments, is found not to be so economical as the introduction of a straining piece between the heads of the verticals.

Taking the two trusses fig. 5 and 6, of the same span and rise, and divided into five equal spaces, giving four points of support for the load, which we will suppose to be distributed equally at the several points.

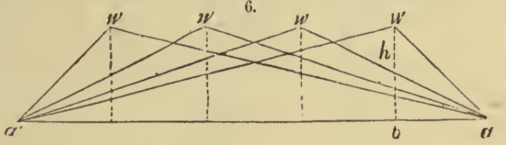
5.



In truss fig. 5, let $a\,a' = 5$ and $a\,b$, $b\,c$ each $= 1$. Let $w\,c = h$ and $w\,b = \frac{2}{3}\,h$. The points $a\,w\,w\,w\,w\,a'$ may be considered as points in a circular arch, and in equilibrio under the weights $w\,w\,w\,w$.

The horizontal thrust on the tie, produced by the weights $w\,w$ &c., is $= \frac{3\,w}{h}$.

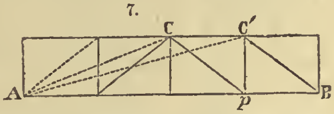
6.



For, as already shown, the action of tension in this case will be represented by $\frac{a\,b}{\frac{2}{3}\,h}\,\mathrm{w} + \frac{a\,b}{\frac{2}{3}\,h}\,\mathrm{w} = \frac{3\,w}{\frac{2}{3}\,h} = \frac{3\,w}{h}$.

In the case of the independent braces, fig. 6 being an equal space and rise, $a\,a$ and h, and loaded with the same weight at the point, $w\,w$, &c. Each pair of braces will exert a certain thrust, and the tension on the tie will be expressed by the sum of the several thrusts produced by all the weights, or $\frac{4}{5}\,\frac{w}{h} + \frac{3}{5}\,\frac{2\,w}{h} + \frac{2}{5}\,\frac{3\,w}{h} + \frac{1}{5}\,\frac{4\,w}{h} = \frac{4\,w}{h}$ is the tension on the tie, which is $\frac{1}{3}$ greater than in fig. 5, hence this latter form of truss would require more timber than that of fig. 5, to bear the same load; and attended with the inconvenience of the long braces, which would not bear the thrust communicated to them as advantageously, as the shorter pieces in fig. 5, but on the other hand the condition of equilibrium may be disregarded, as the weight may be removed from any of the braces without destroying the stability of the structure, whereas in fig. 6, to remove the weight from either of the points w, would destroy the equilibrium, and the truss would yield at once; to prevent this a system of bracing is introduced between the verticals (on the dotted lines), making the whole amount of timber about the same, probably, as in fig. 6, yet the truss with diagonal braces between the verticals, is preferable to that in which independent pairs of braces sustain the points at which the weight is applied, although the latter, as before remarked, is less liable to change of shape by a variable load; the practical inconveniences attending the construction of this form of truss, however, render it every way inferior to the other for long spans.

7.



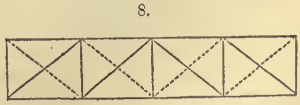
This form of diagonal bracing is the key to almost all our bridge constructions; we therefore extract from Haupt the principles of bracing and counter-bracing.

If the truss, fig. 7, be loaded at c', the effect of the oblique force $c'\,a$ upon the angle c, evidently, is to force it upwards, and this would be the diagonal of a parallelogram constructed upon $a\,c$ and $c\,c'$.

This result is of the greatest practical importance, and the existence of a force acting upwards appears to have been overlooked by many practical builders, as in some very important structures no means have been used to guard against its effects.

The consequence is, that in a straight as well as in an arched truss, a weight at one side produces a tendency to rise at the other side.

8.



The effect of this upward force is to compress the diagonals in the direction of the dotted lines, and extend them in the direction of the braces; but as the braces, from the manner in which they are usually connected with the frame, are not capable of opposing any force of extension, it follows that the only resistance is that which is due to the weight and inertia of a part of the structure. When the load is uniform this is sufficient, because the weight on one side is balanced by an equal weight upon the other, and every part is in equilibrium. But when the bridge

is subjected to the action of a heavy weight, as a locomotive engine or a loaded car rapidly passing over it, and acting with impulsive energy upon every part at different instants, it is obvious that no adequate resistance is offered by a truss composed of only the three series of timbers already described. Yet we find that such a truss has been used for a large proportion of the bridges that have been erected, sometimes with, and sometimes without the addition of an arch, an appendage which, although it adds to the vertical strength, diminishes but little the effect of the force under consideration. No one who has had an opportunity of observing it, can have failed to notice the great vibration produced in such bridges by the passage of a loaded vehicle. In long bridges, the undulations produced by the passage of a car can be felt at the distance of several spans.

The remedy for this defect is obvious; it is only necessary to prevent the diagonal, in the direction of the dotted line, from shortening, or in the direction of the brace from lengthening, and the upward force will be effectually resisted.

This requires either that counter-braces should be introduced in the direction of the dotted diagonals of the last figure, or that the braces themselves should be capable of acting as ties, or additional ties placed in the direction of the braces.

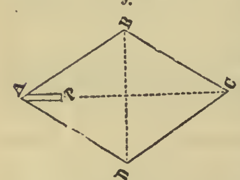
It follows, from the preceding exhibition of the effect of a variable load, that no bridge, either straight or arched, which is designed for the passage of vehicles, and particularly of railroad trains, should be constructed without counter-bracing or diagonal ties. It is only in aqueducts, when the load is always uniform, that they can with any propriety be omitted.

Effects of counter-bracing.—The consideration of the action of counter-braces leads to some very singular but important results.

Let the truss be loaded with a weight so as to produce some deflection, it has been shown that the diagonals in the direction of the braces will be compressed, and in the direction of the counter-braces extended. Suppose that the extension of the last named diagonals is sufficient to leave an appreciable interval between the end of the counter-brace and the joint against which it abuts, and that into this interval a key, or wedge of hard wood or iron, is tightly introduced; it is evident that, upon the removal of the weight, the truss, by virtue of its elasticity, would tend to regain its original position; but this it cannot do, in consequence of the wedges at the ends of the counter-braces, which prevent the dotted diagonals from recovering their original length, and the truss is therefore forcibly held in the position in which the weight left it; the reaction of the counter-braces producing the same effect that was produced by the weight, and continuing the same strain upon the ties and braces.

The singular consequence necessarily results from this, that the passage of a load produces no additional strain upon any of the timbers, but actually leaves some of them without any strain at all.

9.



To render the truth of this assertion more clear, we will confine ourselves to the consideration of a single rectangle, and suppose that the effect of the flexure caused by an applied weight has been to extend the diagonal A C by a length equal A p, and to compress the brace B D by an equal amount.

The point p will evidently be drawn away from A, leaving the interval A p. If a wedge be tightly fitted into this interval, without being forcibly driven, it evidently can have no action upon the frame so long as the weight continues; but upon the removal of the weight it becomes forcibly compressed, in consequence of the effort of the truss, by virtue of its elasticity, to return to its former position. This effort is resisted by the reaction of the wedge, which causes a strain upon the counter-brace A C sufficient to counteract the elasticity of the truss; and as no change of figure can take place, it follows that the brace B D cannot recover its original length, and therefore continues as much compressed as it was by the action of the weight.

The effect of a weight equal to that first applied will be to relieve the counter-brace A C, without adding in the slightest degree to the strain upon B D.

As regards the effects upon the chords, it is evident that the strains are only partial, and tend to counteract each other. The maximum strain in the centre is estimated by the force which would be required to hold the half truss in equilibrium if the other half be removed; and this is dependent only on the weight and dimensions of the truss. In fact, if we examine the parallelogram A B C D, we find that the effect of wedging the diagonals will be to produce strains acting in opposite directions at A and B, and destroying each other's effects; the strains produced by wedging any rectangle cannot therefore be continued to the next, and of course can have no influence upon the maximum forces at the centre.

As the vibration of a bridge is caused principally by the effort to recover its original figure after the compression produced by a passing load, it follows that if this effort is resisted, the vibration must be greatly diminished, or almost entirely destroyed.

This accounts for the surprising stiffness which is found to result from a well-arranged system of counter-braces.

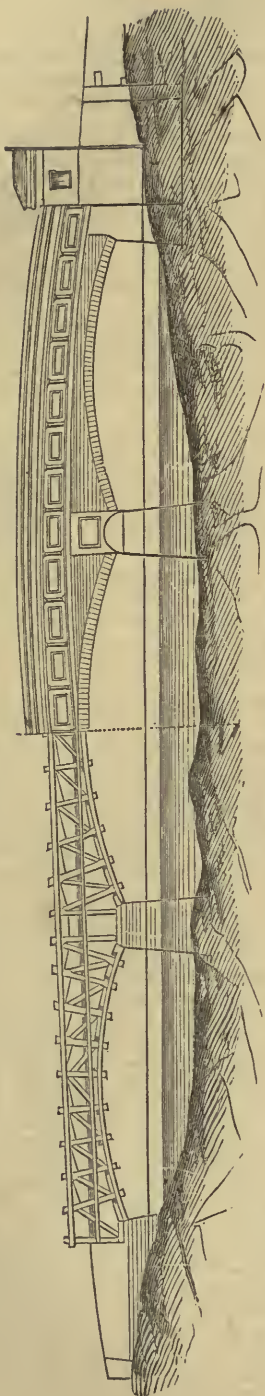
Inclination of braces.—1. The braces must not be so long as to yield by lateral flexure.

2. The chords being unsupported in the intervals between the ties, these intervals must be limited by the condition that no injurious flexure shall be produced by the passage of a load. On the other hand, as the ties approach each other, the angle of the brace increases, and when the intervals become small, the number of ties and braces is greatly increased, and with them the weight of the structure.

The true limit of the intervals can be readily determined when the size of the chords and the maximum load are known; for it should evidently be such that when the load is at the middle, the flexure should not exceed a given amount.

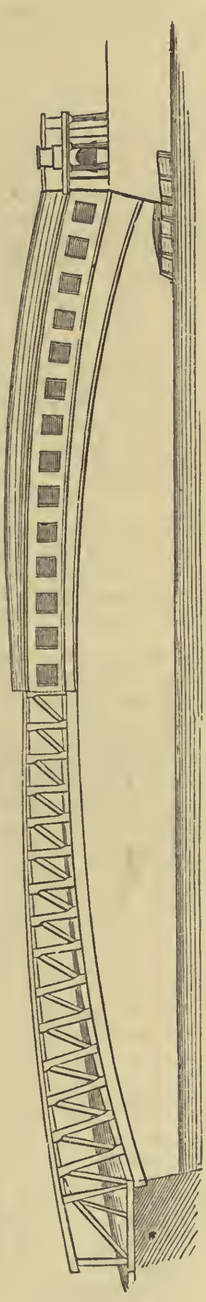
Figs. 638 and 639 represent bridges of which the braces, posts and chords are entirely of wood, but in more common forms wrought iron is used for such parts as are subjected to tension.

638.



Elevation of Schuylkill Bridge. Longitudinal Section.

639.



Elevation of the Upper Schuylkill Bridge. Longitudinal Section.

The most popular form of bridge in use in this country is Howe's truss, similar in form to fig. 8, the bottom and top chords being composed of timber in several thicknesses, the main braces being double, and the counter-braces single, the tension rod or post being of iron. The braces abut on an angular block either of wood or iron, and the tension rods pass through the centre of the block.

In Pratt's bridge the posts are wood, and suspension rods supply the place of braces.

The peculiarity of McCallum's bridge, is in the arrangement through which the arched upper chord by means of the arch-braces bearing on the abutment, together with the counter-brace tension-rods acting on the lower chord, conduce to a uniformity of action highly advantageous to the durability of the bridge.

Suspension Bridges.—Various opinions have been entertained as to the form best adapted for the objects of a suspension bridge. These objects are,—1st, the obtaining a roadway across a river in a position where it is necessary to allow the passage of vessels beneath it, and where it is not possible to form piers or abutments sufficiently close together to allow of an ordinary arch being constructed. 2d, the judicious arrangement of the suspending chains, rods, and roadway bearers, to effect the greatest firmness and rigidity with the least expenditure of material.

The different forms may be arranged under the following heads. First,—those in which the planking of the roadway, (except a small portion near the abutments,) rests solely on the main suspending chains, as in Chinese bridges generally, and some in South America.

Second,—those in which the roadway side beams, carrying the planking, railing, &c., are only connected with the main suspending chains by vertical rods, as in the Menai Bridge and numerous others.

Third,—those in which the roadway platform is entirely supported by ropes, chains, or wires proceeding obliquely from the top of the abutments, as in some bridges of rope, canes, or bamboos in Asia, and light wire bridges in Europe.

Fourth,—those in which the roadway platform is partly supported by ropes, chains, or wires proceeding obliquely from the top of the abutments, partly by rods descending obliquely from the main chains, and partly by the main suspending chains themselves; which last diminishing in weight as they approach the middle of the span, are linked to the central portion of the roadway by short rods, which being nearly in continuation of the upper parts of the main chains, would, if strong enough, support that part of the roadway, and complete the curve, rendering the central link of the chain nearly unnecessary.

In all suspension bridges, chains are carried from the top of the abutments to the rear, and called back chains. There is one of these to each of the bridge chains, whether they carry the rods on each side, as in those of the second class, or go directly to the platform, as in the third and fourth classes. These back chains are connected with links secured on the top of cast iron saddles on the abutments at one end, and firmly bolted to cast iron anchor plates or blocks of masonry in the solid ground or rock at the other.

In the annexed plate is shown an elevation of the Niagara Falls Suspension Bridge, constructed by John Roebling, C. E. of the United States. This bridge has a span of 821 feet 4 inches, from centre to centre of towers. Its form is a slightly curved hollow beam or box, of a depth of 18 feet; width of bottom 24 feet, and of top 25 feet. The lower floor is used for common travel, while the upper is appropriated to railway business and sidewalks. The two floors are connected by two trusses of a simple construction, so arranged that its resisting action operates both ways, *up* as well as *down*. The suspenders are 5 feet apart. The beams of the upper and lower floor are connected by posts arranged in pairs, leaving a space between for the admission of the truss rods, which extend each way to the fourth pair of posts at an angle of 45°. These rods therefore cross each other and form a diamond work. They are 1 inch diameter, their screw ends 1⅛ inch.

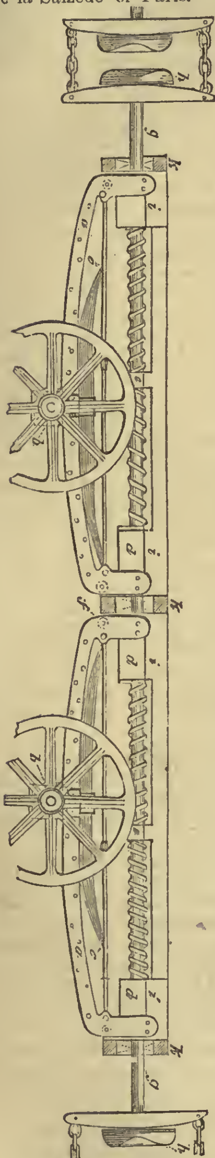
There are 4 cables of 10 inches diameter, each composed of 3,640 wires of small No. 9 gauge, 60 wires forming one square inch of solid section, making the solid section of each cable 60.40 square inches, wrapping not included. Each of the four large cables is composed of seven smaller ones, which are called *strands*. Each strand contains 520 wires; one of these forms the centre, the six others being placed around it; the ends of the strands are passed around and confined in cast-iron shoes, which also receive the wrought iron pin that forms a connection with the anchor chains. During the wrapping process the whole mass of wire was saturated with oil and paint, which, together with the wrapper, will protect the cables effectually against all oxidation. There are 64 diagonal stays, of 1⅝ inch diameter rope, above the floors, equally distributed among the four cables. They are fastened to the suspenders by small wrappings, so as to form staight lines; they are not continued over the towers to the anchorage, but are secured to the saddles, and allowed to move with them. To the under side of the lower floor 56 stays are attached, which are anchored in the rocks below, and occupy positions calculated to insure against horizontal as well as vertical motions. The anchorage of the back chains was formed by sinking 8 shafts into the solid limestone rock that here composes the uppermost stratum of the cliffs. Three of the pits on the New York side are sunk to a depth of 25 feet. The fourth one, south-east, was sunk only 18 feet, on account of the great influx of water, and difficulty of baling. The surface of the rock on the Canada side being 10 feet higher than on the New York side, the depth of the shafts was increased that much, and the height of the towers above reduced in proportion. Each shaft has a cross section of 3 × 7 feet, enlarged at the bottom to a chamber of 8 feet square. The anchor chains are composed of 9 links, all of which are 7 feet long, except the uppermost or last one, which is 10 feet. The first or lowest link is composed of 7 bars, 7 × 14 inches, and is secured to a cast-iron anchor plate by a pin of 3½ inches diameter ground upon its seat. The next link is composed of 6 bars of the same size, and 2 half bars on the outside. The aggregate section of each is 60 superficial inches; from the fourth link up, the link on the chain curves and the section is gradually increased to 93 superficial inches.

On the top of each column a cast-iron plate was laid down, well bedded in cement, 8 feet square

and 2½ inches thick, and strengthened by three parallel flanges for the reception of two independent saddles. Each saddle rests on ten cast-iron rollers, 5 inches in diameter and 25½ inches long, placed close together. The ordinary pressure upon each tower being about 500 tons, makes each roller bear 25 tons. These rollers admit of a slight movement of the saddles, whenever the equilibrium between the land and the suspension cables is disturbed, either by changes of temperature or by passing trains.

The success of this extraordinary bridge may now be considered as established. The trains of the New York Central, and of the Great Western Rail Road in Canada, have been crossing regularly since its completion, averaging over thirty trips per day.

BRONZING. *Improvements in the Brassing and Bronzing the surfaces of steel, iron, &c.*, by Charles de la Salzede of Paris. This invention consists in coating cast-iron, steel, lead, zinc, and tin, with brass or bronze, by means of a galvanic battery. The solution to be used consists of 5,000 parts, by weight, of distilled water, 610 parts subcarbonate of potass. 25 parts chloride of copper, 48 parts of sulphate of zinc, 305 parts of nitrate of ammonia, and 12 parts of cyanide of potassium The cyanide of potassium is dissolved by itself, in about 120 parts of distilled water taken from the above quantity. The other salts above mentioned (except the nitrate of ammonia) are then added to the remainder of the water, and the mixture is heated to from 144° to 172° Fahrenheit, when they are entirely dissolved the nitrate of ammonia is added, and the solution allowed to stand 24 hours; the solution of the cyanide of potassium is then added, and the whole allowed to stand till it is quite clear; the clear solution is then to be drawn off with a siphon, and put in the decomposing trough. The subject to be covered with brass is then to be attach- to the zinc pole of a battery; and to the other pole of the battery a large plate of brass is to be attached, which must be also immersed in the solution. The battery must, the patentee says, be a powerful one: he advises to use Bunsen's or Grove's. When it is intended to bronze, instead of the 48 parts of sulphate of zinc, 25 parts of chloride of tin must be used; the other ingredients are to remain the same. Another solution recommended by the patentee, consists of 5,000 parts of distilled water, 15 parts of chloride of copper, 35 parts of sulphate of zinc, 500 parts of subcarbonate of potass, and 50 parts of cyanide of potassium for brassing; and for bronzing, 12 parts of chloride of tin, instead of the 35 parts of sulphate of zinc; this solution, the patentee says, must be used at a temperature of from 25° to 36° cent. The proportions, the patentee says, may be varied within certain limits.



Section of Bergin's Buffing Apparatus.

BUCKET-WHEELS. See WATER-WHEELS.

BUFFING APPARATUS. A contrivance for receiving the shock of a collision between railway carriages, consisting of powerful springs and framing.

The buffing apparatus first used upon the Liverpool and Manchester Railway consisted of elliptic iron springs, or bows, of several thicknesses, placed transversely across the middle of the frame-work of the carriage which received the shock of whatever blows or jerks the buffer-heads might receive, by the aid of rods communicating with the same. Mr. Bergin, of Dublin, contrived an improved buffing apparatus for the carriages of the Dublin and Kingstown Railway.

It is supported upon the axles of the wheels, and is totally unconnected with the frame of the carriage, whereby it does not partake of the rise and fall of the latter, according to the weight acting upon the vertical springs; and two strong iron rods are passed through the whole length of the carriage, which rest upon small rollers, to which the buffer-heads are attached, spiral springs being wound round them, which receive the effect of all shocks, by the help of collars formed upon the rods, and the introduction of stops to the springs.

On American Rail Road Cars the coupling and buffing apparatuses are usually combined in one. The cars are attached to each other by a single link of chain, inserted in the jaws of the buffer-heads, and retained by iron pins passing down through the buffer-heads and links. This arrangement is sometimes made self-acting, to obviate the necessity of standing between the cars to insert the links and pins. The buffing bars are of iron, with convex heads at their points of junction, and bear against springs, attached to the bottom of the car, the draught acting from the centre.

To obviate the oscillations of cars and wagons, which produce strains on the axles and other parts, injury to the road-way, and deterioration to freight; the connection between the parts of a train should resemble as much as possible the jointing of the vertebræ in an animal's back-bone by which means the lateral action of a car would be neutralized by the support of the neighboring ones. The methods at present adopted for coupling and drawing trains are open to great improvement. The mode of coupling cars in freight trains without spring-buffers or draw-bars is liable to lead to accidents from the play which must necessarily be allowed between the cars to admit of their going round curves, since each time the speed is slackened, the cars close up, and at a fresh start the chains

are exposed to a sudden jerk. The best mode of connection is the coupling screw, by means of which the cars are drawn together so that the buffers are pressed into close contact, and their springs a little compressed. In this manner the train is formed into one complete column, and the change of speed to which it is subject does not produce the partial collision mentioned.

BUHL-WORK, OR BOOL-WORK. The terms appear to be corrupted from Boule, the name of the original inventor, and now refer to any two materials of contrasted colors inlaid with the saw. In France this kind of inlaid work is called *marqueterie.* It consists in representing flowers, animals. landscapes, and other objects, in their proper tints, by inlaying. It also includes geometrical patterns composed of angular pieces laid down in succession, as in ordinary veneering, and is chiefly used in ornamenting cabinet work. In buhl-work the patterns generally consist of continuous lines, as in the honey-suckle ornament. Two pieces of veneer of equal size, such as ebony and holly, are scraped evenly on both sides, and glued together, with a piece of paper between. Another piece of paper is also glued outside one of the veneers, and on this the pattern is drawn. A small hole is then made for the introduction of the saw, a spot being chosen where the puncture will not be noticed.

The saws used in buhl-work are of peculiar construction, and of different sizes. The frames are of wood or metal; three pieces of wood halved and glued together constitute the three sides of a rectangle; two pieces are then glued upon each side, each at an angle of 45° across the corners; the whole when thoroughly dry is then cut round to the desired curve. Screws for giving tension to the blade are commonly added, but seldom used, as the frame is only sprung together at the moment of fixing the saw, and by its reaction stiffens the blade. A handle is attached to the saw frame at the bottom. In the piercing saw of metal the height from the blade to the frame is usually eight inches, and in the ordinary buhl-saw of wood from twelve to twenty inches, to avoid the angles of large work.

The buhl-cutter sits astride a horse or long narrow stool; the work held in the left hand, is placed in a vice at one extremity of the horse, having a flexible jaw under the control of the foot; the saw, which has been previously inserted into the hole in the veneers, and fixed in its frame, is grasped in the right hand, with the fore-finger extended, to support and guide the frame. "The several lines of the work are now followed by short, quick strokes of the saw, the blade of which is always horizontal; but the frame and work are rapidly twisted about at all angles, to place the saw in the direction of the several lines. Considerable art is required in designing and sawing these ornaments, so that the saw may continue to ramble uninterruptedly through the pattern, whilst the position of the work is as constantly shifted about in the vice, with that which appears to be a strange and perplexing restlessness. When the sawing is completed, the several parts are laid flat on a table, and any removed pieces are replaced. The entire work is then pressed down with the hand, the holly is stripped off in one layer with a painter's palette knife, which splits the paper, and the layer of holly is laid on the table with the paper downwards, or without being inverted. The honey-suckle is now pushed out of the ebony with the end of the scriber, and any minute pieces are picked out with the moistened finger; these are all laid aside; the cavity thus produced in the ebony is now entirely filled up with the honey-suckle of holly, and a piece of paper smeared with thick glue, is then rubbed on the two to retain them in contact. They are immediately turned over, and the toothings or fine dust of the ebony are rubbed in to fill up the interstices; a little thick glue is then applied, and rubbed in, first with the finger, and then with the pane of the hammer, after which the work is laid aside to dry." When dry it is scraped at the bottom, and is then ready to be glued on the box or furniture to be ornamented, as in ordinary veneering; it is afterwards scraped and polished. An ebony honey-suckle may be inserted in a ground of holly in the same manner; and these form the *counter* or *counterpart-buhl*, in which the pattern is the same, but the color reversed.

Three thicknesses of wood may be glued together, as rosewood, mahogany, and satin-wood, which, when cut through, split asunder, and recombined would produce three pieces of buhl-work, the grounds of which would be of either kind with the honey-suckle and centre of the two other colors respectively. These are called "works in three woods," and constitute the general limit of the thicknesses. Buhl-works of brass and wood are also sometimes made by stamping instead of sawing.

BULLETS. *Manufacture of by Rolling.* At the Arsenal, at Woolwich in England, they now manufacture leaden bullets by drawing and compression. These bullets have the advantage of being without *blows* or air cavities, and are rolled out of round bars of lead, which are passed between rolls formed like the roulettes used for ornamental work on the lathe. The rolls are constructed with hemispherical cavities, each one of which forms one-half of the ball, whilst the corresponding cavity forms the other half; the bullets are then finished by removing the extra metal, and being rolled together in a barrel.

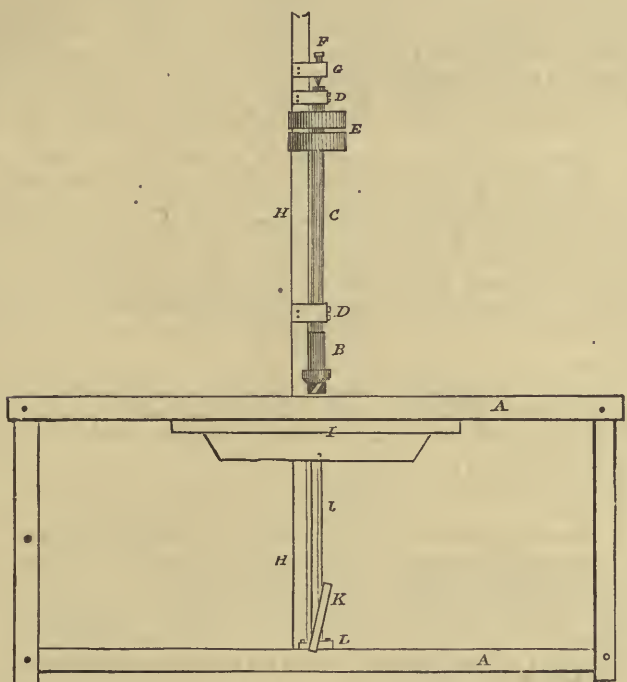
The bars of lead from which the balls are compressed are cast in moulds, 36 inches in length by 75 in diameter. These bars are then brought to the machinery, and are first passed through a roller, which condenses the lead, and prepares it for the second operation, that of compressing it into shape or form for the die. Thirdly comes the die. which by its regular movement forward is brought into contact with the masses of lead prepared, and as the die recedes, a boy moves up the bar for its next movement, and so on; following it up with other bars of lead arranged at his right hand, so that the die in its forward movement always finds its work prepared, and leaves the balls formed in a belt of lead. The fourth and last operation is that of cutting the balls out of the belt, which is done by a punch, exactly the diameter of the bullet, and which is brought over it and worked by a boy with his foot. The advantage of the compressed over the cast bullet is its perfect solidity; whereas the cast has a flaw, more or less, in every bullet. The belted or rifle ball should, therefore, always be made by compression. The following is a description of a machine invented by Wm H. Ward, of Auburn, N. Y., for manufacturing bullets from lead wire. The wire is coiled upon rests at the top of the machine, and suspended by means of arches, from which the lead is fed downwards into the machine, where it is measured and cut off as required for each bullet, after which it is forced forward into dies, and formed into the desired shape by compression. This machine is capable of making musket, rifle, and pistol

elongated, hollow, and conical expansion bullets; also round or shell balls, all at the same time. Each corner being double with two sets of dies and punches, gives eight bullets to one revolution of the machine. The machine may be worked up to twenty-five turns in a minute, which is equal to 200 bullets per minute, or 12,000 per hour.

BULLET-WOOD. See Woods, *varieties of*.

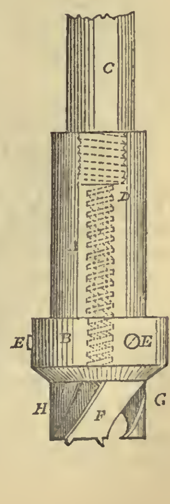
BUNG-CUTTING MACHINE. We here present two views of a machine invented by Messrs Dowdy & Sweet, No. 35 Cross-street, of this city. Fig. is a side elevation, and fig. a view of the cutter-stock and cutters. A is a stout table. H is a strong upright-post in the middle of the table. To this post the cutter-shaft C is secured by proper bearings D D, to allow it to revolve. F is a screw which passes through a bearing G, into an opening in the head of N. J is an elevating bed or rest for the plank that is to be cut into bungs. It is fixed on a treadle J, by a foot-spring K; when pressed upon towards L, the bung-bed is elevated through an opening in the middle of the

620.



table, and as the foot presses K, so is the plank fed up to the cutter till the bung is cut, when the foot being released, the bung is driven out by a spiral spring, which will be better understood by Fig. 621.

621.



A is the cutter-stock. It is of a cylindrical form, with an opening through the centre, and a thread a short distance at the upper end to screw in the shaft C. In the centre of the cutter-stock is a spindle with a spiral spring on it, represented by D. The spring does not reach to the ends of the spindle. By an opening in C, the shaft is allowed to pass into it, when the plank is fed into the cutters; but when the bung is cut, this spiral spring in the centre of the cutter-stock recoils as the feed-table is lowered, and throws out the cut bung. This is the object and use of the interior spiral spring and spindle. G F H are the cutters. Each is a distinct piece, and each performs a different office. They are all set on to the cutter-stock, which is turned on the outside, leaving them to sit around it like a ring, where they are covered with a snug collar B, and a screw E E, for each cutter, secures them to the cutter-stock. The inside of the cutters is like a cup, and they are arranged almost like screws of different pitch. F has two little spurs on it; one on the inner side, and the other on the outer. These cut the cresses of the groove in the plank for the bung, when H follows after and scoops it out, cutting on the outside of the bung. Both of these cut straight without any taper. G is the taper cutter. It is graduated in the edge to the bottom of the cutter-stock; therefore it gradually planes the taper of the bung, after the other two cutters have done the rough work. This makes the work easy on the machine, which cuts out about 20 bungs per minute, hand fed, with great ease. On the bottom of the stock, in the inside of the cutters, there is a small knife that rims off the edge of the bung. This machine has been in operation successfully for some time.

BURNETTIZING, the process for preventing the rapid decay of timber, by the use of chloride of zinc. The liability of nearly all kinds of timber in common use to rapid decay, when exposed to alternate wet and dry, or when placed in damp and badly ventilated situations, has led to various devices for the purpose of increasing its durability under such circumstances.

In 1838, a patent was granted in England to Sir William Burnett, for a process for preventing decay in certain vegetable and animal substances by the use of chloride of zinc. This process, called Burnettizing, has been extensively used in England as a preventive of the decay of timber; and it has been more extensively used in this country for the same purpose than any other process. No patent was taken out for the United States. It was first introduced at Lowell, Massachusetts, where, in 1850, the Proprietors of the Locks and Canals on Merrimac River, at the joint expense of the manufacturing companies, erected the necessary apparatus for carrying on the process. Although it is not in all cases a preventive of decay, the advantages are more than sufficient to justify its application to most kinds of timber in common use, when placed in situations favorable to rapid decay. It has also a distinct effect in rendering wood less liable to warp and crack when placed in dry situations.

The apparatus at Lowell consists of a cast-iron cylinder, in which the timber to be prepared is placed; this cylinder is sixty feet long, and five feet diameter inside, with one head movable; the iron generally an inch thick. A pair of rails, about two feet gauge, are laid in the bottom of the cylinder, and also on the same line and level, about seventy-five feet outside the cylinder; a low truck, about sixty feet long, runs on these rails. When it is required to charge the cylinder with timber, this truck is drawn out, loaded, the load chained down to prevent its floating, and the truck then drawn into the cylinder.

A little below the level of the cylinder, and parallel to it, is placed a wooden cistern, to hold the solution while the cylinder is being loaded and unloaded, and at times when the apparatus is not in use; this cistern is about fifty feet long, seven feet wide, and four feet deep, and was originally constructed for Kyanizing by immersion. The air-pump is twelve inches in diameter, and three feet stroke. The force-pump four inches in diameter, and two feet stroke. The pumps are worked by a small steam engine of about fifteen horse-power, which also works the windlass by which the truck is drawn in and out of the cylinder. The boiler of the engine is also used in winter to supply steam to thaw frozen timber; this is done by admitting steam into the cylinder, charged with the frozen timber, for several hours before the vacuum is obtained. The steam engine and boiler are both much larger than necessary for these purposes.

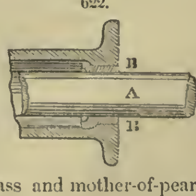
The process is as follows:—

	Time occupied.	
	Hours.	Min.
"The truck being outside the cylinder, is unloaded and reloaded with about seven thousand feet, board measure, of lumber, usually of various kinds and dimensions; from one to two hours is usually thus occupied, depending upon the dimensions and variety of sizes,—average, say - - - - - - - - - -	1	30
"Drawing in the truck and packing cylinder head - - - - - - -		15
"Exhausting the air, and maintaining a vacuum of twenty-seven or twenty-eight inches of mercury - - - - - - - - - - - - - -		45
"Changing pumps, and at the same time filling the cistern by atmospheric pressure from the cistern, with a solution of one hundred parts of water and one and a half parts of dry chloride of zinc by weight, and getting up the pressure in the cylinder to one hundred and thirty pounds to the square inch above the atmosphere - - - -		20
"The pressure of one hundred and thirty pounds to the square inch above the atmosphere is maintained - - - - - - - - - - - - -	2	30
"Draining off the surplus solution by gravitation from the cylinder to the cistern -	1	45
"Unpacking head and drawing out truck - - - - - - - -		15
"Time occupied in preparing one batch," - - - - - - - - - -	7	20

By allowing the solution to drain off during the night, two batches per day are easily done.

Whenever it is required to prepare large quantities of timber, uniform in kind and dimension, such as railroad sleepers, an improvement in the above process would be, to maintain the pressure until a certain quantity of the solution was taken up; but with the great variety in kind and dimension usually prepared at the same time, this is impracticable; as the lumber of small thickness gets more than its due proportion, and the pressure is kept up so long in order that the larger sizes may be sufficiently saturated. The chloride of zinc is received from the manufacturers in the form of concentrated solution containing about 55 per cent. of the dry chloride. The amount taken up by the wood varies very much, depending upon the kind, dimensions, and dryness of the wood; as the process is conducted at Lowell, it varies from about ten pounds to forty pounds of the concentrated solution to a thousand feet board measure, or from two to eight ounces to a cubic foot.

622.



BUSH. A piece of metal, usually made of hard brass, and fitted into a plumber-block, in which the journal turns; they are also sometimes termed *pillows*, and the blocks, *pillow-blocks*. The guide of a sliding-rod is also termed a *bush*. Thus, in Fig. 622, A is the piston-rod, B B the bush.

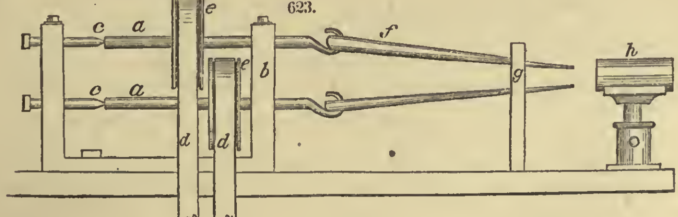
BUSHES, *metal for lining*. See Details of Engines.

BUTTON MACHINERY. Buttons may be divided into two general classes,—those with shanks, or loops of metal, for the purpose of attaching them to garments, and those without shanks; and each class is manufactured from a great variety of materials, and by a variety of methods. Of buttons with shanks the greater number are composed of metal, although glass and mother-of-pearl are also employed for the purpose. Metal buttons are formed in two different ways, the blanks or bases of the buttons being either cast in a mould, or stamped out of a sheet of metal; the former method is generally employed for making white metal-buttons, and the latter for plated and gilt buttons. To cast

buttons, a great number of impressions of the pattern of the button are taken in sand, and in the centre of each impression is inserted a shank, the ends of which project a little above the surface of the sand, and fused metal is poured over the mould. When cool, the buttons are taken from the moulds, and after being cleansed from sand by brushing, are placed in lathes, the edges are turned, the face and back smoothed, and the projecting part of the shank also turned. The buttons are then polished by rubbing the faces upon a board spread with rotten-stone of different degrees of fineness, and afterwards by being held against a revolving board covered with leather, upon which is spread a very fine powder of the same material; finally, they are arranged on a sieve or grating of wire, and immersed in a boiling solution of granulated tin and cream of tartar, by which means their surfaces become covered with a thin layer or wash of the metal, which improves their whiteness without injuring their polish. The blanks of plated buttons are cut by a fly-press out of copperplate, coated on one side with silver. They are then annealed in a furnace, and afterwards stamped by the descent of a weight, as in a pile-driving machine, the die being fixed in the lower surface of the weight. The soldering of the shank is performed on each button separately, by the flame of a lamp and a blowpipe: the edges of plain buttons are next filed smooth in a lathe, and the buttons are afterwards boiled in a solution of cream of tartar and silver; they are then placed in a lathe, and the backs brushed, and afterwards burnished with blood-stone. The metal used for gilt buttons is an alloy of copper and zinc. This metal is rolled out into sheets, and the blanks stamped out, which are then planished, if intended for plain buttons; but if for figured buttons, the impression is now given. The shanks are next attached, which is effected as follows: each blank is furnished with a pair of small spring tweezers, which hold the shank down upon it on the proper place, and a small quantity of solder and resin is applied to each. They are then exposed upon an iron plate to a heat sufficient to melt the solder, by which the shank becomes fixed to the button; and whilst still warm they are plunged into nitric acid, to remove the oxide formed on the surface by the heat employed in soldering the shanks. They are then placed in a lathe. the edges rounded, and the surfaces rough-burnished, which renders them ready for gilding. Five grains of gold are fixed by act of parliament, in England, as the least quantity to be employed in gilding a gross of buttons of one inch in diameter. An amalgam is formed of gold and mercury, and the buttons are placed in an earthen vessel along with the amalgam, together with as much aquafortis as will moisten the whole, and the mixture is stirred with a brush until the buttons are completely whitened. To dissipate the quicksilver the buttons are shaken in an iron pan, placed over a fire, until the quicksilver begins to melt, when they are thrown into a felt cap, and stirred with a brush, to spread the amalgam equally over their surfaces; after which, they are returned to the pan, and the mercury volatilized completely by the increased heat, leaving the gold evenly spread in a thin film over the surface of the buttons; they are then burnished in a lathe, which completes the operation. The better sort of buttons undergo the gilding process twice or thrice, and are distinguished accordingly as "double" or "treble gilt." Glass buttons are formed of glass compressed, while in the fluid state, in moulds, in which the shank is inserted, and when the glass becomes cold, the shank is firmly retained in its place. In mother-of-pearl buttons the method of inserting the shank is extremely ingenious: a hole is drilled at the back, and undercut—that is, larger at the bottom than at top; and the shank being driven in by a steady stroke, its extremity expands; on striking against the bottom of the hole, it becomes firmly riveted into the button, forming a kind of dove-tail joint.

Buttons without shanks are of two kinds; the first are simply disks of horn, bone, wood, or other material, with four holes drilled through the face, for the purpose of sewing them to the garment. Horn buttons of this description are made from cow-hoofs by pressing them into heated moulds. The hoofs having been boiled in water until they are soft, are first cut into plates of the requisite thickness, and after into squares of the size of the diameter of the button, and afterwards reduced to an octagonal form by cutting off the corners. They are then dyed black by immersing them in a caldron of logwood and copperas mixed. A quantity of moulds somewhat resembling bullet-moulds, and each furnished with a number of steel dies, are then heated a little above the point of boiling water, and one of the octagonal pieces of horn is placed between each pair of dies, and the mould being shut is compressed in a small screw-press, and in a few minutes, the horn becoming softened by the heat, receives the impression of the die, after which the edges are clipped off by shears, and then rounded in a lathe. The holes in buttons of this description are drilled by means of a lathe, represented in the annexed engraving. Four spindles, of which two only, *a a*, can be seen, are supported in bearings at *b*,

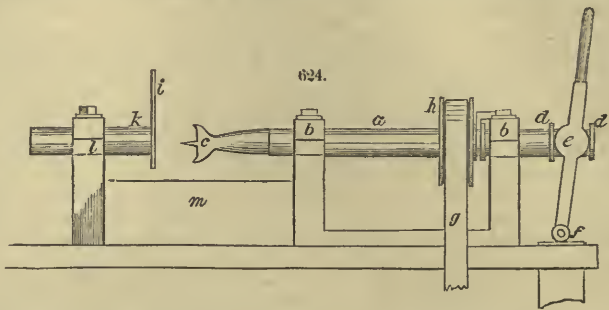
623.



and by the centre points *c c* are made to revolve with great velocity by means of two bands *d d* passing over pulleys *e e* fixed upon each of the spindles, each band driving two spindles, and receiving motion from a wheel worked by a treadle. At the end of each of the spindles *a*, is a hook uniting them to four other spindles *f f* by similar hooks at one end, the other end of the spindles passing through four small holes in the plate *g*, and the projecting points being formed into small drills. The button is placed in a concave rest *h*, and pushed forward against the drills by a piece of wood. The standard *g* can be

exchanged for another with holes more or less apart, and the rest *h* can be set at any height to suit different-sized buttons. As the spindle-holes in the plate *g* are nearer together than the holes in the standard *b*, the spindles *f f* converge; the hooks in the spindles are therefore necessary to form a universal joint. The second description of buttons without shanks consists of thin disks of wood or bone, called moulds, covered with silk, cloth, or other similar materials. The bone for the moulds is made from refuse chips of bone sawed into thin flakes, and brought into a circular form by two operations, illustrated by the accompanying engraving. On one end of the spindle *a*, which revolves in bearings

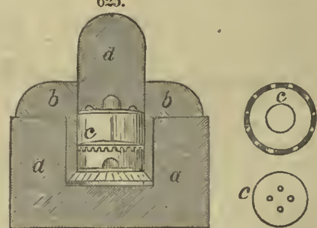
624.



at *b b*, is screwed a tool *c*, and on the other are two collars *d d*, between which a forked lever *e* embraces the shaft, the fulcrum of which is at *f*. The spindle *a* is put in rapid motion by a band *g* passing over the pulley *h*, and over a band-wheel worked by a treadle; and the workman, holding the material *i* for the mould in his right hand, against a piece of wood *k* firmly held down in the iron standard *l* by two screws, by means of the lever held in his left hand, he advances the tool *c* against the material *i* of the mould; the central pin of the tool drills a hole through the centre of the intended mould, whilst the other two points describe a deep circle cutting half through the thickness of the material, and the flat surface is cut smooth by the intermediate parts of the tool. The tool is then drawn back a little by the lever *e*, and the material shifted to bring a fresh portion of the surface opposite the tool, and when as many moulds as the plate of the material will afford, are thus half cut through, the other side is presented to the tool, and the central point of it being inserted in the hole made in the first part of the operation, the other two teeth cut another deep circle exactly opposite the former one through the remaining substance of the material, and the mould is left sticking on the tool; by drawing back the lever *e* the tool recedes, and the mould, meeting a fixed iron plate, is pushed off the tool, and falls into a small box *m*.

Covered buttons having come into very general use, various improvements have been introduced in the manufacture of them, and patents for this purpose have been granted to various parties. The following is Mr. Sanders' method of making covered buttons: a piece of the material with which the mould is to be covered is cut of a circular shape, somewhat larger than the intended button; upon this is placed a disk of card of the exact size of the button, and next a disk of paper coated with an adhesive composition, which will become soft and sticky by heat; and upon these is laid a button-mould *e*, having four holes, through which threads or strings have been passed to form the flexible shank. These circular disks being put together, are then laid over a cylindrical hole in a metal block *a*; this hole being exactly the size of the intended button, and the covering of the button being larger than the hole, when the disks are pushed down into the hole, the material of the covering will wrinkle up on the edges round the other disks. The tube *b b* is then introduced into the cylindrical hole, and its lower edge being bevelled inwards, will, as it is pressed down, gather the plaits of the cloth on the edge of the button; towards the centre is a metal ring or collar *c*, having teeth round its edge, somewhat like a crown-saw, which is now passed down the tube *b*, and driven with considerable force by the punch *d*, and the block *a* having been previously heated, the adhesive matter will be softened, and cause the several disks to stick together, which, when taken out and become cold, will be very firm and retain its shape.

625.



Button shanks are made by hand from brass or iron wire, bent and cut in the following manner: The wire is lapped spirally round a piece of steel bar. The steel is turned round by screwing it into the end of the spindle of a lathe, and the wire by this means lapped close round it till it is covered. The coil of wire thus formed is slipped off, and a wire fork or staple with parallel legs put into it. It is now laid upon an anvil, and by a punch the coil of wire is struck down between the two prongs of the fork, so as to form a figure 8, a little open in the middle. The punch has an edge which marks the middle of the 8, and the coil being cut open by a pair of shears along this mark, divides each turn of the coil into two perfect button shanks or eyes.

Harding's Improvements.—These improvements in the manufacture of buttons and other dress fastenings, consist in the arrangement and construction of the parts whereby they are secured to the dress, for which two separate methods are given. According to the first method, the button is formed with a shank of a single wire, which after projecting a sufficient length from the back of the button to pass

through the garment, is turned at right angles, and coiled in the form of a spiral in a plane parallel to that of the button. The spiral consists simply of about two turns, and terminates abruptly. On securing this button to the garment, the end of the spiral is inserted through a small eyelet hole just sufficient to admit the entrance of the wire; the button is then turned round, and the wire screwed through the hole in the garment until the whole of the spiral passes underneath the vertical shank then occupying the hole, and the button is thereby secured, in which position it is held until the button is drawn from the garment and turned in the contrary direction. This mode of securing dress fastenings is also applicable to other fastenings, such as clasps, &c., the mode of attachment of which is precisely similar, the spiral and shank being attached to the article in any suitable manner to occupy the proper position for the purpose.

The second fastening is for a similar purpose, but for securing the ordinary description of shank button, or other dress fastening having a suitable shank. It merely consists of a piece of doubled wire, so as to form an eye; the continuations of the wire form a hook and clasp pin after being threaded through the shank of the button; the pin portion is sprung into the hook part whereby the wire is securely retained in its position. The button shank is first introduced through an eyelet hole, and the fastening placed at the back as described.

BUTTON-WOOD. See Woods, *varieties of.*

BUTTRESS. A piece of strong wall that stands on the outside of another wall to support it, or applied as an ornament.

CABLE. See Chain Cable.

CALCINATION. The chemical process of subjecting metallic bodies to heat with access of air, whereby they are converted into a pulverulent matter, somewhat like lime in appearance. The term *calcined*, is, however, now applied to any substance which has been exposed to a roasting heat.

CALCULATING MACHINES. Machines of this kind are designed to produce arithmetical and other tables, which shall be rigorously correct. In navigation and the higher branches of astronomy the use of such tables is very great, and being constructed by human heads and hands, they all contain errors of greater or less magnitude. The principle upon which these machines are constructed may be described as follows. In the manner in which quantities are combined in the common system of numeration, the value of each figure is ten times greater than it would be if it occupied a position one place to the right. Thus, in the number 1829, although 9 is greater than 2, yet the 2 in this position represents a larger sum than the 9, because it occupies a place to the left of the 9. The quantities really expressed by the figures 1829 are 1000, 800, 20, 9; but in practice we omit the cyphers, and place the significant figures side by side, preserving their proper position from the right hand. If a wheel be constructed on whose axis is a pinion with leaves or teeth; if these teeth work into another set of teeth or cogs on the periphery of another wheel, and if the teeth on the latter wheel are just ten times as numerous as those on the pinion, this system being made to revolve, the pinioned wheel will revolve just ten times as fast as the other. This produces a kind of analogy between the decimal notation and the working of the wheels, for it takes 10 units to make up one figure or unit in the second place in common numeration, and it requires 10 revolutions of the pinioned wheel to impart 1 revolution to the larger wheel. This is the fundamental principle in calculating machines. In such machines there are a number of dial-faces, each marked with figures from 1 to 10; these dial-faces are fixed upon wheels, the teeth of which work into the pinions of other wheels, on which are similarly divided faces or discs, so that while one face indicates units, another indicates tens, a third hundreds, and so on. These wheels and dial-faces may be differently arranged in different machines, but the principle is the same in all.

A calculating machine, called the Difference Engine, was constructed by M. Babbage for the English government at an expense of £20,000, to be used in preparing logarithmical and trigonometrical tables. A valuable feature introduced into this machine is the power of printing the tables as fast as it calculates them. Another machine, called the Analytical Engine, was invented by the same gentleman, of greater power than the first. This contains a hundred variables, or numbers, susceptible of changing, and each of these numbers may consist of twenty-five figures. The distinctive characteristic of this machine, is the introduction into it of the principle which Jacquard devised for regulating, by means of punched cards, the complicated patterns of brocaded stuff. See Abacus.

CALEMBERG. See Woods, *varieties of.*

CALENDER. A machine used in the manufacture of cotton and linen goods. Calendering is the finishing process by which the goods are passed between cylinders or rollers, and made of a level uniform surface. The machine consists of a number of rollers contained in a massive frame-work; the rollers are connected with a long lever loaded with weights at the further extremity, by which or by means of screws almost any amount of force may be applied, and the surface texture of the cloth varied at pleasure. With considerable pressure between smooth rollers, a soft silky lustre is given by equal flattening of the threads. By passing two folds at the same time between the rollers, the threads of one make an impression on the other, and give a wiry appearance with hollows between the threads. The rollers are made of cast-iron, wood, paper, or calico, according to the uses for which they are designed. The iron rollers are sometimes made hollow for the purpose of admitting either a hot roller of iron, or steam when hot calendering is required. The other cylinders were formerly made of wood, but it was liable to many defects. The advantage of the paper roller consists in its being devoid of any tendency to split, crack, or warp, especially when exposed to a considerable heat from the contact and pressure of the hot iron rollers. The paper takes a fine polish, and being of an elastic nature, presses into every pore of the cloth, and smooths its surface more effectually than any wooden cylinder, however truly turned, could possibly do.

In a five rollered machine, the cloth coming from behind, above the uppermost or 1st cylinder, passes

between the 1st and 2d; proceeding behind the 2d, it again comes to the front between the 2d and 3d; between the 3d and 4th it is once more carried behind, and lastly brought in front between the 4th and 5th, where it is received and smoothly folded. At this time the cloth should be folded loosely, so that no mark may appear until it is finally folded in the precise length and form into which the piece is to be made up, which varies with the different kinds of goods, or the particular market for which the goods are designed. When the pieces have received the proper fold, they are pressed in a hydraulic press previous to being packed.

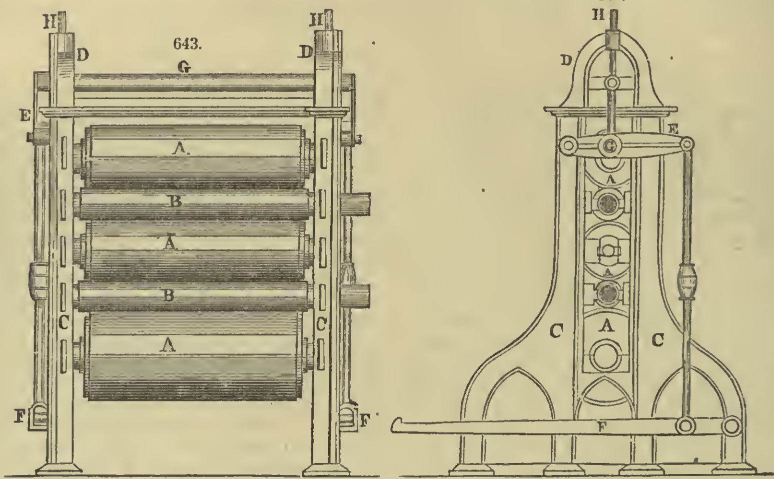
From the great weight of calendering machines it is necessary that they should be fixed on the basement floor. After the cloth has received its final gloss from these machines, it is taken to the cloth-room to be measured preparatory to being folded and packed for sale or transportation.

CALENDER WITH FIVE ROLLERS, Designed and Constructed by Messrs. A. More and Son, Glasgow. Fig. 644, an end view; Fig. 643, a side elevation; the same letters of reference denote the same parts in each view.

A A A, three cylinders or rollers made of paper, the construction of which will be noticed afterwards.

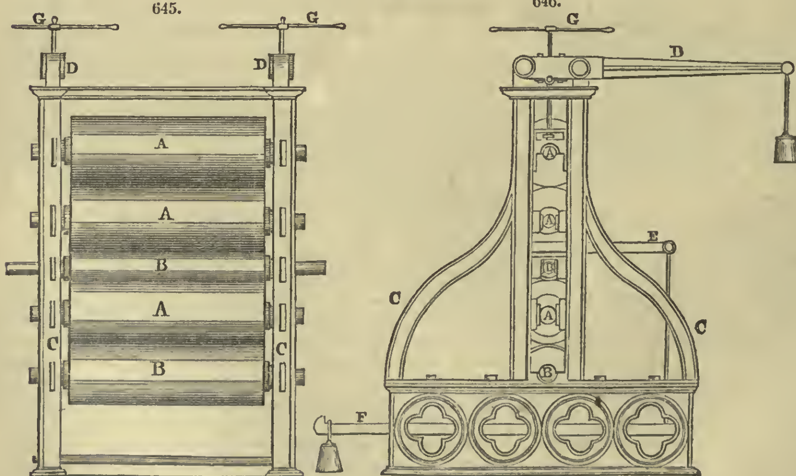
B B, two cast-iron cylinders, made hollow to allow of the introduction of hot bolts of iron within them; or of steam, when it is required or preferred.

643. 644.



SCALE.—1-4th inch = 1 foot.

645. 646.



SCALE.—1-5th inch = 1 foot.

C C, the two side-frames or cheeks, into which are fitted the several brass bushes for the cylinders to turn upon.

D D, top guides, into which the cross-head G, and elevating screws H H, work.

E E, top-pressure levers, connected by a strong rod of iron with the under-pressure lever F. This

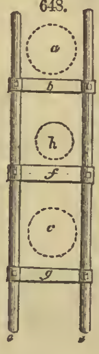
system of levers is connected with the cross-head G, by two strong links of iron. The elevating screws H H pass through the cross-head, and rest upon a strong cast-iron block, into which is fitted the brass bush of the top paper roller. By means of the screws, the cross-head and levers can be raised or depressed as required, and when the calender is working warm and requires to be stopped, the elevating screws are screwed up for the purpose of lifting the paper rollers off the hot cylinders, to prevent their being injured by the heat.

The construction of the paper rollers or cylinders is as follows: Upon each end of an arbor of malleable iron, of sufficient strength to withstand the necessary pressure without yielding, is fastened a strong plate of cast-iron, of the same diameter as the roller to be made; the plate is secured in its proper place by a ring of iron, cut in two, and let into a groove or check turned in the arbor. When the roller is finished, the annular pieces are kept in their groove by a hot hoop put upon the outside of them, and allowed to cool. A plate is fitted on the other end, of exactly the same size, and in the same manner.

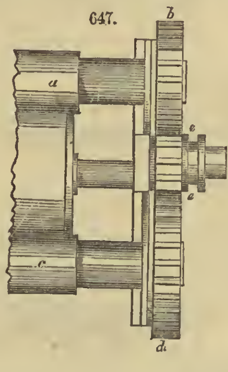
In building the rollers, one of the plates is taken off the arbor, but the other is allowed to remain in its place. The paper sheets of which the rollers are to be made, have each a circular hole cut in the centre of it, of exactly the same diameter as the arbor. The sheets are then put upon the arbor, and pressed hard against the fixed plate. When the arbor is filled with paper, it is put into a strong hydraulic-press, and pressed together,—always adding more paper to make up the deficiency caused by the compression, until the mass will press it no harder. The half rings are then put in their place, to prevent the plate from being pressed back by the elasticity of the paper. The roller is now to be dried sufficiently in a stove, the heat of which causes the paper to contract so as to be quite loose. The roller is then again taken to the press, and the unfixed plate being removed, more paper is added, and the whole again compressed, until the roller is hard enough for the purpose to which it is to be applied. It is next turned truly in the lathe till it acquires a very smooth surface.

The wood-cut, Fig. 647, shows the manner in which the calender is geered to make it a *glazing* calender. In this cut, *a* marks the top cylinder of the calender, upon which is keyed a spur-wheel *b*; and *c* is the under cylinder, upon which is also keyed a spur-wheel *d*. The intermediate or carrier-wheel *e e*, when drawn into geer, reduces the speed of the under cylinder *c*, one-fourth. Now, the cylinder *a*, being the one that gives motion to all the rollers, and revolving always at the same speed, the cloth

648.



647.



in its passage through all the rollers below the cylinder *a*, is carried through at a speed *one-fourth* less than if it passed only below the cylinder *a*; consequently, when it comes into contact with *a*, it is rubbed, and thereby *glazed*, in consequence of the cylinder *a* moving one-fourth quicker than the cloth, as above stated.

The wood-cut, Fig. 648, shows the manner in which the rollers are lifted clear of each other when the machine is stopped. In this, *e e* are two rods of iron, attached to the block or seat of the top roller; *b f g*, three bridges of malleable iron, capable of sliding upon the rods *e e*; but held fast upon the rods when once they are adjusted to their proper places by pinching screws. The bridge *b* is placed half an inch clear of the bearing of the cylinder *a*, when all the rollers are resting upon each other; the bridge *f* is placed *one inch* below the bearing of the paper roller *h*; and the bridge *g* is placed one inch and a half below the bearing of the cylinder *c*. When the pressure screws of the calender are lifted, the blocks of the top roller being attached to them, the rods *e e* are lifted also, and along with them the different rollers as the bridges successively come into contact with their respective bearings.

The manner of passing the cloth through the calender varies very much, according to the amount of finish required upon it. The various methods are accomplished by different arrangements of the geering, so that a calender calculated to do all the different kinds of finishing becomes a very complicated machine, on account of the quantity of geering required. For common finishing, the method of passing the cloth through the calender is as follows:—The cloth is passed alternately over and under a series of rails placed in front of the machine, so as to remove any creases that may be in it, and is then introduced between the lower roller A and cylinder B; returns between the lower cylinder B and the centre roller A; passes again between the central A and the upper B, and again returns between the top pair A, B, where it is wound off on a small roller, (hid in the drawings by the framing of the machine,) pressing against the surface of the top roller A. When this small roller is filled with cloth it is removed, and its place supplied by another, to be in succession filled as the motion of the machine progresses.

Water-Mangle with two copper, and three wooden rollers; designed and constructed by Messrs. A. More and Son.—This machine, Figs. 645 and 646, differs nothing in principle, and little in general construction, from the five-rollered calender above described, except in this—that it is intended for wet goods. It is drawn to a scale slightly less, but the views given and the lettering of the parts correspond to those of the preceding figures.

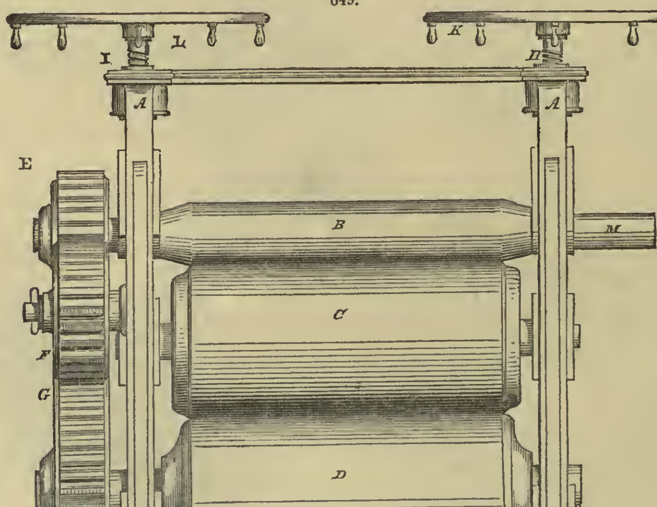
A A A, the three wooden rollers, and B B, the two copper rollers of the mangle. These last consist of a copper cover upon a cast-iron body, through which passes a wrought-iron arbor, differing from those of the wooden rollers in being round, whereas these are square between the bearings. The smaller of the two copper rollers, namely, the third in order, is in this arrangement the driver, the mangle being driven like the calender, by a system of reversing geer not shown in the drawings.

The pressure in the mangle is brought on by a system of levers, which differ slightly from that described. In this, indeed, there are strictly two distinct pressures: that brought on the axis of the middle roller by the lever E, which is connected by a link with the weighted lever F; and that transmitted through the whole system of rollers by the single-weighted lever D. The weight of this last is regulated by means of a set-screw, which turns in a nut in the jaws of the lever D, and bears upon the set-block which rests upon the arbor of the top roller. This pressure is thus transmitted downwards from the top roller throughout the whole set, and at the middle roller B is added to the pressure obtained by the lever E. By this arrangement, the pressure between the three under rollers is greater by the pressure of E, than it is between the upper pair; but, for very high pressure the lever D may be locked by set-pins and the set-screws turned down by the hand-wheel G, until the requisite degree of pressure is obtained.

The manner of passing the cloth through this machine is the same as that already described in the calender, with this single exception, that before the cloth enters between the lowest roller A, and the small cylinder B, jets of water from a pipe, perforated with small holes, extending the whole width of the machine, are allowed to play upon the cloth, so as to impart to it sufficient moisture for causing it to receive the requisite degree of smoothness preparatory to the starching process, and at the same time allow the cylinder B to free it from any impurities that may be remaining in it, by forcing them back with the expressed water.

CALENDER. *Description.* A, two cast-iron frames. B C D, three cylinders. E F G, three cog wheels. H I, two force-screws. K L, two fly-wheels with handles.

649.

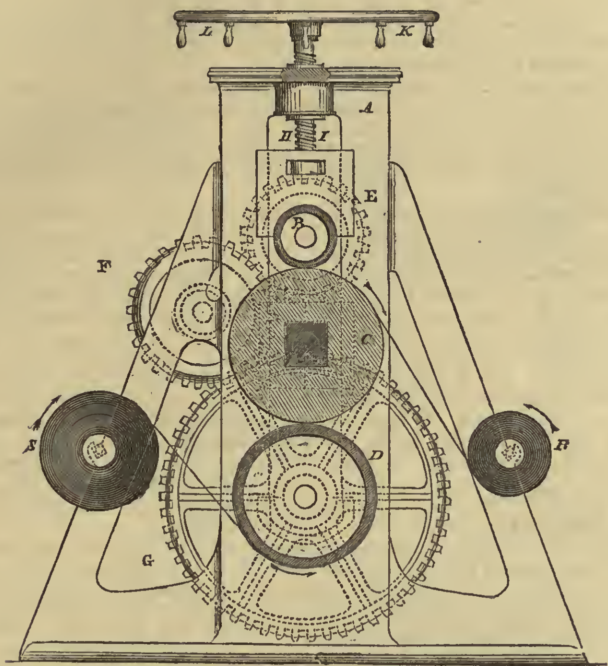


The cylinder B, which is in cast-iron, and hollow, is heated by another iron cylinder heated red hot. The material of the cylinder C is pasteboard, its axle is of wrought-iron. These three cylinders must be perfectly round and parallel.

The wheel F forms the communication between E and G, which rest upon the cylinders B and D. The relation of F to the circumference of the cylinders is such, that when the machine is set to work

these cylinders slide, causing friction, and thus give a gloss to the cloth. The friction is variable according to the nature of the tissue.

650.



In order to set the machine in motion, the fly-wheels K and L being turned in order to press the screws H and I against the pillows of the first cylinder B, the cloth is placed between the rollers in the direction indicated by the arrows.

CALICO PRINTING. The art of producing a colored patttern on cloth by the application of coloring substances. The processes employed are applicable to linen, silk, worsted, or mixed fabrics, although they are usually referred to cotton cloth or calico.

The invention of *cylinder* or *roller printing,* is attributed to two persons, one a Scotchman named Bell, the other named Oberkampf, a calico printer at Jouy in France.

The cylinders upon which the pattern is engraved, one cylinder for each color, are mounted on a strong frame-work, so that each cylinder revolves against two other cylinders, one of which is covered with woollen cloth, and dips into a trough containing coloring matter properly thickened, so that, as it revolves, it takes up a coating of color and distributes it over the engraved roller, which transfers the pattern to the cloth. The cloth to be printed passes over a large iron drum covered with several folds of woollen cloth, so as to form a somewhat elastic printing surface: an endless web of blanketing is made to pass round this drum, which serves as a sort of guide, and defence, and printing surface to the calico which is being printed. The superfluous color is removed from the engraved roller by a sharp-edged knife or plate usually of steel or gun-metal, called the *color doctor*, so arranged, that the color scraped off shall fall back into the trough; another plate of steel removes the fibres which the roller acquires from the calico.

As many as eight colors may be printed at once by one machine, but very great nicety of arrangement is required to bring all these rollers to bear upon the cloth, so as to print at the exact spots required for forming a complicated pattern.

The printing cylinders are of copper, and vary in length from 30 to 40 inches, according to the width of the calico; the diameter varies from 4 to 12 inches. Each cylinder is bored through the axis, and accurately turned from a solid piece of metal. To engrave a copper cylinder by hand with the multitude of minute figures which exist in many patterns, would be a very laborious and expensive operation, and the invention of Mr. Jacob Perkins in America, for transferring engravings from one surface to another by means of steel roller dies, has long been applied to calico printing with perfect success. The pattern is first drawn upon a scale of about 3 inches square, so that this size of figure being repeated a number of times will cover the printing cylinder. This pattern is next engraved in intaglio upon a roller of softened steel, about 1 inch in diameter and 3 inches long, so that it will exactly occupy its surface. This small roller which is called the *die*, is next hardened by heating it to redness in an iron case containing pounded bone-ash, and then plunging it into cold water, its surface being protected by a chalk paste. This hardened roller is put into a rotatory press, and made to transfer its design to a similar roller in a soft state called the *mill;* the design which was sunk in the die now appears in relief on the mill. The mill in its turn is hardened, and being put into a rotatory press, engraves or indents upon the large copper cylinder, the whole of the intended pattern.

It is often necessary to apply some substances to the cloth which shall act as a bond of union between it and the coloring matter. These substances are usually metallic salts called *mordants*, which have an affinity for the tissue of the cloth as well as for the coloring matter when in a state of solution, and form with the latter an insoluble compound. The usual mordants are alum, and several salts of alumina, peroxide of iron, peroxide of tin, protoxide of tin, and oxide of chrome. Mordants are useful for all vegetable and animal coloring matters which are soluble in water, but have not a strong affinity for tissues. The action of the mordant withdraws them from solution, and forms with them upon the cloth certain compounds which are insoluble in water.

To prevent the mordant or the coloring matter from spreading beyond the proper limits of the design, *thickeners* are used to bring it to the required consistency; the most useful are wheat starch and flour, but many other materials are used for this purpose. The colors, with the proper thickeners, are prepared in vessels furnished with steam jackets, for raising the contents to the required temperature.

There are eight different styles of calico printing, each requiring different methods of manipulation, and peculiar processes.

1. The *madder* style, (so called from its being chiefly practised with madder,) to which the best chintzes belong, in which the mordants are applied to the white cloth with many precautions, and the colors are afterwards brought up in the dye-bath. These constitute permanent prints. 2. The *padding style*, in which the whole surface of the calico is imbued with a mordant, upon which afterwards different colored figures may be raised, by the topical application of other mordants joined to the action of the dye-bath. 3. The *resist style*, where the white cloth is impressed with figures in resist paste, and is afterwards subjected first to a cold dye, as the indigo vat, and then to a hot dye-bath, with the effect of producing white or colored spots upon blue ground. 4. The *discharge style*, in which thickened acidulous matter, either pure or mixed with mordants, is imprinted in certain points upon the cloth, which is afterwards padded with a dark colored mordant, and then dyed, with the effect of showing bright figures on a dark ground. 5. *China blues;* a style resembling blue stone ware, practised with indigo only. 6. The *decoloring style*, by the topical application of chlorine or chromic acid to dyed goods. This is sometimes called a discharge. 7. Printing by steam, a style in which a mixture of dye extracts and mordants is topically applied to calico, while the chemical reaction which fixes the colors to the fibre is produced by steam. 8. Spirit colors; produced by a mixture of dye extracts, and a solution of tin. These colors are brilliant but fugitive.

The processes actually required for finishing a piece of cloth in the madder style, as for example, in producing a red stripe upon a white ground, are numerous. The bleached cloth is submitted to nineteen operations, as follows:—1. Printing on mordant of red liquor, (a preparation of alumina,) thickened with flour and dyeing; 2. Ageing for three days; 3. Dunging; 4. Wincing in cold water; 5. Washing at the dash wheel; 6. Wincing in dung-substitute and size; 7. Wincing in cold water; 8. Dyeing in madder; 9. Wincing in cold water; 10. Washing at the dash wheel; 11. Wincing in soap water containing a salt of tin; 12. Washing at the dash wheel; 13. Wincing in soap water; 14. Wincing in a solution of bleaching powder; 15. Washing at the dash wheel; 16. Drying by the hydro-extractor; 17. Folding; 18. Starching; 19. Drying by steam.

CALICO: *Machine for printing in four colors.* In this machine the pressure is normal, in all the engraved rollers, by the means of the levers P. These rollers are turned by a belt communicating with the prime mover. The regulators are adjusted by screws, to which are attached hands, indicating, upon dials, the space to be run by the rollers in order to reach the regulators: this is known without stopping the works.

The engraved rollers can be brought up to the pressing cylinder, or withdrawn from it, without changing the places of the color-vessels or of the scrapers, for all the different pieces fixed against the pillows on the turning pieces of the engraved rollers, move with these last. Finally, there is an apparatus placed behind the under cloth, the intermediate cloth, and the stuff to be engraved, by which the workman governs these three pieces at will.

The engraved rollers are sometimes made of copper, sometimes of brass, or of copper and tin. The first are to be preferred, being less apt to be injured; with such a cylinder 30,000 pieces can be printed with the most delicate patterns.

The brass cylinders will be injured in proportion to the acidity of the printing-mixture, the zinc being attacked. Those in whose composition tin is introduced are more hard, but also more difficult to engrave. Some of these cylinders are hollow, others are massive: either may be used.

The diameter of the cylinders varies from 0·23 to 0·82 feet, according to the option of the manufacturer, and also to the dimensions of the pattern.

The dimensions of the pressing-rollers make no difference in the impression: the lesser ones should, on certain considerations, be preferred, for the engraved rollers always yield under the pressure of the first, so that it becomes necessary to give a curve to the pressing-roller equal to that of the engraved; and as the pressure it exercises is inversely to the augmentation of its diameter, it becomes necessary to increase the weight on the subterraneous levers, thus giving still more chance to the engraved cylinders to bend.

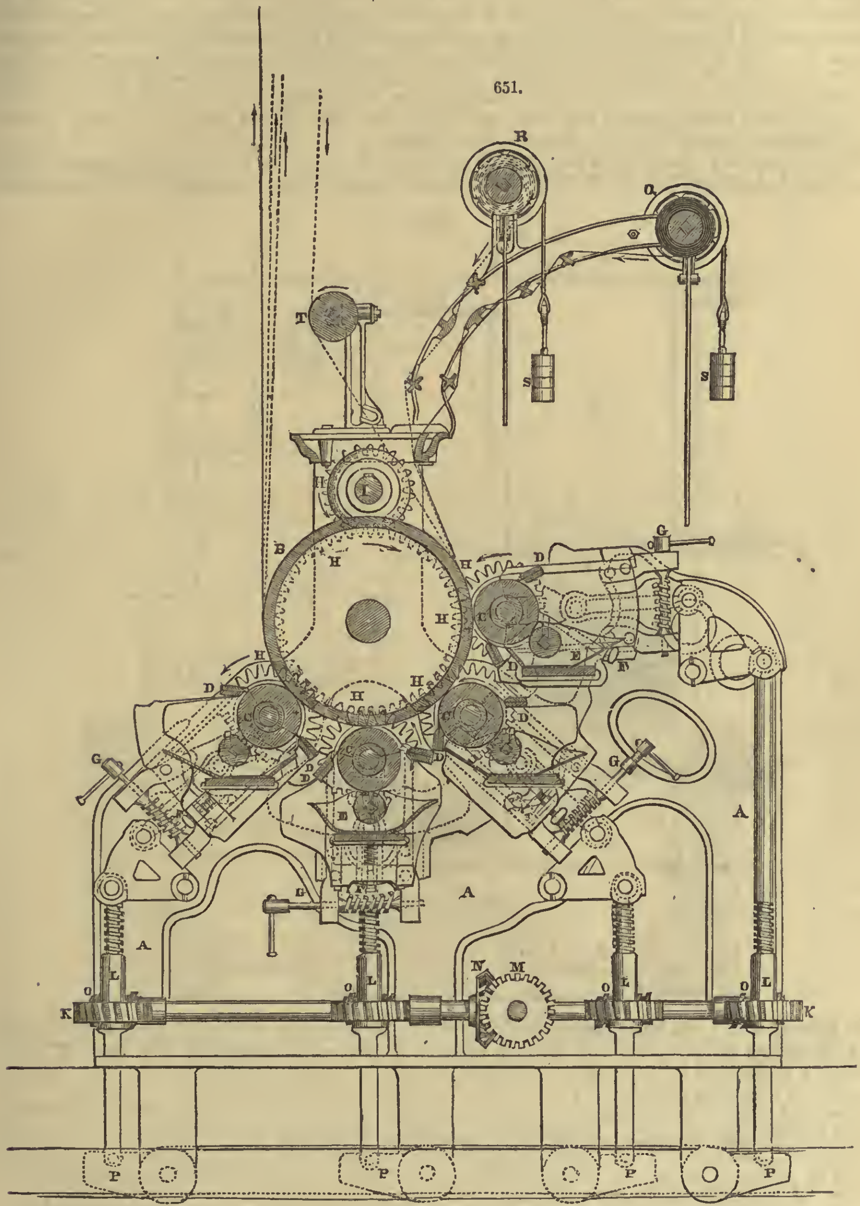
M. Huguenin thinks that a pressing-roller having only a diameter of 0·856 feet, for machines printing only one color, and that of those printing several colors, the smallest possible must be used. In some manufactures these rollers are wrapped with a band of a tissue, the warp of which is flax, and the weft of worsted, having the property of not lengthening under pressure; at the centre of the roller, this envelope is 0·062 feet thick, at the extremities 0·032 feet. The most modern improvement in this respect is the introduction of a tissue of cotton and caoutchouc.

The furnishing rollers have their circumference enveloped in a woollen cloth; their speed is inferior to that of the engraved cylinders; their diameter is generally about 0·328 feet.

The vessels in which the rollers dip are made of copper or wood. It is necessary to keep them sup

plied with a constant quantity of printing material, for the rollers would soon only skim over the surface of the fluid and leave but a feeble impression; to this end a reservoir pours a continual supply. A partition is placed in a position which enables it to clear the roller of the froth with which its surface may be covered.

651.

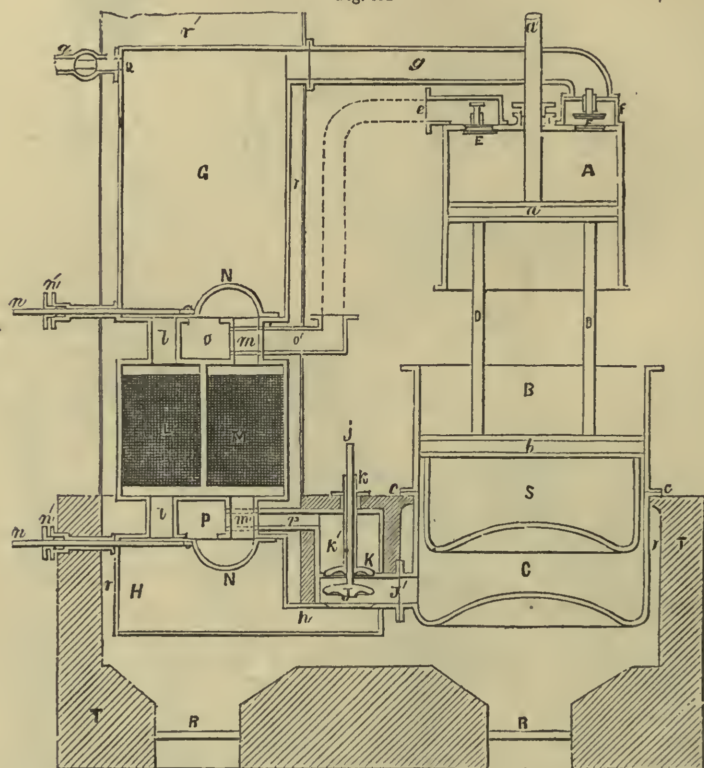


A A, frame-work.
B B B B, pressing cylinder.
C C C C, engraved cylinder.
D D D D, scrapers.
E E E E, vessels containing the coloring matter: they are raised and lowered at pleasure, by the screws F F F F.
G G G G, endless screw, guiding the regulators.
H H H H, pinions and wheels which turn all the machinery.
I, a shaft communicating with the moving power.
K K K K, wheels adapted to the female screws L L L L, which put the levers in communication with the pillows of the rollers.
M, a wheel communicating with the driving power, whose office is to press the rollers; it also moves the wheel N, and the endless screws O O O O, which are engaged with the wheels K K K K.
P P P P, levers which are loaded with weights in proportion with the pressure required: they are situated beneath the floor.
Q, the cylinder round which the cloth to be printed is rolled.
R, the cylinder round which the intermediate cloth is wound.
S, a weight which keeps the cloth stretched on the cylinders Q R.
T, a roller used to give an inclination to the cloth when printed, and regulate the speed

CALORIC ENGINE, *Ericsson's Patent.* The invention consists in producing motive power by the application of caloric to atmospheric air or other permanent gases or fluids susceptible of considerable expansion by the increase of temperature. The mode of applying the caloric being such, that after having caused the expansion or dilatation which produces the motive power, the caloric is transferred to certain metallic substances, and again retransferred from these substances to the acting medium at certain intervals, or at each successive stroke of the motive engine, the principal supply of caloric being thereby rendered independent of combustion or consumption of fuel; accordingly, whilst in the steam-engine the caloric is constantly wasted by being passed into the condenser, or by being carried off into the atmosphere, in the improved engine, the caloric is employed over and over again, thereby dispensing with the employment of combustibles, excepting for the purposes of restoring the heat lost by the expansion of the acting medium and that lost by radiation, also for the purpose of making good the small deficiency unavoidable in the transfer of the caloric.

We now proceed to describe the structure of the improved engine for producing motive power, reference being had to fig 652, A and B are two cylinders of unequal diameter, accurately bored and provided

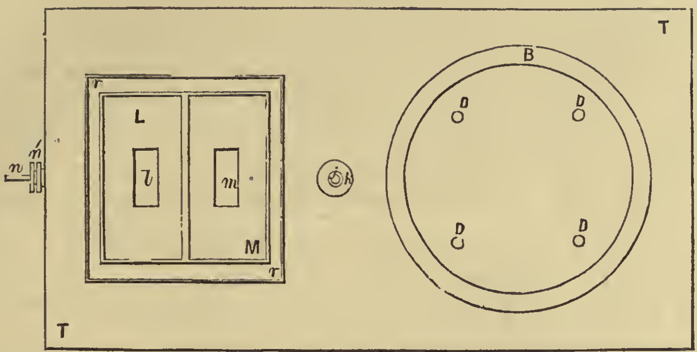
Fig. 652



with pistons *a* and *b*, the latter having air-tight metallic packing rings inserted at their circumferences. A is the supply cylinder, and B the working cylinder, *a'* piston-rod attached to the piston *a* working through a stuffing-box in the cover of the supply cylinder. C is a cylinder with a spherical bottom attached to the working cylinder at *c c;* this vessel is called the expansion heater. D D, rods or braces connecting together the supply piston *a*, and the working piston *b*. E is a self-acting valve opening inwards to the supply cylinder; F, a similar valve, opening outwards from said cylinder, and contained within the valve-box *f.* G is a cylindrical vessel, which is called the receiver, connected to the valve-box *f*, by means of the pipe *g.* H, a cylindrical vessel with an inverted spherical bottom, is called the heater. J, a conical valve supported by the valve stem *j*, and working in the valve-chamber J', which chamber also forms a communication between the expansion heater C and heater H, by means of the passage *h.* K is another conical valve, supported by the hollow valve-stem *k*, and contained within the valve chamber *k'*. L and M, two vessels of cubical form filled to their utmost capacity, excepting small spaces at top and bottom, with disks of wire net, or straight wires closely packed, or with other small metallic substances, or mineral substances, such as asbestos, so arranged as to have minute channels running up and down. These vessels, L and M, with their contents, are termed regenerators. *l l*, *m m*, pipes forming a direct communication between the receiver G, and the heater H, through the regenerators. N N, two ordinary slide-valves, arranged to form alternate communications between the pipes *l l* and *m m*, and the exhaust chambers, O and P, on the principle of the valves of ordinary high-pressure steam-engines; *n n*, valve-stems working through stuffing-boxes *n' n'*; *p*, pipe communicating between

the valve chamber k' and exhaust chamber P; o', pipe leading from exhaust chamber O; Q, pipe leading into the receiver G, provided with a stop-cock q. R R, fire-places for heating the vessels H and C; r r r r, flues leading from said fire-places, and terminating at r'. S, a cylindrical vessel attached to the working piston b, having a spherical bottom corresponding to the expansion vessel C. This vessel, S, which is the heat-intercepting vessel, is to be filled with fire-clay at the bottom, and ashes, charcoal, or other non-conducting substances towards the top, its object being to prevent any intense or injurious heat from reaching the working piston and cylinder. T T, brick-work or other fire-proof material surrounding the fire-places and heaters. Fig. 653 represents a sectional plan of fig. 1.

Fig 653.



Before describing the operation of the improved engine, it will be proper to observe that the piston-rod a' only receives and transmits the differential force of the piston b, viz., the excess of its acting force over the reacting force of piston a. This differential force imparted to said piston-rod may be communicated to machinery by any of the ordinary means, such as links, connecting-rods and cranks, or it may be transmitted directly for such purposes as pumping or blowing. The conical valves K and J may be worked by any of the ordinary means, such as eccentrics or cams, provided the means adopted be so arranged that the valve K will commence to open the instant that the piston b arrives at the full up-stroke, and be again closed the instant the piston arrives at full down-stroke, whilst the valve J is made to open at the same moment, and to close shortly before, or at the termination of the up-stroke. In like manner, the slide-valve N′ is to open and close as the piston b arrives respectively at its up and down stroke, similar to the slide-valve of an ordinary high-pressure engine.

Before starting the engine, fuel is put into the fire-places R R, and ignited, a slow combustion being kept up until the heaters and lower parts of the regenerators shall have been brought to a temperature of about 500°. By means of a hand-pump, or other simple means, atmospheric air is then forced into the receiver G through the pipe Q, until there is an internal pressure of some 8 or 10 pounds to the square inch. The valve J is then opened, as shown in the figure; the pressure entering under the piston b will cause the same to move upwards, and the air contained in A will be forced through the valve F into the receiver. The slide-valves N N being, by means of the two stems n n, previously so placed that the passages l l are open, the air from the receiver will pass through the wires in L into the heater H, and further into C, the temperature of the air augmenting, and its volume increasing as it passes through the heated wires and heaters. The smaller volume forced from A will, in consequence thereof, suffice to fill the larger space in C. Before the piston arrives at the top stroke, the valve J will be closed, and at the termination of the stroke the valve K will be opened; the pressure from below being thus removed, the piston will descend and the heated air in C will pass through k' p P and m into the regenerator M, and in its passage through the numerous small spaces or cells formed between the wires, part with the caloric, gradually falling in temperature until it passes off at o', nearly deprived of all its caloric. The commencement of the descent of the piston a will cause the valve F to close and the valve E to open, by which a fresh charge of atmospheric air is taken into the cylinder A. At the termination of the full down-stroke, the valve K is closed and the valve J again opened, and thus a continued reciprocating motion kept up. It will be evident that after a certain number of strokes the temperature of the wires or other matter contained in the regenerators will change; that of M will become gradually increased, and that of L diminished. The position of the side valves N N should, therefore, be reversed at the termination of every fifty strokes of the engine, more or less, which may be effected either by hand, or by a suitable connection to the engine. The position being, by either of these means, accordingly reversed to that represented in the drawing, the heated air or other medium passing off from C will now pass through the partially cooled wires in L, whilst the cold medium from the receiver will pass through the heated wires of M, and on entering H will have attained nearly the desired working temperature. In this manner the regenerators will alternately take up and give out caloric, whereby the circulating medium will principally become heated, independently of any combustion, after the engine shall have been once put in motion.

The relative diameter of the supply and working cylinder will depend on the expansibility of the acting medium employed; thus, in using atmospheric air or other permanent gases, the difference of the area of the pistons may be nearly as 2 to 1, whilst in using fluids, such as oils, which dilate but slightly, the difference of area should not much exceed one-tenth. In employing any other medium than atmospheric air, it becomes indispensable to connect the outlet pipe o' and the valve-box e of the

outlet valve E, as indicated by dotted lines in the drawing, these dotted lines representing the requisite connecting-pipe. The escaping air or fluid at o' will, when such a connecting-pipe has been applied, furnish the supply cylinder independently of other external communication, and the acting medium will perform a continuous circuit through the machine under this arrangement; the operation being in other respects as before described. The working cylinder may be placed horizontally or otherwise, and it may be made double acting; a heat-intercepting vessel may be applied at each end of the working piston, as also an expansion heater at each end of the working cylinder.

Stirling's Air Engine. Mr. Robert Stirling, a Presbyterian clergyman in Scotland, and an amateur in mechanical matters, made an engine the subject of a patent dated Oct. 1, 1840, which was described before the Institution of Civil Engineers, in 1846, by his brother, John Stirling. We present the description by Mr. S., as it appeared in the English mechanical magazines at the time. It will be seen that the Ericsson engine is but a slight advance on the engine of Stirling, the principal features being substantially the same in each: Stirling used the same air, as well as the same heat, over and over, while Ericsson takes fresh air every stroke. By the latter arrangement, cold air is obtained for the pump without taking trouble to cool the air of the exhaust for that purpose, but it involves the necessity of continually compressing a fresh quantity, a loss which can be but imperfectly compensated for by allowing the air to act expansively. Whether the gain or loss is greater in this arrangement has not yet been satisfactorily shown, either in theory or practice.

The principle upon which the movements of this air-engine depend, is the well-known one in pneumatics, that air has its bulk or pressure increased when its temperature is raised, and diminished when its temperature is lowered.

Two strong air-tight vessels are connected with the opposite ends of a cylinder, in which a piston works in the usual manner. About four-fifths of the interior space in these vessels is occupied by two similar air-tight vessels or plungers, which are suspended to the opposite extremities of a beam, and capable of being alternately moved up and down to the extent of the remaining fifth. By the motion of these interior vessels, which are filled with non-conducting substances, the air to be operated upon is moved from one end of the exterior vessels to the other, and as one end is kept at a high temperature, and the other as cold as possible, when the air is brought to the hot end, it becomes heated and has its pressure increased, and when it is brought to the cold end, its heat and pressure are diminished. Now, as the interior vessels necessarily move in opposite directions, it follows, that the pressure of the inclosed air in the one vessel is increased, while that of the other is diminished. A difference of pressure is thus produced upon the opposite sides of the piston, which is thereby made to move from the one end of the cylinder to the other, and by continually reversing the motion of the suspended bodies or plungers, the greater pressure is successively thrown upon a different side, and a reciprocating motion of the piston is kept up. The piston is connected with a fly-wheel in any of the usual modes, and the plungers, by whose motion the air is heated and cooled, are moved in the same manner, and nearly at the same relative time with the valves of a steam engine.

The power is greatly increased and made more economical by using somewhat highly-compressed air, which is at first introduced, and is afterwards maintained, by the continual action of an air-pump. The pump is employed in filling a separate magazine with compressed air, from which the engine can be at once charged to the working pressure.

If all the heat, however, which is necessary to raise the air to the required temperature, were to be thrown away or lost every time that the air is cooled, the power produced by its expansion and contraction would be much more expensive than that which is gained by the use of steam. In order, therefore, to understand how the work of a good steam-engine has been done, with about one-third of the fuel consumed by it, it is necessary to point out the method by which the greater part of the heat is preserved, and is used repeatedly, in expanding the air, before it is finally wasted or lost.

For this purpose, when it is necessary to cool the air, after it has been brought to its greatest heat, it is not at once brought into contact with the coldest part of the vessels. This would indeed effectually cool it, but the heat when thus extracted would be entirely lost, because it could never again be taken up by a body warmer than itself. Instead of this, therefore, the air is made to pass from the hot to the cold end of the air-vessel through a multitude of narrow passages, whose temperature is at first nearly as great as that of the hot air, but gradually declines till it becomes nearly as low as the coldest part of the air-vessel. Now, as every body by contact will give out heat to one that is colder than itself, the air, when it enters the narrow passages, must give out a portion of its heat, even to the hottest part of these passages, and must continue in its progress to give out more and more, as the temperature of the passages is diminished, till at last when it is ready to escape into the cold part of the vessel, there is only a small portion of the heat to be extracted, in order to bring it to the lowest temperature required. By far the greater part of the heat, therefore, has been left behind, in the metal which forms the passages, and which is so contrived and arranged, as to retain that heat until it is again required for heating the air. It must be evident also, from the manner in which the heat has been distributed, or spread out, over the whole length of those passages, that it is capable of being again employed in heating and expanding the air; for when the cold air is again made to enter the passages for the purpose of being heated, it immediately comes into contact with matter that is hotter than itself, and consequently begins to acquire heat, even at its first entrance; and as it is successively applied to surfaces of a greater temperature, it continues to receive more and more heat, so that when it comes at last to the hot end of the vessel, it requires but a small addition to its temperature to give it the elasticity which is necessary to move the piston. Thus, instead of being obliged to supply, at every stroke of the engine, as much heat as would be sufficient to raise the air from its lowest to its highest temperature, it is necessary to furnish only as much as will heat it the same number of degrees, by which the hottest part of the air-vessel exceeds the hottest part of the intermediate passages.

This arrangement or contrivance for the heating and cooling of air and other fluids, which may be

termed the economical process, forms the foundation of all the success which has been attained in producing power, with a small expenditure of fuel.

This principle was devised and acted upon by Mr. R. Stirling nearly thirty years ago, but until the present time it could not be said to have been beneficially applied to the production of power. The several means by which the principle is at last rendered effective, consist, chiefly, in the employment of various means for keeping the piston-rods air-tight, and enabling the pressure of the air to be raised to such an extent as to bring the engine into a small compass, and in the introduction of an effective refrigerating apparatus for extracting the waste heat and bringing the air to a lower temperature than could otherwise have been attained.

The greatest difficulty which was encountered, consisted in the proper application of the heat to the outside of the air-vessels. When applied directly by radiation from the fire to the spherical bottom of the vessels, it necessarily heated one part too much and another part too little, and the overheated part was not only liable to rapid oxidation, but by its expansion the other parts were strained and cracked. The heat is now applied chiefly by means of the hot-air which passes through the furnace; and it is found that, instead of requiring more fuel to keep up the heat, by this method it is accomplished with a considerable less quantity. It is found also that when the flues for distributing the heat over the surface are properly constructed, the air-vessels are very equally heated, and neither show a hurtful tendency to oxidation, nor to that unequal expansion by which the air-vessels might be destroyed.

The first engine of this kind which, after various modifications, was efficiently constructed and heated, had a cylinder of 12 inches in diameter, with a length of stroke of 2 feet, and made 40 strokes or revolutions in a minute. This engine moved all the machinery at the Dundee Foundry Company's works for eight or ten months, and was previously ascertained to be capable of raising 700,000 lbs. one foot in a minute. Finding this power to be too small for their works, the Dundee Foundry Company erected their present engine, with a cylinder of 16 inches in diameter, a stroke of 4 feet, and making 28 strokes in a minute. This engine has now been in continual operation for upwards of two years, and has not only performed the work of the foundry in the most satisfactory manner, but has been tested (by a friction brake on a third mover) to the extent of lifting nearly 1,500,000 lbs. It was found difficult to keep this load steadily applied for any length of time, owing to the strap becoming heated; but the engine has been worked for a whole day with a measured burden of 1,250,000 lbs., besides driving three extensive lines of shafting 370 feet in length; and this work is performed with an expenditure of 1000 lbs. of Scotch Chew coals, including the quantity necessary to raise the heat in the morning, and to maintain it during the two hours for meals, when the work was usually stopped. The coals used in this case were of inferior quality, and at least one-fourth less capable of producing heat than ordinary English coals. Taking this into account, and deducting 150 lbs., the quantity which was ascertained to be necessary for raising the heat in the morning, leaves a consumption of 600 lbs. in 12 hours. But little has yet been done in improving the furnaces, the principal attention having hitherto been devoted to ascertain the best method of heating the air-vessels, without regard to the economy of fuel. This result, although not so favorable as might be expected, is given to show the early capabilities of the engine. This engine requires only about a cubic inch of oil to keep the piston and the rod in order for two days, and in consequence of this, the friction of the cylinder and piston is decidedly less than it is in a steam-engine. In like manner the valves of the air-pump and safety-valves being free from moisture, do not show any tendency to get out of order. The leather collars are also very durable, that of the piston-rod usually lasting about three months, and the others six or nine months; and upon the whole, the working of the machine, besides the saving of fuel, is altogether more economical and less troublesome than that of a steam-engine.

It was perceived from the beginning, that in order to render the heating and cooling of the air complete and economical, it would be necessary to make the passages through which it is conveyed from one end of the air-vessels to the other, as narrow as possible. This is rendered necessary by the very defective conducting power of air, and the consequent difficulty of heating and cooling it. But on the other hand, the contraction of the passages, in which the air is heated and cooled, greatly increases the force which is necessary to pass it through them; so that, if they were made extremely narrow, the whole power of the engine might be consumed in transferring the air.

Mr. Stirling exhibited the model of the engine, and explained that the object was to raise the temperature of the air in the air-vessel, to such an extent as to obtain a difference of 500° between the heated and the cooled states. The air when heated might be taken at 650°, and after it had passed through the capillary passages, and the refrigerator, its temperature was 150°. The working pressure varied during each stroke from 160 lbs. to 240 lbs. per square inch.

CAM. If the axle of a wheel be situated in any other point than its centre, the wheel thus rendered *eccentric*, may produce by its revolution an alternate motion in any part exposed to its action. Circles, hearts, ellipses, parts of circles, and projecting parts of various forms, are made to produce alternate motion, by continually altering the distance of some movable part of the machine from the axis about which they revolve. Such projecting parts are called *cams*. See ECCENTRICS.

CAMBER. The convexity of a beam, frame or girder.

CAMERA OBSCURA. A converging object-glass adjusted to the shutter of a dark room, will concentrate the rays which come from external objects; and if these objects are very distant, compared with the focal distance of the glass, and situated nearly in the direction of its axis, it will give distinct images which may be received upon a white screen. These images are inverted; but in order to render them erect, it is sufficient to bring to the object-glass, instead of the direct light of the object, that of the image, already reflected and inverted by a metallic mirror. This apparatus is called a *camera obscura*. A plate of ground glass may be substituted for the screen, and for the room, a box fitted by means of a curtain to receive the head. It can then be transported with ease, for the purpose of landscape sketching.

Camera Lucida. If a quadrangular prism be cut in such a manner that the rays coming from neigh-

boring objects, and falling nearly perpendicularly upon its first surface, shall twice experience total reflection at its interior faces, and then, emerging perpendicularly through its last surface, arrive at the eye, an erect and horizontal image of the object, will appear to come through the prism. But if the pupil of the eye be so placed, that the rays thus reflected shall occupy only half of it, the other half jutting a little over the edge of the prism so as to admit the rays coming directly from a piece of pasteboard placed below; it is evident, that in this manner the spectator will see at once, with the same eye, the image and the screen upon which it appears to be thrown. If then he wishes to sketch the outlines with a fine pointed pencil, he will see at the same time the point of this pencil and the image, and there will be nothing to prevent his delineating it. This ingenious instrument was invented by Dr. Wollaston, and is frequently used by draughtsmen in copying details from Topographical Drawings.

CAMWOODS. See Woods, *varieties of.*

CANALS. Canals are open channels of water for the purposes of navigation, water supply for cities and manufactories, for drainage, for irrigation, &c. The form and size of the canal will depend upon the purposes to which it is to be applied. For navigation, on the size of the boats and the amount of traffic. For water supply, drainage, &c., on the amount of water to be supplied or discharged.

The following Table is from Wm. J. Mc Alpine's Report to the N. Y. Legislature, in 1853.

NAME.	State.	Length in miles.	Cost.	Cost per mile.	Width at surface. Feet.	Depth of water. Feet.	Locks.				Burthen of boats. Tons.

For the enlargement of the Erie canal, the following dimensions have been adopted:—Width at water-line, 70 feet. Width at bottom, 28 feet. Depth of water, 7 feet. Width of tow-path, 14 feet.

The Caledonian canal in Scotland is remarkable for its size, which will admit of the passage of frigates of the second class. Its principal dimensions are as follows:—Width at water-line, 100 feet. At bottom, 50 feet. Depth of water, 20 feet. Length of locks between mitresills, 180 feet. Width of chamber at top, 40 feet. Lift of lock, 8 feet.

Crossection. In canals of this country the interior slopes are generally uniform, from $1\frac{1}{4}$ to $1\frac{1}{2}$ horizontal, to 1 perpendicular, the slopes being paved or rubbled near the top, to prevent the wash. The tow-paths are about two feet above the level of the water, and from 6 to 12 feet wide. The path should slope outwards from the canal so that the surface water and earth may not be carried into the channel. With regard to the supply of water necessary for a canal, or for a level of canal, it embraces the quantity required for the service of the navigation, that is, the number of times the chambers of the locks will require to be used in the passage of boats, and the losses arising from evaporation, from leakage through the soil and through the lock gates, the necessary first fillings of the levels and the chance of accidents or breaches, and the emptying of the levels for repairs. In estimating the quantity expended for the service of navigation the problem is simple, knowing the capacity, form and number of locks, the size of boats and the contemplated amount of traffic. With regard to the other losses it must be a great deal a matter of conjecture. From experiments made by Mr. J. B. Jervis on the Erie canal, the total loss from evaporation, filtration, and leakage through the gates, is about 100 cubic feet per minute for each mile. Having determined the amount of water required, the source of the supply must be guaged, and if the minimum flow of the stream be not sufficient, reservoirs must be constructed to equalize the supply. For the forms and dimension of locks, see "Locks of Canals."

On the cost of transportation on canals, we again extract from the able Report of Mr. Mc Alpine.

The cost of transportation of coal in 1848 on the Chesapeake and Ohio canal from Cumberland to Georgetown, a distance of 184.4 miles, was \$78.06, or $4\frac{1}{4}$ mills per ton per mile, including the interest on the cost of the boats and fixtures, annual repairs and depreciation on the same, cost of towing, wages of men, cost of loading and unloading.

The cost of transportation of coal on the Schuylkill canal is \$44.54 for 108 miles, or $4\frac{1}{10}$ mills per ton per mile; the cost on the Delaware and Hudson canal is about the same.

The cost of all expenses of running, towing, and decrease of value of horses, office and personal expenses, and part cost of loading and unloading on the Erie canal in 1852, was $2\frac{9}{10}$ mills per ton per mile. Mr. Seymour, the late State engineer, estimated the whole cost at $3\frac{1}{2}$ mills per ton per mile. The charges for transportation on the Erie canal in 1851 and 1852 (except late in the season) have averaged \$2.50 per ton for down, and \$2.35 per ton for up freight (exclusive of the charge for State tolls), being at the rate of 6.9 and 6.5 mills per ton per mile.

The charges for transportation of coal on the Schuylkill canal in 1852, was \$0.65 for 108 miles, or 6 mills per ton per mile; and on the Delaware and Hudson canal, about $5\frac{1}{2}$ mills per ton per mile. On the latter canal they have ascertained that the cost of transportation has been reduced more than forty per cent. by enlarging the canal from a capacity for boats of 50 tons to that of 115 tons.

In 1848, the Delaware and Hudson Canal Company determined to enlarge the dimensions of their canal for the purpose of accommodating the increased amount of trade, and to cheapen the cost of transportation. This has been accomplished at an expense of about $2\frac{1}{2}$ millions of dollars.

The engineer of that work, R. F. Lord, Esq., prepared very careful estimates of the saving in the cost of transportation which the enlargement would effect, as follows: "The charge for freight on the old canal which was competent for boats of 50 tons, was \$1 per ton for 108 miles, or nearly one cent per ton per mile. The estimated charge for freighting with the canal enlarged for boats of the following tonnages, was:

"For 100 tons, 65 cents, equal to $5\frac{6}{10}$ mills per ton per mile.
116 tons, 58 cents, equal to $5\frac{4}{10}$ mills per ton per mile.
136 tons, 50 cents, equal to $4\frac{6}{10}$ mills per ton per mile.

The company determined to enlarge the canal to the last mentioned capacity, which has been done, and boats now carry from 115 to 141 tons, at a saving in the cost of transportation equal to that estimated.

Canals for the supply of water to cities or to manufactories, are generally walled at the sides, and are deeper in proportion to their width than those used for the purposes of navigation. The area of their section is to be proportioned to the quantity to be supplied. The mean velocity is usually from 1 to 2 feet per second. The greater the velocity the more the inclination of the surface and the consequent loss of head and fall. It becomes then a matter of calculation, how much may be saved by the first investment by the construction of a canal of small area, and a consequent continual loss of available power. For the rules for calculating the flow of water in canals, see Hydraulics.

The velocity of the water in a water-course should be neither too slow, for then the course chokes with weeds, nor too fast, for then the bed of the channel may be disturbed, and besides, too much fall must not be lost in the inclination of the course.

A velocity of 7 to 8 inches per second is necessary to prevent deposit of slime and growth of weeds, and $1\frac{1}{4}$ feet per second is necessary to prevent deposit of sand. The maximum velocity of water in canals depends on the nature of the channels' bed.

On a slimy bed the velocity should not exceed $\frac{1}{4}$ f't,	On a shingle bed the velocity should not exceed 4 f't
" clay " " . . . $\frac{1}{2}$ "	" conglomerate " " . . . 5 "
" sandy " " . . . 1 "	" hard stone " " . . . 10 "
" gravelly " " . . . 2 "	This applies to the mean velocity.

The water-courses for water-wheels and general uses of the Freyberg mining district have inclinations varying from 15 inches to 30 inches per mile. The New River which supplies a great part of London, has an inclination of $\frac{470}{1000}$ per mile.

CANARY-WOOD. See WOODS, *varieties of.*
CANGICA WOOD. See WOODS, *varieties of.*

CANDLES, *Wax.* Next to tallow, the substance most employed in the manufacture of candles is wax. Wax candles are made either by the hand or with a ladle. In the former case, the wax being kept soft in hot water, is applied bit by bit to the wick, which is hung from a hook in the wall; in the latter, the wicks are hung round an iron circle, placed immediately over a large copper-tinned basin full of melted wax, which is poured upon their tops, one after another, by means of a large ladle. When the candles have, by either process, acquired the proper size, they are taken from the hooks, and rolled upon a table, usually of walnut-tree, with a long square instrument of box, smooth at the bottom.

CANDLES, *Stearic—Manufacture of.* Among the tallows which are best adapted for the preparation of stearic candles, are those of beef and mutton. All other fatty matter is poor in solid acid, or of too considerable a price. It is, then, the quantity of acid, stearic or margaric, which is found in a given weight of beef or mutton, and the facility in working the same, which ought to determine in giving preference to this or that quality of tallow. The mutton tallow contains the greater quantity of solid acid, and is the more easily worked. That of beef is, generally speaking, to be procured a little cheaper.

The manufacturers of stearic candles, to free themselves from the inconvenience of melting, are generally in the habit of buying from the butchers fat already melted. This method is far from being the best, as it is almost impossible to judge the purity of the tallow when it has been melted, and at the same time gives an opening for imposition to a considerable extent. Thus it would be most important to the manufacturer to purchase the tallow in lumps, in such manner as it is taken from the animal, covered with its membranes, and bound in its cellular tissue, and to melt it himself.

This operation of melting is performed in the slaughter-houses of Paris in a very simple manner. They have a great copper, from 6·56 feet to 7·21 feet diameter, and from 3·28 feet to 3.93 feet in depth, swelling at the bottom as in a stewpan, and widening at the top, so as to be enabled to rest upon a circular oven. This is constructed in such manner that the hearth, of a breadth of 1·32 feet, is exactly under the copper, from its circumference to its centre. The flame and hot air heat at first the whole of the bottom surface, and then circulate twice round the cylindrical part of the copper before passing up the chimney. They throw the fat in this copper by an inclined plane, which proceeds from the upper story, and during the melting they stir it with a long rod. When they have reached a proper degree of fusion, which is generally obtained in about four or six hours, according to the nature of the fat, they turn it out, first into a large iron-plate reservoir, of the same size as the copper, and which is furnished with two cocks, from which it is drawn off into slightly conical vessels, so as to form large lumps of a conical shape.

It is well to place under the copper a large funnel, the same as in a forge, to conduct the gas which escapes from the fat during the operation to the chimney. There should be also in the same factory a screw-press, for compressing the membranous part, in order that no portion of fat may be lost.

The different operations in general use for the manufacture of such candles are generally divided as follows:

1st. The formation of soap; the object of which is to combine the acidulated fat with the lime, to produce the glycerine, and obtain the stearate, margarate, and oleate of lime. The glycerine dissolves itself in the water necessary for this preparation.

2d. The pulverizing of the lime soaps.

3d. The decomposition of these same soaps by sulphuric acid diluted with water.

4th. The cleansing of these stearic, margaric, and oleic acids—first, by water slightly acidulated, and secondly, by pure water.

5th. The moulding and crystallization of the now obtained acid fats.

6th. The melting of the crystalline masses into small layers instead of large rolls.

7th. The cold-pressure of the acids thus formed into layers.

8th. The hot-pressure of these layers now reduced.

9th. The purification of the solid acids by water slightly acidulated at first, and secondly by pure water.

10th. The melting and moulding of the solid acids into moulds; then the clipping of the candles.

11th. The bleaching of the candles.

12th. The polishing, packing, &c., for removal.

Description of the Machinery.—Fig. 652 represents the general plan of a manufactory, indicating the utensils which are employed.

Fig. 653 is a sectional view of this manufactory, vertically and longitudinally; and the figures 654, 655, 656, and 657, represent in elevation, or sectionally, the details of the principal utensils, and the means of communicating the movement.

The Formation of Soap.—This operation is performed in a large vat, generally constructed of wood, slightly conical in form, and provided with several frets all the way up. The bottom and the lid are of wood, and its capacity is sufficiently great to contain, easily, more than 70·58 cubic feet. They generally place about 1100 lbs. of tallow, with a proportion of water rather more than enough to easily dissolve the same, and which would be about 200 gallons. This is heated by steam from a leaden pipe *g*, winding in a serpentine manner, and placed at the bottom of this trough. This pipe is perforated with a number of small holes, across which the steam passes as it proceeds from the coppers A or A′, with which it is in communication. When this is melted, they add, by degrees, 165 lbs. of lime well mixed; and they allow this preparation time to mingle, taking, at the same time, great care to stir it by means of an agitator *p*, composed of many branches united by a cross-piece, and having a

kind of knife fixed at each of the four arms. This contrivance is mounted upon a vertical beam o to which is given a rotary movement by the wheel n fixed to the upper part of the beam.

This wheel is acted upon by a pinion n' adjusted upon the horizontal beam, which communicates with the prime mover by the two pair of cog-wheels $l\,l'$ and $j\,j'$, mounted on one part upon the vertical beam k, and on the other part upon the horizontal beam F, as seen in Figs. 652 and 653. An energetic stirring is most important, because it more fully completes the formation of soap, and economizes, consequently, the sulphuric acid.

Generally, in the greater part of the manufactories, says Mons. Dumas, they use, perhaps, 33 lbs., and sometimes more, of sulphuric acid, to the 220 lbs. of tallow, while they ought only to use from 19 to 22 lbs. to 220 lbs. of tallow. It is often, then, a third too much, and an experienced manufacturer would do well to pay attention to this.

They had proposed to give the movement to this agitator by means of a cord, but they found they were obliged to give up this, as they could not obtain a regular movement—during one part of the operation the matter, being very compact, would present a great resistance, and the rope would give.

The time for the formation of soap is generally from 6 to 8 hours. At the end of this period they draw off, by means of a tap q' placed in the bottom of the trough, the liquid part which has absorbed the glycerine, and they take from the trough all the solid which remains there, which is now a formation of stearate, margarate, and oleate of lime, in the form of a very hard soap; this they throw upon the floor, upon which rests the trough J.

Pulverizing.—To pulverize the soap, they use, in many manufactories, a roller of cast-iron K, which they pass to and fro in an alternate movement, and generally by manual labor. Mons. Dumas proposes to have the soap pass between two cylinders moistened by a stream of cold water, which should bathe it; a precaution most indispensable, because the soap, heated by the pressure, would soften, and render itself more often in cakes than in powder.

Troughs for Decomposition.—The two troughs J^1 and J^2, into which is conveyed the solid matter after it has been broken, are designed for the decomposition of these matters by the action of sulphuric acid much diluted with water. Like the former, in shape they are slightly conical, and nearly of the same dimensions, heated by steam by a serpentine pipe q'. They ought, also, as with the former troughs for the formation of soap, to be cased with lead, so as to be protected from the action of the sulphuric acid. It would be quite as well to fit up both with a mechanical agitator, though in many manufactories they are not so. These troughs are generally on a lower floor, under the trough for the formation of soap, so that they can easily dispose of the matter.

The quantity of sulphuric acid necessary for the decomposition of these lime soaps can be easily determined. For 1100 lbs. of tallow, according to Mons. Dumas, they would use 165 lbs. of lime; or for 220 lbs. of lime the equivalent in sulphuric acid is equal to 36·7 lbs., at 66° centigrade. Consequently, for 165 lbs. of lime will be necessary 275 lbs. of this acid. In practice they add from 10 to 15 per cent. to this quantity, and the acid being, we suppose, at 66°, they dilute it by twenty times its quantity of water. At the end of about three hours the decomposition of these soaps is effected. They then displace the mass. The fat acid comes to the surface, and the sulphate of lime is precipitated to the bottom.

Cleansing the Acids.—For this purpose they withdraw, by means of a tap q', which is placed underneath, and which, like the preceding ones, is cased in lead, and equally heated by steam by a serpentine pipe placed in the bottom. It is as well to have a second trough L, similar to the preceding one, to complete the cleansing, in which they work only with pure water. The passages R, inserted in the interior of the roof, serve to establish a communication with the two troughs of decomposition J J′, and with those of cleansing L L′, and to carry the liquid off or into the lower reservoirs. As much as possible of sulphuric acid and lime are drawn off into a series of zinc moulds M, which are arranged in rows along the entire length of the workshop, in such manner, that in drawing it off into the first mould it flows gently into the adjoining moulds, which is easily done by attaching to each brim of the moulds a gutter, which carries off the superfluous matter at its proper height.

These moulds present the form of a rectangular prism from 27 to 39 inches in length, from 6¼ to 7 inches in breadth, and about 16½ feet only in height. Thus are formed layers of solidified acid, which are taken away (after being wrapped in woollen serge) to the vertical hydraulic press N, which is constructed exactly similar to the ordinary presses, of which it is easy to see the construction by reference to the design, Fig. 653, where it is shown in vertical section.

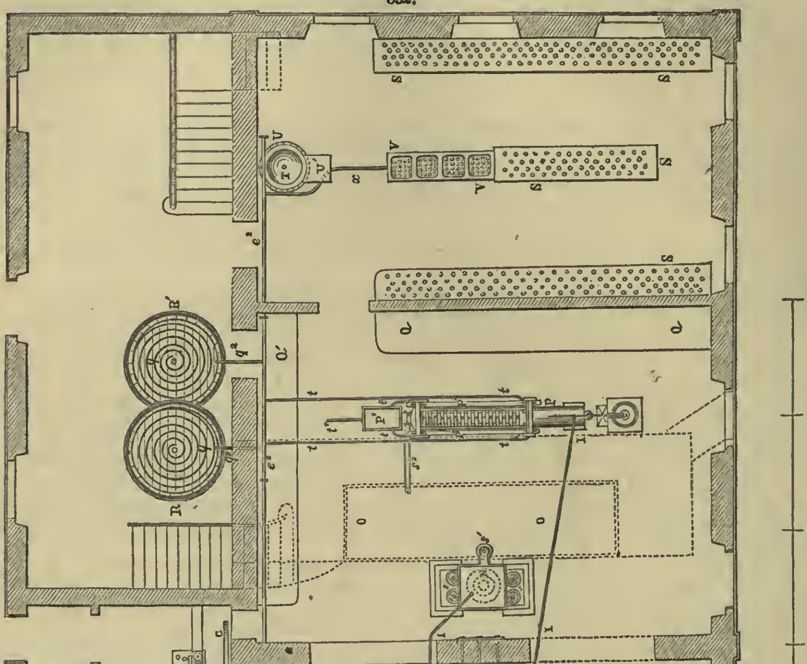
The drawing off into these moulds, such as we have endeavored to show, is only a modern application. Previously the acids were drawn off into larger moulds, which could contain about 7 gallons, and which were a little wider at the top, so that the matter could be the more easily extracted. These rolls were broken into smaller pieces by the action of a knife with an alternate movement, similar to a knife for cutting straw into small parts. Since the use of these newly-invented moulds, they economize nearly one-horse power in the impelling force.

Cold Pressure.—The vertical hydraulic press ought to be constructed to obtain a pressure of 440,000 lbs. A great part of the oleic acid flows cool to the action of this press, but, however, the latter portions can only be extracted by the aid of a certain temperature. Other presses of horizontal construction, and which are heated by steam, are employed. Such is the press represented in P P′, upon the plan, Fig. 652, and upon the vertical section, Fig. 653.

Hot Pressure.—This press is heated; also the wrought-iron plates P^3, between which are placed the links which proceed from the vertical press, and which, in issuing from this press, are enveloped in horse-hair material, in place of woollen serge.

On the opposite side to the piston of the press is a cast-iron rectangular chest P^2, airtight, in which is enclosed a similar action of plates. The steam proceeding from the generators A or A′, passes by the pipes e, e^1, e^2, t, finds its way into the double sides, as also into the double bottom of the press, to heat it. It afterwards passes by the pipes t', which carry it into the chest P^2, where there is a full

652.



action of plates P^3 to be employed as soon as the press will have ceased to work, and where they may take away those that they have used. They can still heat these plates by boiling water in a trough, also in cast-iron. It is shown by Fig. 653 in what manner these plates can be raised to furnish heat to the press, or reciprocally.

They have provided for this purpose, in the upper part of each of them, an eye, which permits the introduction of a hook fixed to the extremity of the cord u, which passes into a throat of cast-iron to the pulley. The upper part of the locket of this pulley ends with an elongated eye, to enable it to glide easily the entire length of an iron way fixed to the plank, and below the press, lengthwise—so that one of the plates being raised, they can advance the locket in a perpendicular line. They can transport them in succession either from the press to the chest, (which serves as a heater,) or from the chest to the press.

The pressure of the piston of the press often ranges from 880,000 lbs. to 1,100,000. Some, after a certain time of working, have had the bottom of the cylinder carried away by the pressure; and, in certain factories, others have been destroyed by the rupture of the long braces, which connect the heads of these presses, and which were not sufficiently strong in themselves.

The oleic acid which flows from the vertical press, or from the horizontal one, into a lower receptacle O, by the pipes S^1 S^2, from which it is drawn for the receiver into the flat vessels, by the cooling, deposites the stearic acid that it had absorbed in consequence of the increased temperature which it underwent during the action of the horizontal press.

The two pressures completed, the oleic acid is regarded as sufficiently separated, and the residual matter, formed by the stearic and margaric acids, is of brilliant whiteness; they only equal about 45 to 50 per cent. of the tallow employed.

The injecting-pumps are shown by H and H, Figs. 652 and 653, which clear the two horizontal and vertical presses. They are put into action by the horizontal beam F, which communicates with the impelling power, which is an engine of about 4-horse power—a power more than sufficient to put in motion the necessary apparatus of this manufactory.

Upon the horizontal beam E is a cast-iron upright wheel f, which commands the wheel f^1, fixed upon the horizontal beam g. This has, at its extremity, two small winches, which, by the accession of two rods h, impart to the pistons of the injection-pumps i i^1 the movement for casting the water that they draw into the great bodies of the presses N, P^1. The heads of the vertical press are supported at a convenient distance by four cast-iron columns, interlaced by large iron bolts all the way up, and the liquid matter falls upon the lower plate, which unites with the piston, and upon which they have adjusted a small trench or gutter, to allow it to flow by the pipe s^1, finished in its upper part in form of a funnel, and which conducts it into the reservoir O.

Purification of the Solid Acids.—The lumps of stearic and margaric acids which are taken from the horizontal press, are carried to the trough R, to be there purified by dilute sulphuric acid.

This trough is constructed exactly similar to the preceding—cased in lead, and heated by steam, by the pipe q^2, which conducts the same in the serpentine q, which liquefies the acids. It must be understood that this cleansing has for its object to disengage the fat acids from the remotest trace of lime that they may contain. After this operation, it only remains to free them also from the acid itself, by purifying with water. They then allow this to remain, or decant it into another trough R^1, situated upon a lower floor, and which only contains pure water, and which should be occasionally replenished. They then allow it to cool, draw it off into moulds, and at length is obtained rolls perfectly fit for working into candles.

Melting and Moulding the White Solid Acids.—They use for this purpose a copper, T, (see Figs. 652, 654, 655,) which are in the interior silver-plated, to prevent the discoloration of the acids. This copper is double-bottomed, to be heated by steam at a temperature which should not ordinarily exceed 100 degrees.

The steam proceeds from the generators into the double bottom by the pipe v, and this, condensed flows off by a pipe v^1. A tap v^2, attached to the pipe which issues from the bottom of the copper, serves to empty it completely. It is surrounded by a coat of wooden staves U, to prevent the cooling of the trough. By the side of this copper they have placed a table V, upon which rests the vessel T^1, which serves to receive the melted matter to be carried into the moulds.

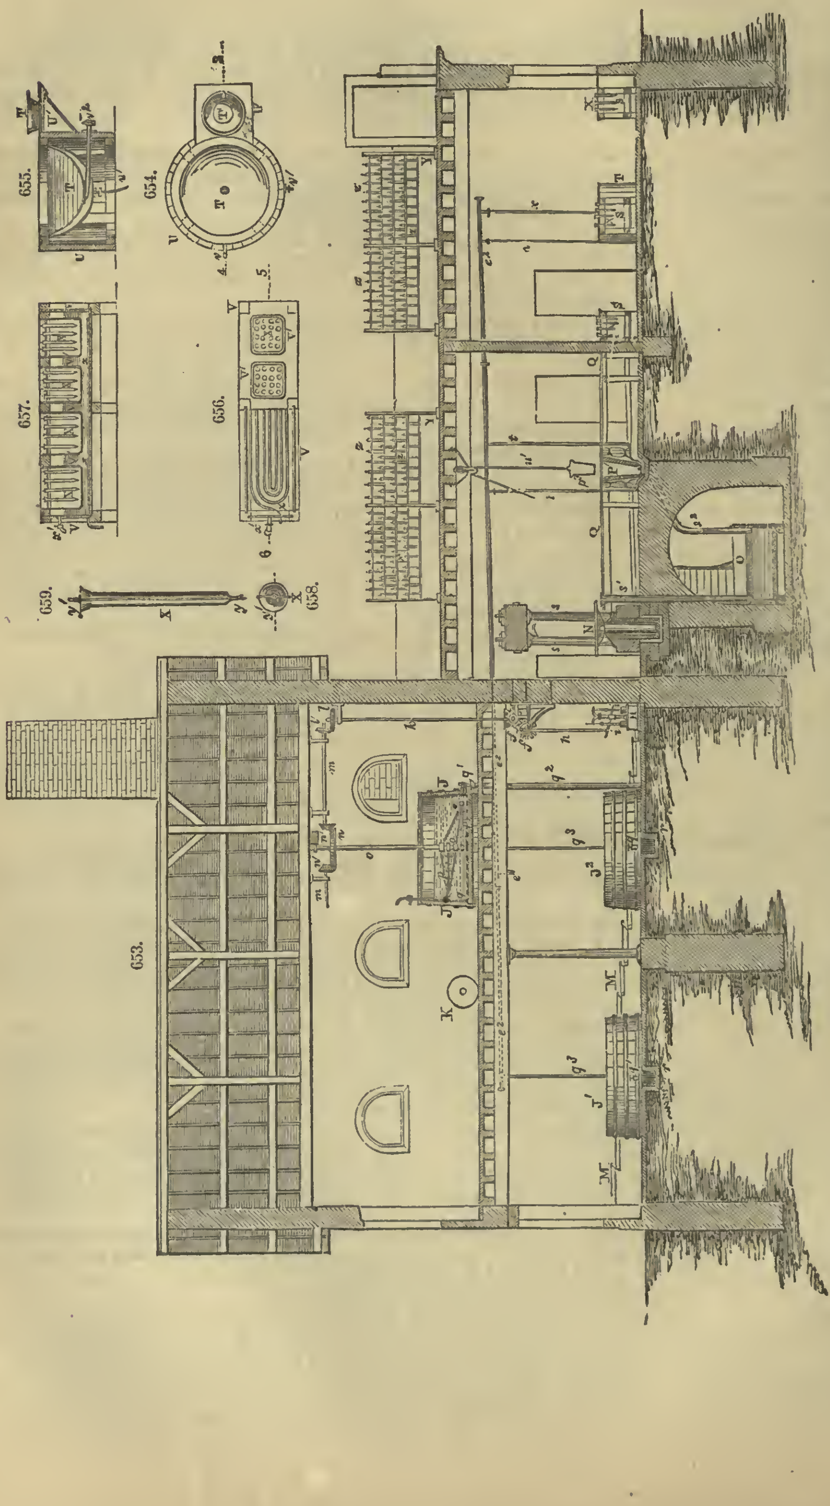
In order to make the candles and the stalactites which form upon them less powdery, they generally add 10 per cent. of sulphuric acid, when they throw in this copper the rolls of stearine. They cool these candles in moulds similar to those represented in plan and in section, Figs. 658 and 659. These moulds are formed of an alloy, composed of one-third pewter and two-thirds lead. It will be perceived that they are slightly conical, and terminated by a kind of funnel.

They fix the wick to the upper part by a bent pin y^1, and to the lower by a little wooden peg y, which closes against the sides of the orifice. These wicks are matted, which prevents the necessity of constantly snuffing the candles; for this purpose, says Mons. Dumas, it will be necessary to dip them in a solution of borax, which forms with the lime a borate which fixes itself in the wick, and serves to consume it.

To fix the wicks, the moulds are placed vertically in the holes of the wooden tables S, conveniently arranged in the workshop, and upon which they allow the candles to cool, after they are drawn off. For this purpose, after the wicks are fixed in the centre of the moulds, they carry them to the hot-water basins, which are brought up to the temperature of boiling water.

This system of heating is brought about by several basins V, represented in plan and section, (see Figs. 656, 657, and 652.) They are entirely surrounded by water, heated by a current of steam coming from the generators by the pipe x in the serpentine x^1, placed in the bottom of the apparatus.

When the moulds are sufficiently hot, they are filled by the aid of a small vessel T^1, which they plunge in the copper T. It should be first ascertained that the acid has commenced to crystallize. This precaution, as much as that of heating the moulds, is very essential to neutralize the crystalli-



653. 654. 655. 656. 657. 658. 659.

Fig. 653: Scale.—5 inches = 33 feet. Figs. 654 to 659: Scale.—8 inches = 13 feet.

zation of the fat acids—a crystallization which would give to the candles a very disagreeable appearance.

After the cooling of the moulds, they remove the small wooden peg which holds the wick, and by means of a punch, they extract the candle. The roll must also be cut, and the candles be put lengthwise. For this purpose many mechanical means have been tried, and which have not produced very satisfactory results; the difficulty to avoid breaking the candle being so great. However, they are at this moment trying the effect of a certain mechanical knife or circular saw, from which much is expected. For this process we believe it is most important that the cutting-blade should possess great rapidity and very little pressure.

Bleaching the Candles.—When the candles are moulded, they should be exposed for some time to the air, to the light, and to a humid atmosphere, that they may possess as white an appearance as possible. This is generally done upon the roof of the workshop itself, which should be constructed in the form of a terrace, where the candles *z* can be arranged upon the trays Y. Space should be economized as much as possible.

Polishing the Candles.—The last two processes which the candles have to undergo, after they have been exposed to the air some time, are the polishing and the packing. The polishing is done by rubbing the candle briskly with a piece of cloth, damped with alcohol or ammonia; and this is generally done by women or children. They have also tried to produce the polish by a mechanical process, having a kind of cylindrical plug or bung of wool or cloth, to which was imparted a regular to-and-fro movement, whilst the candles were immediately placed under the same, and by the means of endless chains, which advanced gradually upon a horizontal table, the candles rested and turned equally at the same time. This process is the invention of a Mons. Davison, of Paris, who has taken a patent out for it for five years. The packing consists in arranging them to form packets of one pound, and they are carefully and neatly secured ready for use.

Boilers, or Steam-coppers of the Machine.—The two boilers A and A′, represented in Fig. 652, are for the purpose of feeding not only the engine, (of 4-horse power,) but also for heating the different troughs; for the formation of soap; for decomposition and cleansing the horizontal press; the copper for melting, and the warmer. These boilers are of 16-horse power. There are some factories which have them as large as 20-horse power. Fig. 652 represents a horizontal projection seen from the top, and shows the disposition of these boilers, with their safety-valves, and also the pipes for conducting steam. In B will be perceived the brick furnace, in which the boilers are imbedded; in *b* the safety-valves; and in *b′* the floats: *c* shows the pipe communications with alimentary pump; *e′ e′* the pipes for conducting the steam to the different apparatus of the machine; and *d d′* the pipes which furnish the steam-engine. All these pipes are of copper, and provided with taps.

Application of the Oleic Acid.—This acid, for a long time in the different factories for the manufacture of stearic candles, was regarded as a superfluous residue, and you may say completely lost, with respect to any advantage that could be derived from it. Messrs. Pelicot & Alcan have been successful in applying it to the purpose of greasing the wool employed in silk-yarn manufactories, or in scouring it.

It is well known, in the picking or combing of wool, that a nap as homogeneous as possible is necessary. It is first prepared with a certain quantity of fat matter. This preparation is so far necessary, that without it the twisting and stretching of the wool would only be accomplished indifferently, and the loss would be greater. The thread thus obtained would be more unequal, and would not possess, for weaving, the quality required for the production of stuffs. Until within the last few years they have employed, for this purpose, vegetable oils, in most of the principal factories at Rheims, Sedan, Elbeuf, &c. In the factories of the south, olive oil was almost always used, whilst in the suburbs of Paris they have given the preference to the oil from grains, which was cheaper, and in some cases a mixture of water and oil is used, brought to a state of emulsion by the addition of a small quantity of potass.

The oil with which wool is impregnated should only remain until immediately after the spinning or weaving. Scouring should commence at that period. The process of scouring varies with the nature of the stuff they propose to manufacture. For cloths and felt stuffs it is done after the weaving, and before fulling. For light and rasé stuffs it is generally done upon the thread, and before the weaving.

At Elbeuf, Louviers, and other places, scouring is accomplished by means of potters' clay saturated with water. The thread being impregnated with this substance, they pass it between two compressing cylinders, which brings it in contact with the greasy matter; this is consequently displaced, mechanically, and is drawn off by the water, which flows in great quantities. This process will take from eight to twelve hours, and it will affect the soundness and color of the tissue; besides, the accidental presence of any small stone in the clay will occasion a rent or imperfection in the same. It is also very uncertain; and if in the first process there is a failure, it becomes more difficult again in the second, in consequence of the deposite of insoluble salts, arising from the application of water. An imperfect scouring prevents the stuff receiving the color as effectively as it should.

The oil which has been used for the greasing becomes entirely unfit for any other purpose; for, on reference to experienced men upon the subject, the result is nearly as follows: 88 lbs. of woollen cloth will imbibe 18 lbs. of oil, and they are diluted by 2843 gallons of water.

In the south, where they manufacture large quantities of common cloth for troops, or for exportation, the vegetable is not always entirely lost in the scouring. To extract this, they employ water mixed with soap and alkali: this is absorbed by heat, and then employed in the fulling of the stuff already scoured. This scouring, although very imperfect, still is, however, more economical than the former. In Sedan, for the manufacture of black cloths, &c., the greasing and the fulling are generally done at the same time. For this purpose they use a solution of soap or urine, and sometimes a combination of both. When they wish to scour the wool in thread, they use soap solution sufficiently powerful.

Messrs. Peligot and Alcan, to remove many of the inconveniences attending these processes, thought

to remedy them by the use of the acid stearic, instead of the vegetable oils. We have seen that the tallow formed into soap is transformed into two fat acids, the one solid and the other liquid. The first is the acid stearic for the manufacture of candles, and the second is the acid oleic. This last, until within the last three years, was not employed for any special purpose. These chemists, in applying it to the woollen factory, have not only rendered a great service to this last, but also to the manufacturer of stearic candles, in augmenting the value of a portion of their residue.

The employment of the acid oleic, besides economizing the actual price of purchase upon that of olive oil, or that from grain, offers this very important advantage—that it is immediately soluble in the carbonate of potash, with which it combines in the formation of soap. The scouring becomes a chemical process—for it consists in immerging the stuff for some instants in an alkaline water, and then washing it in an ordinary apparatus.

The scouring of the threads by this process has a still greater advantage, because it can be effected simply by an alkaline solution, instead of the more costly employment of a considerable quantity of soap, and equally in employing the fresh residues as in former ones.

This process is again very economical, as it furnishes itself the soap to be employed in the fulling, an operation which generally follows the scouring. The oleic acid having the direct property of a true soap, by its combination with carbonate of potash, a property that none of the vegetable oils possess in any degree or shape whatsoever, (and of which an exclusive use was made,) they now obtain, as a consequent residue from the scouring, a liquid combining the properties of soap and alkali, which before they had to provide for the fulling of the stuffs.

Besides the waste in picking, of little moment when they employ the ordinary oils, this is completely saved by the facility of scouring offered by the use of the acid oleic.

From numberless experiments it is proved, that the wool greased by the acid oleic does not become heated, neither does it ignite even when placed in circumstances most favorable for combustion.

The acid oleic, such as is left by many factories of candles, could not be employed for the purpose of greasing wool until it has undergone a complete purification, or been brought into a homogeneous substance possessing all the above-mentioned characteristics. That which they employ at this time in the cloth factories can only be compared, by its clearness and color, to the finest olive oil employed in the same factories.

In certain factories of the stearic candles they manufacture with the acid oleic a hard soap, which is sold to the dealers in large lumps.

Apparatus necessary for the manufacture of Stearic Candles.—Horizontal press, or hot press, as represented in Fig. 653, including injecting-pump.

Vertical, or cold press, with iron columns and injecting-pump.

Cast-iron chest, as in Fig. 655, for the heating of the plates.

The troughs (deal) for cleansing and decomposing, with the iron frets which surround them.

The pipes and lead casing—the agitators and their movement.

Steam-engine, high-pressure, 4 horse power.

Two boilers, each from 16 to 18 horse power. Also many other indispensable accessories, such as moulds, heaters, transmitters of movements, and pipes.

CANNON. See Ordnance.

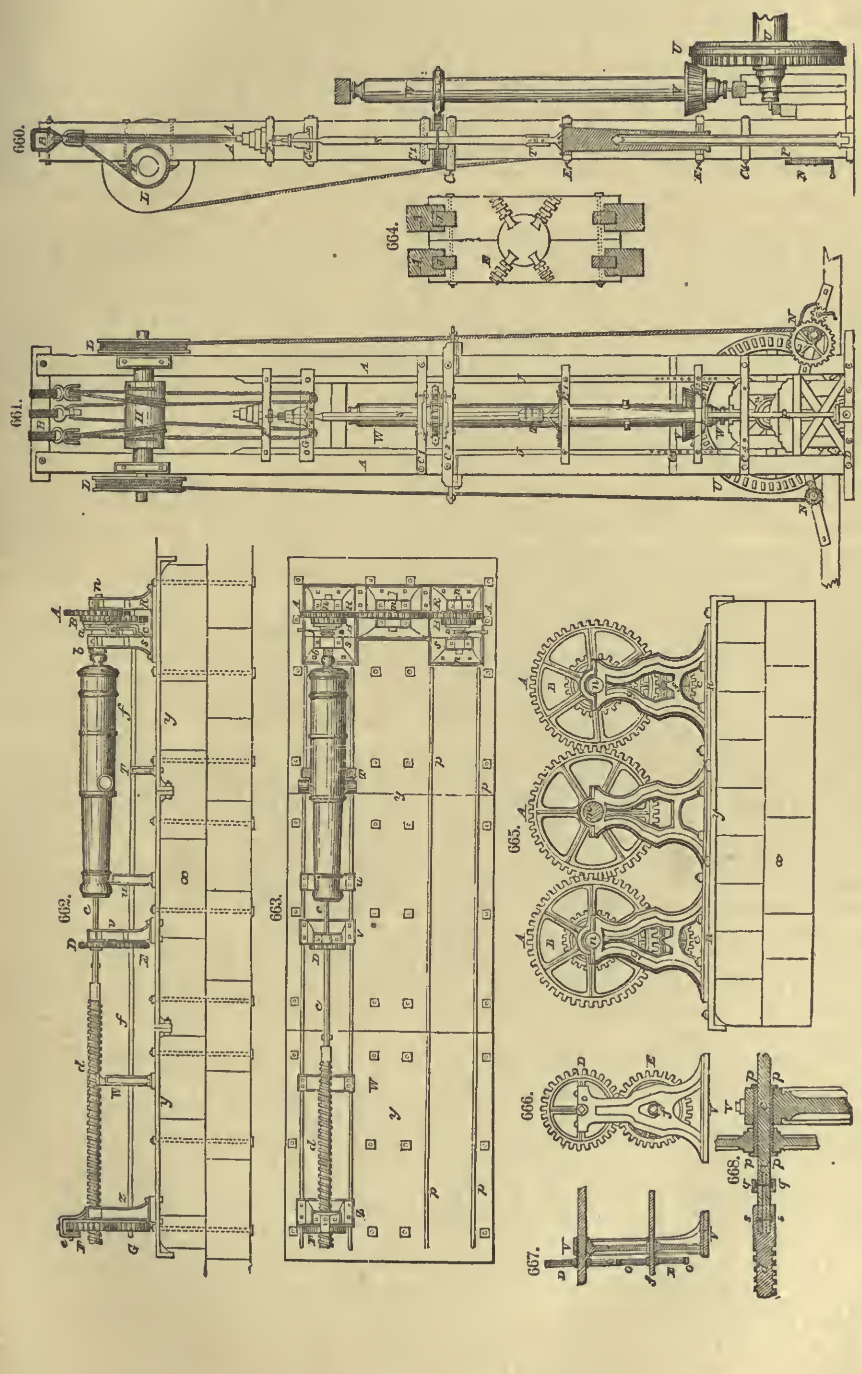
CANNON. *The Machinery for the Boring of.* The manufacture of cannons is divided into two branches, the *founding* and the *boring*. Here we only treat of the latter branch, and restrict ourselves, concerning the founding, to the remark, that formerly the cannons were founded over the core, (as it is called,) or with the bore, which then was perfectly regulated by means of the borer; while at present they are generally founded massive, and afterwards bored in *boring-mills.*

These boring-mills work either *vertically* or *horizontally*. The former were exclusively used until the middle of the last century; the boring consisted only in the enlargement of the founded bore conformable to the calibre, and the opinion prevailed that brass cannons could be bored in no other manner than this. But since then the advantages of the horizontally-working boring-mills have become so apparent, that but few of those working vertically are still extant. A short description of the three principal systems of the latter will therefore be sufficient here.

In the machines constructed according to the oldest and most imperfect system, the cannon rests vertically, and with the grape upwards, in a wooden sledge which runs in the furrows of two side-beams, and can be moved up and down by means of long tackles. Beneath the cannon, and in the direction of its axis, is the borer running in a steel pan and crossed by a beam, by means of which it is turned round by horses. The pressure required while boring, is effected by the weight of the sledge and cannon, and can be regulated by counterbalances. But as the borer is to have some scope, the borer can easily be brought out of its vertical position, and thus the boring assume a false direction without its being noticed instantly.

According to the second system, the cannon rests with its muzzle-face on rollers, while its grape is inserted into the shaft of a dented wheel connected with a moving power, and thus the cannon is turned round its axis. The vertically standing borer is fastened at a sledge, which runs in the furrows of two beams, and can be pressed onwards against the cannon during the operation of the boring, by a lever drawn upwards by a string provided with weight-stones, and passing over a pulley. Both the exact direction of the borer and its uniform pressure against the cannon is hard to be effected; yet the advantage is here, that a false direction of the borer can instantly be noticed by the trembling motion of the cannon and borer.

The third and best system of boring-mills working vertically, is represented by Figs. 660 and 661, in front view, and section through the axis of the cannon and boring-bar. Here the borer is fixed, while the cannon turns round its axis, and moves up and down in a sledge, and by its weight the required constant pressure against the borer is effected. The square piece of the cannon's grape is clamped into the *muff* marked with T, and which at the same time takes up the lower square part of the boring-



660. 661. 662. 663. 664. 665. 666. 667. 668.

spindle S. The latter is, together with the cannon, turned round their common axis by a motive power between the fixed rails C_1 and C_2, by means of the cog-wheel U, the spring-wheel V, and a cog-wheel at the vertical shaft W. The boring-spindle is provided with a bell-shaped runner of brass, whose feet turn on a steel plate inserted into the rail G. In order to secure the position of the boring-spindle, the latter has at its upper end an indentation for receiving the steel point of the bolt F. The cannon is kept in a vertical direction by the slides of the rails E_1 and E_2, provided with adjusting screws. The hitherto described contrivance moves, with the exception of the moving power between the side-beams A, right up and down, the directing-beams I, together with the rails F, G, E_1 and E_2, forming a sledge, which by means of the drawing-machines N, the disks L, their shaft F, and the long tackles fastened to the upper bolt B, can be lifted or lowered at pleasure. Fig. 664 shows the rail E_1 in the upper view, and illustrates the working of the directing and running beams one into the other, and at the same time the fastening of the rails to the directing-beams. The boring-bar is fixed in the sill D, and is kept in its vertical position by the rails C_3 and C_4. The upper rail C_3 is taken off, as soon as the cannon sinks down into its vicinity. The drawing-machine is, during the boring, slackened, so as to allow the weight of the cannon to act freely. With larger calibres, counterbalances may be applied to decrease the pressure.

The first *horizontally* working machine was constructed in 1744 at Strasburg, by Maritz, inspector-general of the foundries in France; and since these were constructed, other machines on the same principle in Spain, Sweden, and England. The boring-mill at Chaillot, in France, is the first where the power of steam was applied; and that of Liege, in Belgium, is the most extensive, comprising twelve horizontal boring-benches put in motion by four steam-engines. In both, the system is that of the cannon turning round its axis, while the borer presses straight onwards against it. Another system prevails in English boring-mills, according to which the borer is not only pressing against the cannon, but at the same time rotating in a direction opposed to that of the cannon. Machines constructed on this system are called cylindrical boring-machines. A third system unites with the contrivance for the movement of the boring-sledge a uniformly advancing support for turning off the cannon.

We shall first describe the machinery according to the above-mentioned system, applied in the boring-mills of Chaillot and Liege.

Figs. 669 to 677 represent a boring-bench and its single parts. In the mill of Liege three of such benches are placed by the side of each other, and are put in motion by a steam-engine, which is directly connected with the shaft of the middle boring-bench, while the dented wheels B are acting upon those of the side-benches. If two boring-benches be placed at the end of each other, so as to have one common axis, they form what is called a boring-road that is connected with the prime mover in the way of running boring-machines, which shall be described below.

Each bench, Figs. 669 and 670, consists of two long beams joined by cross-beams. The first two cross-beams bear the sockets A and C of the axis, the next following two bear the saddles for the grape and the mouth of the cannon, and the fifth and sixth serve as supports for the dented bar of the boring-sledge, so that the beams can be placed and kept exactly in the same level: the timber must be completely dry. The cross-beams are firm with the exception of the fourth one, which by double springs moves in the furrows of the side-beams, as the different length of the cannons requires a corresponding position of the saddle for the mouth.

For connecting the cannon with the axis, the square adjoined piece of the grape is to be put, together with the square of the axis, in the muff D, which is fastened by small metallic wedges, driven in at both sides. The cannon rests horizontally in two collars E and F, which in Figs. 673 and 676 are represented in double scale. The socket of the grape E supports the latter only on the lower side, and can be moved forwards and backwards on the beam. The socket F of the mouth embraces the cannon entirely near its head-moulding, and allows it no other movement than the rotation round its axis. The construction of these sockets (which are to be provided with copper standard-disks *a*, conformable to the calibre) may easily be comprehended by the figures. The iron boring-bar *a*, (Fig. 670,) is put with its back-squared end through the bow G of the carriage-frame, and held fast by a peg. The dented bar H is fastened in similar way to the carriage, being put through the bow *b* to G, and held fast by a fore-lock-bolt. The carriage-frame (Fig. 674) is made of cast-iron, and is moved by means of four wheels, running on the rails *c* of the long beams. The carriage must be of such weight, that it is not subjected to vacillation; while the boring-bars are made as light as possible, yet at the same time strong enough to prevent them from bending.

The means for the movement of the boring-sledge are very various. In the first boring-mills working horizontally a dented bar was applied, put in motion by an endless screw or winch; then by means of chains passing over rollers, and moved by a lever and weight-stones; and by a screw-spindle, whose box was fixed in a wheel. Yet all these means of movement require either an experienced operative, or they do not produce a uniform pressure. For this reason the manner of movement represented in the delineation was applied in the boring-mills of Chaillot and Liege. It consists of a dented bar F, moved onwards by the moving power I, at the axis of the dented wheel R, and by the action of the lever K, charged with weight-stones. The lever K is at both ends provided with the segments N and O, in whose grooves the string of the weight-stone P (which brings about the pressure) and the chain of the iron hinge M are placed. The hinge (Fig. 677) consists of two parallel iron bars joined below by two tenons, which latter stand asunder at equal distance, as two cogs of the obliquely dented wheel R do. By this contrivance a uniform pressure of the borer against the cannon is brought on, but at the same time it has the inconvenience of frequent shifting of the hinge. For this purpose, first the lever L is to be laid in to prevent the retrogression of the dented wheel, and then the weight-stone P is to be drawn up by means of the rope fixed at the segment O, and passing over the roller Q to the axis T; a catch V preventing the retrogression of this axis, turned by the moving power U. As soon as the hinge M is shifted, and the catch V lifted, the weight-stone P begins its action again. In order to cause less interruption, in the most modern French boring-mills, the dented wheel is provided with a barrel, over which

passes a string with a weight-stone at its end. The string must also pass over a roller, which is to be fixed as high as possible, to prevent a frequent hanging of the weights. It is well to provide the string with rings, one foot asunder, so as to be enabled either to increase or decrease the pressure, by hanging several weights one above the other. The movement of the boring-carriage must above all be uniform, without any start or pull. For this reason the screw-spindle is to be preferred to the dented bar, but the difficulty to make it exactly in these dimensions, and its expense, have prevented its general application.

Fig. 675 represents the frame forming the socket for the moving power of the dented bar, and at the same time holding in its lower part a roller with projecting edges, to facilitate the movement of the dented bar, and to keep the latter in the direction of the cannon-axis, conjointly with the notch in the back cross-beam.

A boring-bench arranged in this manner is adapted to great guns of every calibre; however, in more extensive boring-mills, there are several benches of inferior length for the boring of howitzers and mortars.

The *second* system of the horizontally working machines is an imitation of the above-mentioned cylindrical boring machines. Two boring-benches at the side of each other are represented in Figs. 662, 663, and 665, plan and side view. The prime mover being here either the power of steam, water, or animal power, the toothed wheel of the principal axis *m* grasps the cog-wheels A of the two shafts *n*, which belong to the boring-benches, and puts the whole boring contrivance in motion. Sometimes each of the shafts *n* is arranged for two boring-benches, in which case the second ones are placed in the king-pieces of the represented boring-benches, at the other side of the spring-wheels. The cast-iron sockets of these shafts rest on a foundation X, made of square stones, and covered with plates of cast-iron. These plates Y are firmly fixed to the foundation by screw-bolts, and are kept together at the edges by other bolts. At each boring-bench in the socket-plates are two long and well-polished grooves *p p*, for receiving the screw-bolts of the cast-iron saddles and tressels T, U, V, W, Z, as well as the support for the turning off. Along the grooves are cut out in the foundation, channels for the reception of the bolt-heads which are wider than the grooves. By this contrivance the tressels can be moved and adjusted by the screws. The screw-bolts are altogether of the same dimensions, and can be taken out at proper places, which enlargements of the grooves are to be closed by stops of iron. By taking down a tressel from the boring-bench, the female screws need only be unscrewed, and the tressel to be lifted a little, to free it from the bolt.

The socket of the shafts is formed of six iron posts, resting on a strong cast-iron plate, fixed by means of screws. The two middle posts enclose the spring-wheel of the principal axis, while the other, R and S, leave sufficient room for the wheels A, the pinion B, and the pillow-block *a*. The pinions B are screwed on the wheels A, and grasp in the cogs of the moving power *g*. C may be in equal direction with the wheels A. The cannon is, with its grape, connected with the shaft *n* by a muff; it turns round its axis, and is at its mouth supported by the saddle U. The squared shaft *f* of the lower wheel C passes through the post S and the saddle U, between which it is supported by a tressel T, and is immediately behind the resting tressel V and the winding tressel Z, provided with the cog-wheels E and G, which are fixed by means of wedges. The cog-wheel E grasps in D, placed above it, and causes the boring-bar *c* and its screw-spindle *d*, to turn on their axis in a reverse direction to the rotation of the cannon, by which the acting of the borer is strengthened. In order to produce a uniform and properly measured advance of the boring-bar, the system of the screw with moveable box is applied, the cog-wheel G working in the teeth of another one F, which contains the box of the screw-spindle *d*, and turns round this latter with somewhat less celerity than the screw-spindle itself, by the working of the cog-wheel D upon it. In this manner a slow, but uniform advance of the boring-bar is effected. The extent of the pressure of the borer against the cannon depends upon the number of the wheel-teeth, as well as upon the length of a screw-worm of the spindle, and may consequently be altered by a shifting of the wheels.

In order to afford a clearer idea of the whole machine, we shall give a more circumstantial description of its several parts, in whose construction various alterations can be made.

The shafts *n* and *f* are provided with moving-out apparatus, which are not constructed like the common claw-boxes; one of them is represented in Figs. 680 and 681. The shaft $n\ n_1$, is cut through at x, and consists of two parts, of which the front one bears the spring-wheel, while the back one, n_1, passes through the post S, and terminates in a square for the connection with the cannon. Both shaft-parts are connected with each other by a case, embraced at its front collar by a barnacle-ring *f*, which presses against the knobs *d d* of the wheel, and causes a simultaneous rotation of the box and shaft. The front part of the shaft n_1 is squared, and thus put in motion directly by the box, while the part of the shaft *n*, inserted in the box, must be cylindrical, so that the box be put in again, by means of the fork *a*, at every movement of the rotation. Suppose both shaft-ends inserted in the box were square, it would be not only difficult to watch the moment when both shafts are in congruity, but also impossible to prevent a shaking movement. The fork *a* moving round the support *b c*, fixed to the post S, embraces the box at the groove of its weaker back-part, and leans against the projecting edges. Thus, if the handle of the fork be pressed to the left, the box is moved out to the right, i. e. the barnacle-ring *f* leaves the knobs *d*, and the movement of the shaft *n* is not connected with its other half n_1.

The saddle U is represented in Figs. 684 and 685; it has, like all other tressels, in its lower part a socket for the shaft *f*. The slide *o*, forming the holder for the cannon-mouth, is adapted to every length and diameter of the cannon, and is provided with adjusting disks polished with emery. The lower part of the slide is cut off obliquely, and in conformity with the inclination of the wedge, moved by the screws *m n*. Consequently by drawing the female screw *m*, the cannon can be lifted exactly to the required height.

The supporting tressel T of the shaft *f* is represented in Fig. 686; it contains the semicircular socket in its upper part. The squared shaft *f* is at all points, where it rests on the tressels, provided with

brass boxes, which are circular at their outsides, and fastened at the shaft by means of small metallic wedges.

Figs. 666 and 667 represent the resting tressel V, whose upper part contains the holder of the boring-bar *c*. The latter being squared, it is provided with a box *p p*, Fig. 668, circular at its outside, and turning round in the holder, together with the bar, yet not advancing like this. To the projecting squared part of the box the toothed wheel D is fixed, which puts the boring-bar and screw-spindle in a rotative movement. To the lower shaft *f* is fixed the wheel E, which can be kept in constant gearing with the wheel D by the edge *o o;* otherwise the box might, together with the upper wheel, slip out of the socket.

The tressel W, Figs. 682 and 683, supporting the spindle and lower shaft, has at its upper part the slide *b*, and is cut out conformable to the diameter of the screw-spindle.

The hindmost part of the machine is formed by the tressel Z, Figs. 678 and 679, which allows a free passage to the screw-spindle, and is for this reason perforated according to its widest diameter. Above, the tressel contains the holder for the shaft of the wheel *e*, which allows to draw back the boring-bar by means of the winch *x*, and at the same time to increase or decrease the pressure against the cannon, if required. The wheel *e* works in the teeth of the cog-wheel F, which contains the female screw of the screw-spindle, and is kept in constant gearing with the wheel G, by the edge *p p*. Thus, whenever the boring-bar is to be drawn back, the wheel G is drawn off, and the lower shaft *f* moved out.

Should it seem preferable to allow a spring-like movement to the boring-bar, the tressel V may be entirely removed, and then the wheel D is to be fastened at the square end of the screw-spindle, which now, together with the boring-bar, is moving onwards against the cannon.

The third system of the horizontally-working machines is a combination of the two other ones. The arrangement of the wheel-work and shaft-sockets A and B is in substance the same as the above described. The boring-shafts are provided with apparatus to move them out and in; yet the connection of the cannon with the principal axis is arranged in an improved manner. The adjoined piece of the grape has the shape of a regular prism, and is inserted into a box cylindrical at its outside; at the end of the axis is fastened a ring. In the cylindrical excavation, D, the inserted box, has a play of some few lines. Three strong adjusting screws pass through the adjoined piece into the box, and by means of them the cannon can be centred, if required.

In general the cannon is only supported at its mouth by the saddle G with the disk *a;* with great calibres, however, a second saddle G_1 may be applied at the bottom piece or grape. The saddles are made of cast-iron, and moveable in the grooves of the iron plates.

The sledge L, made of brass, terminates below in a guide, which is advancing in the excavation Y, and cut out in such manner that it forms beneath the screw-spindles, two feet armed at the edges with steel rails. At the middlemost and higher part of the sledge, the boring-bar is fixed either by means of a bow and pin, or of two steel rails R, that are to be screwed on, and between which the square of the bar is pressed fast by the screw *d*. The shifting of the borers and the taking out of the bore-chips is so facilitated. The sledge is pressed against the cannon by two screw-spindles E and E_1, passing through the side projections of the sledge, and having their sockets in the iron posts B and N. The female screws are cut out in the brass of the sledge, and at both ends provided with steel armaments. The back ends of the spindles, terminating in squares, bear the toothed wheels O and O_1, being in gearing with each other by the equal wheel O_2, and thus turning in the same direction, and with the same celerity. The spindle E passes through the post N, and is provided with a handspike-wheel P, for the movement of the machine.

Simultaneously with the sledge, a support K, for the turning off, moves along the cannon, and is provided with a female screw for the spindle. It has, like the sledge, a guide sliding on the iron plates or special bolts, and through the upper part of which a brass wing H is moving, and terminates in a foot gliding on the steel rails *c c* of the iron plate Q. The latter is, according to the various descriptions and calibres of the cannon, fixed at the screw-holes *x x*, so that the rails *c c* run parallel with the cannon, while the turner's chisel is always kept in a proper distance from the cannon's axis during the movement of the support. At the front end of the wing H is a moveable rail or peg, for supporting the turner's chisel; by means of an endless screw it can be put back or forward, and an index at its upper side indicates the extent of the change.

At Douai, in France, a steam-engine, 12-horse power, moves four boring-benches, whose shafts make 10 or 12 revolutions a minute; at Toulouse, a water-wheel, 12 or 13-horse power, moves four boring-benches; and at Strasbourg, one boring-bench is put in motion by four horses.

The movement of the cannon on the boring-bench, and the pressure required against the borer, depend generally upon the material and calibre of the cannon. Is the rotation decreased, the pressure may be increased, as otherwise the bit might generate a too great heat, and thus become weak. Iron cannon and wide calibres must revolve more slowly than brass cannon and smaller calibres. In the boring-mill of Liege, the cannon revolves once in 8 seconds, and in that of Douai it revolves at the rate of 10 or 12 times a minute. It seems that 12 times a minute is considered as the maximum.

The pressure, depending chiefly upon the hardness of the metal, cannot be indicated precisely. In the second of the horizontally-working machines, above described, the advance of the boring-bar depends upon the number of teeth of the several wheels. If, for instance, the wheels B, C, D, E, and F, have 36 teeth each, while the wheel G has only 34 teeth, the wheel F, together with the female screw of the spindle, will make $\frac{34}{36}$ of one complete rotation of the spindle; and thus the boring-bar will advance only by $\frac{2}{36}$ of that distance, by which it would have moved onwards, if the female screw were fixed. If the length of a screw-worm be half an inch, the spindle will advance by $\frac{2}{36} \times \frac{1}{2} = \frac{1}{36}$ inch. Should the wheels B, C, E, and F have 36 teeth each, while the wheel D has 35, and G only 34, the spindle will revolve at the rate of $\frac{36}{35}$, and the female screw at that of $\frac{34}{36}$ of one complete rotation of the cannon, while the boring-bar is advancing by $\frac{36}{35} \times \frac{2}{36} \times \frac{1}{2} = 0{\cdot}0286$ inch.

The following table gives the number of teeth both of the spring-wheels and of the wheels E and F

The middle wheel of the lower axis, and that with the female screw, are at all events provided with 36 teeth; by inserting a fresh boring-bar, the proportion of the advance can be altered without much trouble.

Borer.		The Material, Description, and Calibre of the Cannon.	Number of teeth of the wheels.			Advance of the boring bar by inches.		Remarks.
			B, C, E and F.	D.	G.	During one rotation of the cannon.	In an hour.	
Plain borer and widening borer.	Brass cannon.	From 48 to 24 pound cannon, mortars, carronades, and howitzers, of wide calibre	36	35	34	0·0286	10·29	The length of a screw-worm is ½ an inch.
		From 18 to 12 pound cannon and howitzers of small calibre	36	35	33	0·0428	15·41	
		From 6 to 4 pound cannon	36	34	33	0·0441	15·88	
	Iron cannon.	From 48 to 24 pound cannon, mortars, and howitzers of wide calibre	36	36	33	0·0416	14:97	The cannon revolves at the rate of 6 times a minute.
		From 18 to 12 pound cannon and howitzers of small calibre	36	34	33	0·0441	15·88	
		From 6 to 4 pound cannon	36	36	32	0·0554	19·44	
Auger or forehand-borer.		Fly-borer of the mortar-pieces and auger of the carronades, and from 48 to 24 pound iron cannon...........	36	36	35	0·0139	5·00

Bottom-borer.		Bottom-borer of the cannon, chamber bottom-borer of the mortar-pieces, and vault-borer for the holes of the mortar-pieces...........................	36	35	35	0·0143	5·148	

To convey the cannon from the foundry to the boring-mill, a *crane-carriage* can be applied in case of their being connected with each other by a railway; which, of course, is to be held aloft by supporting-posts, that the cannon can be lowered down to the boring-bench. The carriage runs on four cast-iron wheels X, on the rail *a*. (See Figs. 671 and 672.) Its upper frame, made of solid timber, bears two shafts W_1 and W_2, T_1 and T_2, moved by winches Y. The shaft W_2 serves to move the carriage onward, and the end of the rope cast round it is fixed to a hook in the intended direction of the carriage. Sometimes this shaft is left out entirely, and the carriage provided at both ends with hooks to hang ropes, which either are fastened to windlasses at both sides of the railway, or are connected with the principal axis of the boring-mill by rollers. To the ropes of the second shaft is attached the draw-beam Z by means of strong iron hooks, to which the cannon is fixed with ropes. The axle T_1 is provided with double ratchets.

By means of this crane-carriage the cannon is lifted from the pit, freed from the mould, and then conveyed to the boring-bench, on which it is placed horizontally. In a similar manner it can be removed as soon as the boring operation is accomplished.

Before the cannon is encased on the boring-bench, its eccentricity must be examined; for which purpose it is to be placed on two separate saddles, where it is, by means of the trunnions, turned round its axis and meanwhile examined. If the eccentricity nowhere exceeds four lines, the cannon may forthwith be encased; but in the contrary case its centre must previously be precisely regulated.

For the purpose of severing or turning off the *lost head*, the lever A, Fig. 676, centred on a pin at the front saddle or tressel F, or at a particular post, moves in a plane vertical to the cannon, and has in its lower part a hole, into which is inserted the chisel-shaped blade C. At the lever's end is the weight P, and above it a moveable ear or handle, serving as box for the support T, which, at its upper part is provided with screw-threads. By means of this screw the chisel can be approached to the axis of the cannon, while the weight prevents the rising of the apparatus. The boring-mill being put in motion, the lost head is turned off to a minute remnant, whereupon a stroke completes the severing.

For the purpose of the cannon being centered, near the cannon a cross-piece of timber is put beneath the boring-bar, which is then, by means of small wedges, to be brought to the required height and direction. This done, and the front face of the cannon having been chalked, the borer is slightly pressed against it, while the cannon revolves. If no shaking of the boring-bar be perceived, even by increasing the pressure, the borer is correctly centred; but if it be the case, the boring-bar must, by the wedges, be adjusted till no shaking is perceivable. Now the boring may commence.

The shape of the borer has in the course of time greatly varied. Formerly a hollow borer or wimble was used for boring massively founded cannon over the core, as it was called. Having bored to a certain depth, the core was, by a peculiar contrivance, pushed off, and upon this the boring operation completed with borers. This was performed in boring-mills, working vertically.

At present there are chiefly four descriptions of borers in use, viz :—The *auger*, the *bottom-borer*, the *plain* or *calibre borer*, and the *widening-borer*.

The terms of *cross-borer*, *disk-borer*, *bore-knife*, *chamber* and *fly borer*, *vault-borer*, &c., have relation

partly to peculiar positions and shapes of the bits, partly to the place and manner of their application, and can be ranged in the above-named descriptions.

The *auger* consists commonly of a bit of steel as broad as the first boring requires. Frequently hardened iron is used instead of steel. This auger is used in the boring-mill of Liege. It has two edges and an angular form in the fore part. The angle must be the more obtuse, the greater the motive power, the pressure, and the hardness of the metal. By this bit the first boring is preserved to the distance of four lines from the cannon's bottom, where it ends in a conical form. With middle calibres the bore of the cannon is now only to be somewhat widened and polished, by means of the plain borer, while with larger calibres one or more widening borers are still to be applied.

The older French auger, here and there still in use, consists of three blades, the first of which having the form of the auger and widening the bore to two-thirds of the whole boring diameter. Behind it, in the bit-head, is a hole, through which the second blade is put, that cuts onward and sidewise, and widens the bore by eight lines. Behind, and in a right angle with this blade, is a third, which widens the bore to the diameter required for its being polished.

In German boring-mills, augers are used; they leave four lines of the bore, and penetrate to near the bottom of the cannon or howitzer. In recent time the form of a saw, like that of the bore-knives, has been adapted to the auger; and thus, by one single boring, the operation can be completed so far that only the plain borer is still to be applied. In Vienna the augers have not only this form, but are also provided with shovel-edges.

In order to be assured of the correctness of the first boring, a strong wooden rule as broad as the bore, is to be put in; and in case it can penetrate to the bottom, and be turned without any obstacle, the boring is faultless and can be pursued.

The boring with the auger is immediately followed by that with the *bottom-borer*, though with larger calibres, an application of some widening borers is to be made previously. The bottom-borer is intended to widen the cone made by the auger, and give the required shape to the bottom. Its boring-blade is three or four lines thick, and forms a rectangle, rounded off in the fore part, which at the same time is the cutting part. The frame or head of the borer is, by means of its tail and by two screws, fixed to the boring-bar.

The next is a bottom-borer, as constructed in France; and another one intended for giving a hemispherical form to the bottom. The latter can be forthwith applied, in which case it consists of a metallic head provided with two side-blades, and an upper rounded edge; four wooden prisms secure the run of the borer. Frequently the head receives a cylindrical form, and the boring-blade is inserted, in the way of a plane-iron; in which case the borer is called a *disk-borer.*

The bottom-borer is followed by the *polishing* or *plain borer*, which commonly only takes away the two last lines of metal and polishes the bore, by freeing it from boring-rings. Its head forms a cylinder, a quarter of which is cut out, and on the level of its edge an oblique steel blade is screwed fast The screw-holes in the blade are elliptically formed, as the boring is to be repeated several times, and meanwhile the discharge of the blades is gradually increased until the normal calibre is attained.

The plain borer is used in the boring-mill of Liege. It consists of two small boring-blades, which, in the fore part, have exactly the form of the bottom, and are fixed to the tongue of the boring-head by means of three screw-bolts. The discharge of the blades is effected by strips of tin-plate inserted behind their back.

The boring of the howitzers and mortars is in general done in the same manner as that of the cannon, with the only exception that a greater number of borers is applied. The auger is succeeded by the calibre-borer of the chamber; it is intended to polish the chamber; and as its blades are crossing each other, it is also called the *cross-borer.* The third and fourth borers have the same frame, into which the blades are inserted one after the other. At last follows a polishing-borer. The gradual discharge of its two blades is effected by inserted small strips of tin-plate.

Field-howitzers, with spherical chambers, are in France bored with borers of the following description:—A common auger makes a bore, which is by two lines less wide than the chamber. Next follows the borer which bores out the fly or middle part of the bore to two lines of its diameter; a cylinder of the same diameter as the first bore serves as guide to it. The third borer has a similar guide, and is intended for boring out the spherical chamber. Then follow the polishing-borers

The mortars are, in the boring-mill of Liege, bored in the following manner:—First is applied the small auger, which makes the bore by four lines less wide than the chamber. Next follows the great auger, which is inserted into a particular boring-bar, and penetrates to the fore part of the chamber. Its blade can either be formed single, or be composed of three blades; the joined piece of the boring-head serves as support. After this the chamber-borers are applied.

In case the chamber is to be conically formed, the *bore-knives* are commonly used, which are constructed in the following manner:—At the boring-bar is a long groove for receiving the dented iron rail, which is held by the bands. The bar is moved by the axle, and by means of the lever, and at its front end is a notch, into which the boring-blade is inserted after the plate has been removed. The lever is worked by an operative. The first bore-knife to be inserted is in the form of a saw, and brings about an undulatory surface in the chamber; yet with the advantage of taking away much metal. The second one is plain, and cuts away all elevations completely.

Another instrument for boring conical chambers is represented by Figs. 687 and 688. The blade *a* is, by means of the bar *b*, moved onwards in grooves formed by the lists *p p*, and is, like the bar *b*, screwed in the plates *m* and *n*. The surface of the instrument is plain, whereas the lower base is rounded according to the form of the chamber, (see Fig. 691.)

The boring of spherical chambers is very different; it requires a great number of borers. To show their contrivance and application, we will shortly describe the boring of a French foot-mortar. First an auger is applied, whose diameter is by 4 lines less than the neck of the chamber. Next follows the

blade, together with another rounded in accordance with the form of the chamber. Fig. 699 illustrates the shape of the borings, which are marked with ciphers in their order of succession. All these blades are inserted into the head of a particular boring-bar. The chief part of the head is provided with a tongue, and a cover or moveable lip B, on which all blades are screwed. The grooves of the blades are adjusted to the lists. Now as soon as they have attained the bottom of the chamber, they glide backwards in consequence of the pressure, and commence at the same time the operation of boring out the chamber. First, the blades C, then the blades D, and at last the blades E, are applied, and thus the parts 4, 5, and 6 of the chamber, (see Fig. 699,) are successively cut away. Finally, to complete the boring, the blades and the polishing-borer are applied.

Figs. 689, 690, and 691 represent a borer for giving to the chamber the form of a pear. It is applied after a bore as wide as the chamber-neck having been made. The boring-head has a groove q to let out the bore-chips; and in another groove, partly covered by the rails $p\,p$, run the plates m and n, round which the blade a, and the bar b are fixed. It may finally be remarked that the pear-formed chambers are at present out of use.

The *turning off* is at present commonly done conjointly with the boring of the cannons. Only in boring-mills working vertically, a separate turning-lathe is required, which consists of two long beams 6 or 8 inches asunder, and short cross-beams. In the inside grooves of the long beams are inserted two moveable strong oak blocks, provided with knobs or bunchings at the front, to be inserted into holes of the front and back pieces of the cannon. Near the trunnions is a disk, consisting of two halves, fixed and connected by an endless thong, with a fly-wheel of five or six times greater diameter. In this way the cannon is turned on its axis.

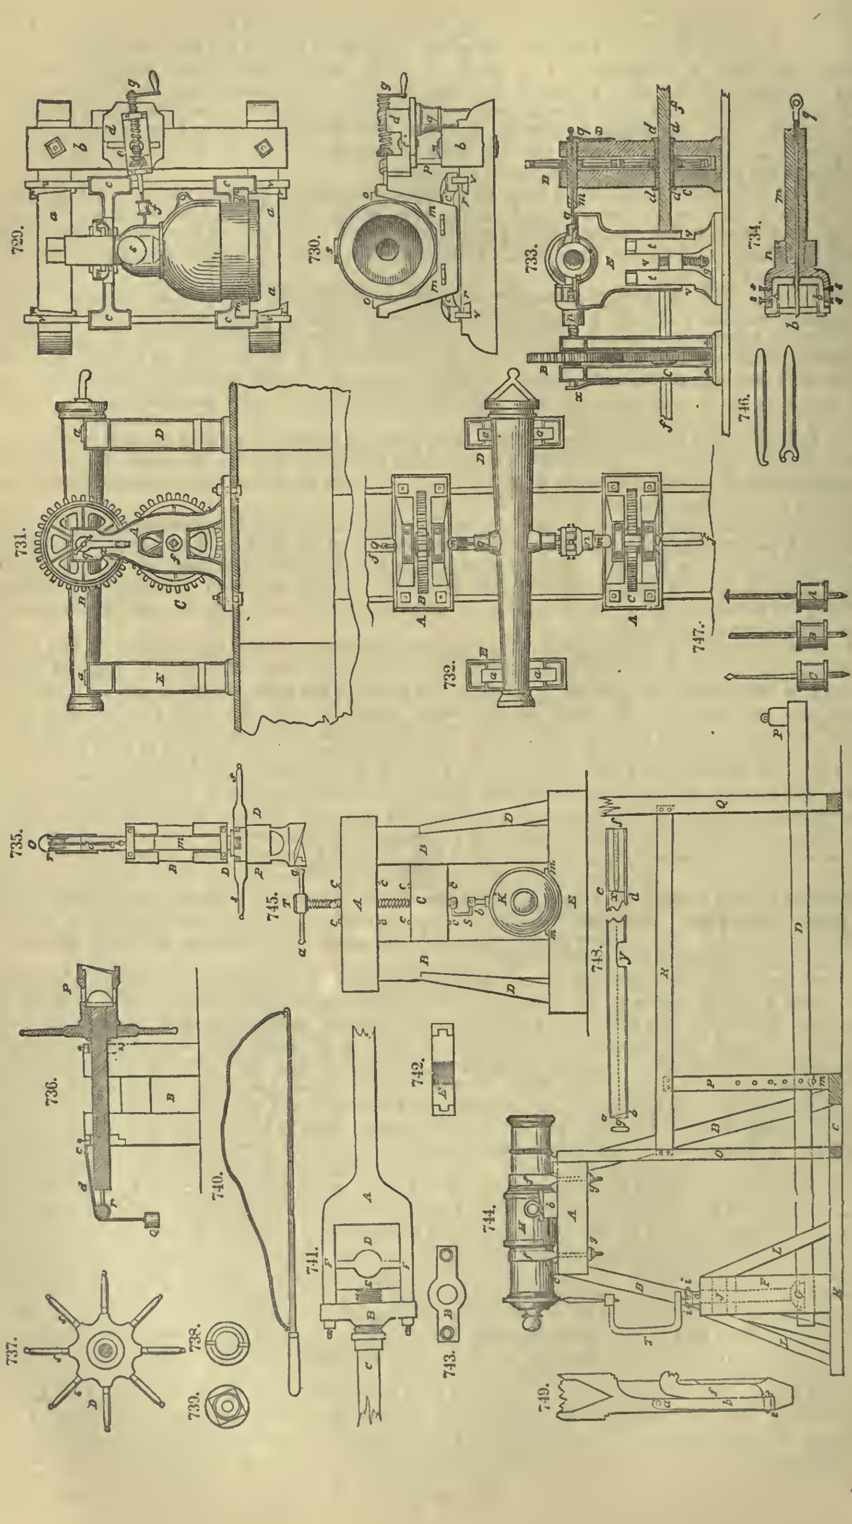
The turning off can be done either off hand, or by clamped chisels. The first method has many advantages, yet requires great labor, and an experienced operative; and the apparatus for working by clamped chisels on moveable supports is very expensive, however applied to brass cannons. The common method is the working off hand combined with fast supports.

The turner's chisels are provided with long wooden handles, and are either crooked (as the French) or straight, (as the English.) The French chisels are dented at the back of the incurvation, to prevent their slipping from the support. There are especially two descriptions of them, the one intended to rough-turn with, and the other for planing, (see Figs. 701, 702, 703, and 704.) The English chisels are straight, and mounted with either triangular or quadrangular pommels; the handles are fastened to them in right-angular direction.

A moveable support according to the old French system is represented by Figs. 692 to 695, and worthy of description here, as it can yet be applied with some modifications. The chisels, Fig. 696, are by means of a bolt fixed in the iron rail A, which in the wings of the brass support N can be moved onwards and backwards by the screw B. The latter passes through the back part of the support, strengthened by the steel plates q. To prevent the rail A from lifting, the two cross-pieces $a\,a$ on the support, are provided with female screws for the pressing-screws C. The support N rests on the brass plate M, and is moved on it by the screw-spindle D, which passes through its midst, where the two ends of the screw-worm are armed with the steel plates Y. The lowest part of the support consists of a foot running in a furrow of the plate, and regulating the progress. For the purpose of facilitating the movement, and maintaining a uniform and easy progress, the steel rails $z\,z$ are inserted along the plate. At one end the screw-spindle is provided with a toothed wheel in gearing with the winch P, by means of the endless screw L. According to the older system, the plate was fixed to the boring-bench by two screw-bolts passing through the cuts X X; but at present one single bolt is applied, and passes through the middle of the plate. The chisels used with the moveable supports are in general shaped as is shown by Fig. 696, a and b. For turning off the moulding and grape of the cannon, particular chisels are used, such as represented by Fig. 696, b and k.

Before the turning off begins, the cannon is placed so that the trunnions lie exactly in a horizontal plane, and then, by means of the instrument, the middle line of the cannon's surface is to be ascertained. Upon this the moulding, edge-rings, and vent are pointed out and marked, so as to prevent the chisel from planing these points. In turning off hand, the beginning is commonly made with the bottom moulding, next follows the edge-ring, and then the grape, and thus the operation proceeds to the head-moulding, while successively the chisels c, d, e, f, g, a, b, h, and i, Fig. 696, are applied. The trunnions are to be rounded off, either off hand, or by a particular contrivance of the machine, illustrated by Figs. 735 to 739. The cannon rests in cross-blocks or standards, and the machinery in the frames B. The spindle m consists of two parts, one of which bears the roller r, round which the string d of the weight Q is coiled. The screw of the spindle is adapted to the female screw in the capsule P, to which is fixed the fly-wheel D. Another machine is represented by Figs. 731, 732, 733, and 734, and all its parts are made of cast-iron or steel. The sockets D and E for the cannon are by screw-bolts fixed in slits of the iron plates of the boring-bench. Each of the standards E, Fig. 733, consists of two parts, whose projections v and t grasp one into the other. The screw g serves for adjusting the required height of the upper part. The standards A A are, like the tressels of the boring-bench, fixed by screw-bolts in the long slits $p\,p$, (see Fig. 663.) Through the lower part of both standards passes the squared axis f of the boring-bench, bearing the round boxes $d\,d$, and the wheels C. Through the upper part of the standards passes the spindle m, on which are screwed the blade-baskets n, and which bears at the same time the wheels B, that, conjointly with the wheels C, bring about the simultaneous movement of both spindles. Each spindle is perforated in its axis for the reception of the steel rod q, which at its back end is provided with a screw-turn, and at its front end with a small female screw. The pressure against the cannon is effected by a strong spring x. The basket n contains four blades b, (see Fig. 734,) which by the pressing-screws s are pressed against the trunnions.

Those parts of the the cannon which cannot be turned off in the above-described manner, because the trunnions and handles hinder it, are elaborated by the chaser or engraver. The instruments he makes use of are represented by Figs. 720 to 727. First, he applies the gouge, (Fig. 723,) carving furrows, whose



729. 730. 731. 732. 733. 734. 735. 736. 737. 738. 739. 740. 741. 742. 743. 744. 745. 746. 747. 748. 749.

edges he then takes away by the plain chisels, (Figs. 720 and 721,) upon which the surface is freed from all inequalities by means of the vaulted mallet, (Fig. 728,) and of the instruments represented by Figs. 724 and 726. The elaboration of the angles and ornaments is accomplished by means of the burin, (Fig. 722.) Finally, the chaser elaborates the written characters, using the instrument, Fig. 727, called in French traçoir, and the common gravers. Fig. 725 represents a scalper or raspatory for dimming the metal between letters working in relievo.

We will give here some statements about the difference in time between the older and modern boring systems. Formerly it was computed that the boring of a 24-pounder might take up 8 or 10 days, its turning off the same space of time, and the transport from one machine to the other 4 days; consequently in total from 20 to 24 days, or from 200 to 240 hours. At present a 24-pounder is bored in 50 hours, the simultaneous turning off prolongs this time to 60 hours at the most, and the transport takes scarcely 10 hours; thus the whole work is done in 70 hours. The boring of smaller calibres is at present completed in 14 hours, and that of the mortar-pieces in from 20 to 60 hours. In the French boring-mills the auger advances $\frac{3}{4}$ of an inch in an hour; the bottom-borer completes its work in an hour, and the plain borer advances one inch in an hour, as also the widening borer. In the modern German boring-mills the borers advance $1\frac{1}{2}$ inches in an hour.*

To make the cannon completely ready for service, the boring of the vent, the placing of the aiming ruler, and the fixing of the priming contrivance remain to be done. For placing the aiming ruler, either a deepening is made in the back edge-ring, or a hole bored in the bottom-piece of the cannon, in the performance of which is used the borer represented by Fig. 744. The frame required for this operation consists of a standard A, of whose four feet C, only the two back ones are to be seen in the figure. The cannon rests on this standard in a horizontal position, is at its ends supported by the wedges C, and at the trunnions by the blocks *b* and wedges *a*, and is fixed by means of the bands *f* and cross-pieces *g*. Between the posts O, P, Q, and R, is the beam D, serving as a lever, having its fulcrum at *m*, and being pressed down by the weight P, by which its front end with the blade G lifts the guide I. Between the cross-rails of the bench F, the guide I can only move vertically up and down; at its upper end it is armed with an iron frame *o*, which can be adjusted by the screws *i i*. It is at the same time provided with a steel plate, through the conical deepening of which the borer T is put.

The boring of the *vent* of the cannon is performed either by a *drill* (which is turned to the right and left alternately) or by the borer T, (see Fig. 744,) which latter is turned in one and the same direction. Commonly the former is used, especially in the boring-mill of Liege, where the machine for this purpose, represented by Figs. 729 and 730, comprises two frames, one for the cannon, and the other for the drill. The frame for the cannon consists of two cross-beams *a a*, united by a long beam *b*; in the former the iron rails *v* are inserted and fastened by the wedges *r*; the cross-pieces *c c* are moveable. The tressels *m m*, with the disks *o o*, are supporting the cannon at both ends, and can be moved aside, if required, on the cross-pieces *c*. The cannon is placed in such a manner, that while the axis of the bore lays horizontally, that of the trunnions is vertical. The boring-apparatus consists of a bench *d*, fixed, by means of the bolt *e*, to a plate, which rests on the posts *q* and *p*, and on which the bench turns on the bolt *e*. The drill *f* is moved onwards against the cannon by a spindle, or by a dented bar and winch, and is turned by means of a bow, Fig. 740, made of bamboo or old steel blades, and whose string (of catgut or horsehair) is coiled round the boring-roll. By moving the bow to and fro, the borer turns alternately to the right and left. For adjusting the bench, the ruler, Fig. 748, is applied. The line *a b* marks the axis of the vent, and the line *c d* indicates the length of the cannon's bore. To this latter line the notch *x* extends. The line *f g* corresponds to the notch *y*. By means of this ruler the point for the vent can be exactly fixed. As regards the borers, in Liege first the auger C (Fig. 747) is applied, then the plain borer B, and finally the borer C. The bits are of the best steel.

To prevent the deterioration of the vent by the violent discharge of gas from it in the moment of the explosion, there must be inserted in it a pipe of iron, or of refined copper, which is replaced by a fresh one as soon as it is worn out. For this purpose the pipe has on its outside a male, and the vent is provided with a female screw. On the lathe the pipe receives the form *a* in Fig. 697. The lower part is made conical, the next following cylindrical, and the upper part squared. The boring out of the vent in the French foundries is performed by means of a machine represented by Figs. 697 and 698. The cheeks B, resting on two standards A, receive the rails C, D, and E, of which the two latter are fixed by the wedges *n n*. The pressure of the drill *p* is effected by the pressing-screw Q. The cutting of the screw-worm is performed on the block *x*, Fig. 700, by means of barnacles or pincers, Figs. 741, 742, and 743. The pipe or core *a* is clamped in the vice *b*, fixed to the block *x*, which in its lower part is firmly immured. The fork-shaped body A of the pincers runs out in a long arm; the cheeks D and E are inserted into the furrows of the arms F; the cross-piece B is held fast by the screws *x x*, and forms the female screw for the end of the lever C. The pincers are turned horizontally round the pipe by two operatives, while a third one is watching the operation. To form the female screw in the vent,

* Field-guns cannot be conveniently served when they have less than one hundred and fifty pounds of metal to each pound of shot, and battering-guns require at least two hundred pounds of metal to each pound of the shot. With any less weight the service of the gun is very difficult, from its excessive recoil; therefore, lightness is not a desirable point in the construction of cannon.

Strength is always desirable; it should be secured, but not at the expense of any other important point. If it were possible to fabricate sound and strong guns of wrought-iron, they would be found deficient in hardness. The projectiles used are of cast-iron, a material much harder than wrought-iron; consequently, the wrought-iron gun is soon indented and worn so much as to prevent all accuracy in firing, and it then is worth little or nothing.

Leaden balls are used in small-arms; but they are inadmissible in cannon, as the great heat of the exploded gunpowder melts the lead, more or less, and changes the form of the ball, thereby reducing its range; besides, lead has not sufficient tenacity to enter hard substances, and therefore is not a suitable material to be used against ships and batteries. Wrought-iron is also more liable to injury from rust, than bronze, or cast-iron; and the smallest crack admitting moisture, would, of itself, in time, seriously injure the gun. The first cost of wrought-iron cannon is the same as that of bronze, and more than six times that of cast-iron. Bronze guns, it may be remarked, after being too much worn for service, can be easily recast, whereas the old wrought-iron is useless for refabrication, and of little value, in such large masses, for any purpose.

the horizontally-working boring-bench, represented by Fig. 719, formerly was used, and is in some places still in use. But at present the vertically-working machine (Fig. 745) prevails. It consists of the frame A, B, C, D, E, a screw-spindle T, (whose female screws are in A and C,) and the borer S. The cannon rests on the beam E.

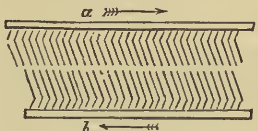
The borers commonly applied are, first the auger, (Fig. 715,) then some widening borers, and a polishing-borer of the shape in 712. With old battering-trains, or cannon of fortresses, in which the pipes are inserted in a heated state, a greater number of borers are required. In France, first an auger is applied, and then six others in the ensuing order of succession: Figs. 708, 709, 710, 711, 712, and 713.

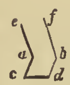
CAPSTAN. A machine employed on board large vessels to assist the mechanical power of the crew, in the operation of weighing the anchor. It is a vertical windlass, consisting of a drum or barrel revolving on a vertical spindle, with holes near its top for the reception of horizontal levers, or *capstan bars*, to which the force of the crew is applied to turn it round. The cable is coiled two or three times round the barrel, and as the capstan is turned round by one part of the crew, another part is engaged in coiling away the slack of the cable as it unwinds from the barrel. See Crab.

CARDS. In preparing cotton or other materials for spinning, they are subjected to the carding process, by which the fibres of cotton or wool are disentangled, and arranged in a regular parallel form called a lap.

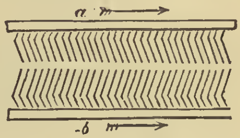
This is an important process, as regularity and perfection in carding are essential to the fineness and beauty of the cloth. Cards are formed of strips of leather, in which are inserted small staples of wire called teeth, having the projecting ends slightly bent in one direction. The strips of leather are fastened to flat surfaces or cylinders of wood or metal, and the cotton is passed between two or more of these surfaces. The teeth of cards are of various sizes, being thicker or slenderer, to adapt them to coarse or fine materials. It is essential that the teeth should be all alike, equally distributed, and equally inclined over the surface of the leather. The teeth are implanted by pairs, and retained in it by the cross part *c d*, (fig. 778,) at right angles with the teeth. The leather must therefore be pierced with twin holes at the distance *c d*, and in such a manner, that the slope of the holes in reference to the plane of the leather, be invariably the same; for otherwise, the teeth would vary with the angle of inclination, and the card would be irregular. The leather should be of the same thickness throughout, so that all the teeth may project an equal distance. Card making requires a degree of precision which is hardly possible with hand work, and they are now manufactured exclusively by machinery.

778.





779.



The following is a description of the card-making machine invented by Mr. Whittemore. Long sheets or fillets of leather of suitable length, breadth and thickness for making cards, are stretched by winding the fillet upon a roller or drum, from which it is conducted upwards between guide rollers, to a receiving roller at the top of the machine, where it is held by a cramp, by which means the leather is kept stretched.

The holes are pierced in the leather to receive the wire staples or teeth of the card, by means of a sliding fork, the points of which are presented to the face of the leather; while the fork is made to advance and recede continually by the agency of levers, operated by rotatory cams upon a revolving main shaft. The leather fillet is shifted so as to bring different parts of its surface opposite to the points of the sliding fork, so that the holes shall be pierced at regular distances. This is done by cams, which shift the guide rollers and confining drums laterally, as they revolve, and consequently move the fillet of leather at intervals to the distance required between the holes.

The wire of which the teeth of the card are made, is fed from a coil on one side of the machine, and brought forward at intervals by a pair of sliding pincers, moving to and fro through the agency of levers, operated by rotatory cams upon the main shaft. The pincers having advanced a distance equal to the length of wire intended to form one staple or two points, this length of wire is pressed upon exactly in the middle by a square piece of steel, and being there confined, a cutter is brought forward which cuts it off from that part of the wire held in the pincers. The length of wire thus separated and confined, is now, by a movement of the machine, bent up along the sides of the square steel holder, and shaped to three edges of the square, that is, formed into a staple; and in the same way the wire is cut and bent into staples, as long as the machine is in operation.

The wire staple is held with its points or ends outwards, in close proximity to the forked piercer before described, and by another movement the staple is moved forward, its points entering the two holes previously made in the leather by the sliding fork.

While the wire staple is being thus introduced, into the leather, its legs or points are to be bent, that is, formed with a knee or angle. This is done by a bar or bed which bears up against the under side of the wire staple when it has been passed half way into the holes in the leather, and another bar above it being brought down behind the staple, bends it over the resisting bar to the angle required, forming the knee in each leg. A pusher now acts behind the staple, and drives it home into the leather, which completes the operation.

In this manner a sheet of card cometimes called card clothing is made, of the kind usually employed for carding wool, cotton or other fibrous materials. The wire staples are set in the leather, sometimes in lines crossing the sheets, which is called ribbed, or in oblique lines, called twilled, which variations are produced by the positions of the notches or step on the periphery of the cam or indented wheel, which shifts the guide rollers, that hold the leather fillet as described.

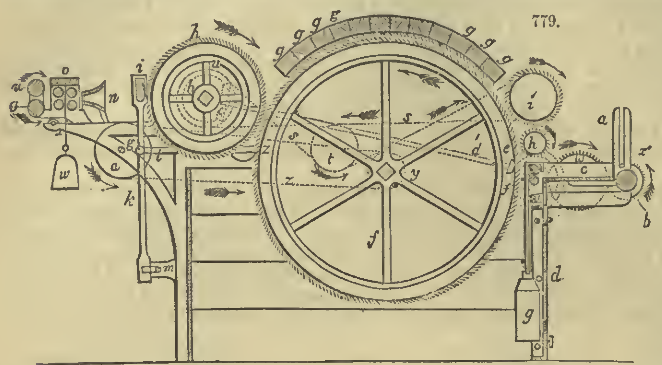
CARDING. In the manufacture of cotton, the carding process is designed to disentangle the fibres of

the cotton, and lay them lengthwise, instead of doubled up as they usually are in leaving the pickers or blowing machiues ; this is effected by the mutual action of two opposite surfaces of card clothing in the carding engine. This machine consists of one or more cylinders, covered with card leather or clothing, and a set of plane surfaces similarly covered, made to work against each other, but so that their points do not come into absolute contact.

In cotton mills making fine work, two carding machines are always used; one coarser called a breaker, which forms a broad thin lap, which is then passed through the finisher which has finer teeth.

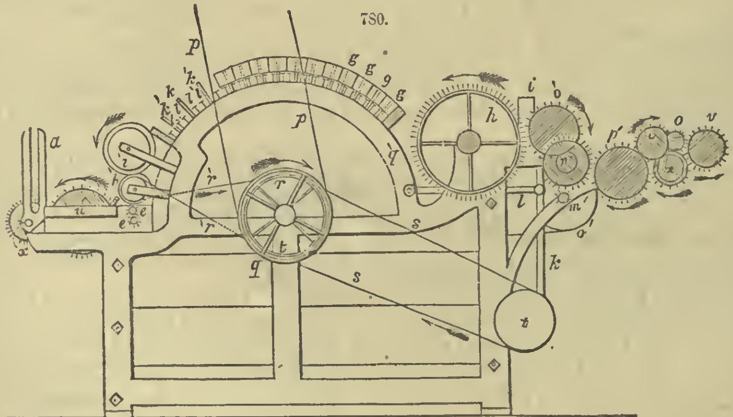
Fig. 779 is a sectional elevation of a carding machine of English construction, and 780 a side elevation of the same machine, (by a mistake in the drawing reversed) showing the driving pullies and geers; *a* is one of two upright slots which receive the ends of the lap rolls; the circumference of the lap rests upon a roller *b*, which assists the unfolding of the lap. The fluted cylinders *e*, receive the lap which passes over the table at *c*; these fluted rollers are $1\frac{1}{8}$ inch diameter, and have 28 flutes in their circumference ; *g* is a weight hung upon the axis of the upper fluted roller, causing it to press upon the under one ; *f* is the main card drum, *g g g* the flat top cards, *h* the small cylinder card for stripping off the cotton, called the *doffer* ; *i* the doffer knife or comb for stripping the fleecy web from the doffer, operated by the lever mechanism, *k*, *l*, *g*, *m*.

779.



The flat top cards, are long narrow strips of wood lined on their under surfaces with card clothing, they are attached over the main card drum by holes at each end, which fit down upon strong iron pins upon the arched cast-iron frame of the engine, as shown at *k k*, fig. 780 ; *l l* are screws which come in

780.



contact with the bottom of the holes, and by these the pins are lengthened or shortened so as to adjust the tops very truly with the drum teeth revolving beneath them ; *h*, is a small cylinder, and *i* another cylinder, both of which are covered from end to end with narrow strips of card laid on spirally. The main drum is covered with card clothing in strips laid to the axis, with smooth leather borders between. The arrows in the figure show the direction in which the cylinders revolve.

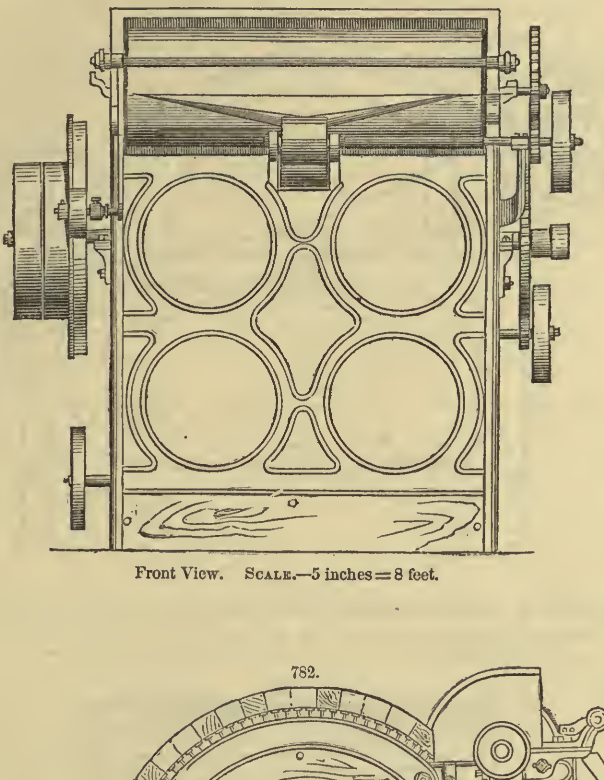
The card end or fleece taken off the doffer *h*, by the crank and comb *i k m*, passes through a tin plate or brass funnel *n*, (fig 779,) by which it is condensed into a riband, which is then passed through the drawing rollers *o*, thence it is conducted by the rollers *u v* into tin cans placed below.

The band, *p p*, (fig. 780,) drives by means of the pulley *g* the drum *f*, (fig. 779,) with a velocity of from 120 to 140 revolutions per minute. The drawing rollers *o and u v*, are operated by the system of geering shown at *p′ o* and *v*, fig. 780, to which motion is imparted by the pinion *m′* on the axis of the pulley *a′* belted to the pulley *y* on the main drum shaft.

The wheel *h* on the doffer cylinder also derives its motion from the pinion *m′* by means of the pinion *n′* and intermediate wheel *o′*. The wheel *n′* turns by the carrier wheel *p′* a wheel *x*, whose axis is shown at *x* (fig. 779.) The axis of *x* carries, towards the middle *f* the engine a very broad wheel, which is represented by a dotted circle. The toothed wheel *v* of the smooth roller *v′*, and the two toothed wheels *o o.* of the under rollers *o o.* work into this broad wheel. The large runner *i* is driven from the

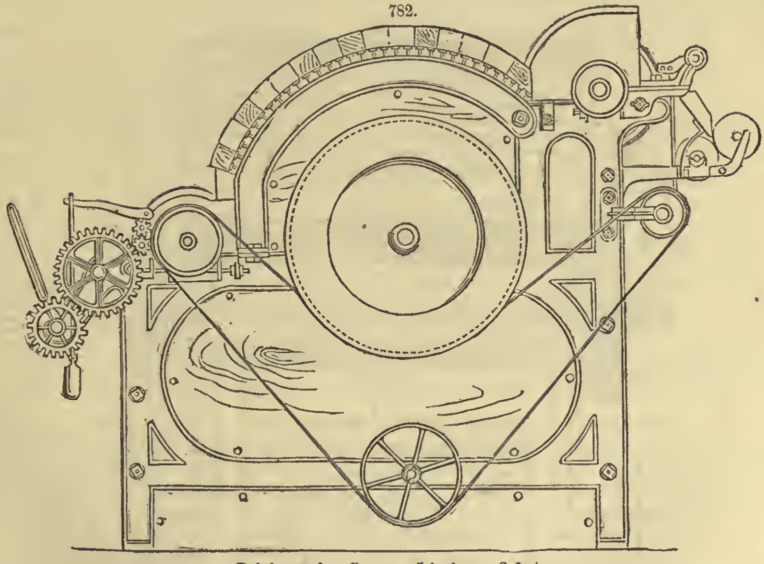
main drum pulley, by the band s', and the pulley u' fig. 779. The motion of the fluted rollers e which feed in the lap, is effected by means of a bevel wheel b' on the end of the doffer, which works into a similar wheel c' on the oblique axis d', (shown by dotted lines) of the pinion e' upon the lower end of the same axis which turns the wheel f', upon the under feed roller. The lever mechanism of the stripper knife i, is operated by the pulley t driven by the band s from the pulley r on the drum shaft. The operation of the cylinders h and i, will be understood by comparing their speed with one another and with that of the main drum, and taking into account the direction in which the carding cylinders revolve.

781.



Front View. Scale.—5 inches = 8 feet.

782.



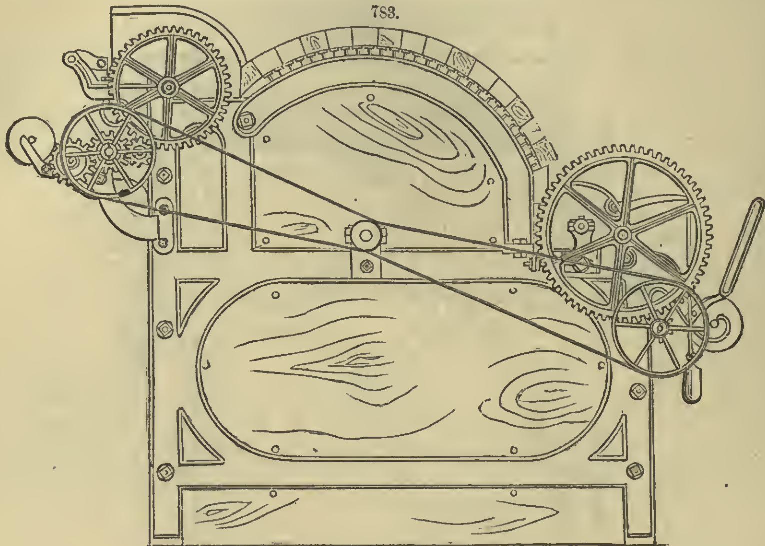
Driving-end. Scale.—5 inches = 8 feet.

The cotton which is delivered to the drum by the feed rollers is caught by the opposite teeth of the large runner i, which on account of its slow speed (98 inches per minute,) may be considered at rest with reference to the drum, and retaining the cotton in its teeth, will commence the carding or separation of the fibres. The small runner h, revolves at a much greater velocity, (5170 inches per minute,) and combs the cotton out of the teeth of the large runner i, giving it up in its turn to the swifter teeth

of the drum, which brings it in contact with the teeth of the top cards, by which the fibres are finally arranged in their proper position. The quantity of cotton, or the thickness of the lap, the velocity of the cards, and of the drawing rollers, must be carefully adjusted to the number or size of the yarn intended to be spun.

Figs. 781-2-3-4, represent the front, sides, and rear elevation of a carding machine as manufactured at the machine-shop, Lowell, Mass., intended for a BREAKER card; the FINISHERS are in general constructed with more top cards.

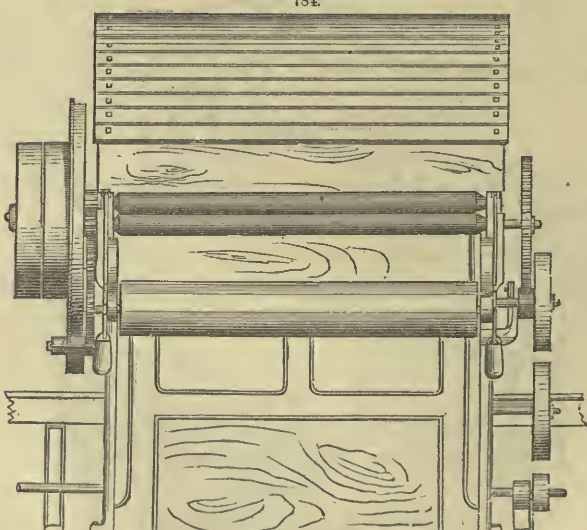
783.



Gear-end. SCALE.—5 inches = 8 feet.

There are but few mills in the United States that use single carding; the greater part use Breakers and Finishers, even those that manufacture the coarsest goods. In the Eastern district the general breadth of the cards is 37 inches, and diameter of main cylinder 36″; doffing cylinder 13″; feeding rollers $1\frac{1}{4}$″

784.



Back View. SCALE.—5 inches = 8 feet.

The main cylinders are made of cast-iron, and covered with broad filleting, instead of sheets. The average speed of the main cylinders is about 100 revolutions per minute. In the Rhode Island district the cards are made of various breadths, from 18 to 36 inches, and are principally wooden cylinders covered with sheets. In the Southern district the general breadth of the cards is 24″ to 30″. There

are some cast-iron cylinders covered with sheets. The average speed of the cylinders in the two latter districts is 110 revolutions a minute, and diameter 36 inches. The stripping is performed by two persons; one, the *top-stripper*, begins at the first cards in the series, and strips every second top all over; that is, the 1st, 3d, 5th, 7th, 9th, 11th, &c., until the whole of the tops are stripped in two or three courses. The cylinder is also stripped by the cylinder-stripper, thus keeping up a constant system of stripping all the time the machinery is in motion.

For the purpose of *sharpening the teeth*, when a carding-engine is first filled with new sheets, fillets, &c. the cylinders are put in motion the right way, and a light emery-board, about 4 inches broad, is traversed over the top of the cylinders, with a very delicate hand; this is called facing up the teeth, because the points of the wires are running against the board, and is intended to cut down any single wires that may be too long. After running the cylinders in this way about fifteen minutes, their motions are reversed, and are mounted on the main and doffing cylinders; these are denominated the fast-grinders, and which, after being properly set, are caused to revolve in an opposite direction to the card cylinders. This operation is continued until the whole of the teeth on both cylinders are ground down to one uniform length; but during the process of grinding, the emery cylinders are made to traverse a little each way, so as to grind the wires to a round point, and prevent them from being hooked. The cards are then dressed up—first with a brush dusted with chalk, and then with emery-boards, called strickles; this latter process is called sharpening, and is continued daily to the *Breakers*, and every second day to the *Finishers*. The *fast-grinders* are not applied above once a year, or only when the cylinders on some parts of the surface have become higher than on the other parts, or, technically, "*off the truth*." By this method of grinding the cards when necessary, and sharpening them every working day, they are always in good order, and consequently produce more perfect work: also, when the practice of sharpening is continued daily, it can be done in much less time; two men can easily sharpen thirty carding-engines in the space of four hours. The card-belts being all fitted with buckles, no time is lost in making them long or short, for the purpose of reversing the motion of the cylinders. The tops are also brushed out and sharpened once a week.

CARPET SHAKING MACHINE. A machine is in successful operation in the upper part of the city* for beating and brushing dusty carpets. The machine consists of a wooden frame 22 feet long, 8 feet high and 5 feet wide, built of 2000 superficial feet of yellow pine timber. It is driven by steam of two horse power, and cleanses the largest carpet in 15 minutes, by running it through the machine twice. Four heavy carpets can be operated on at one time. If the carpet is very dirty, large, and heavy, it takes a few minutes longer, and 2000 yards of carpet can be beaten per day. The carpet to be operated upon is attached to a canvas which is already tacked to and wound upon a windlass; the machine is put in motion and the carpet passes under a set of wooden flails attached to steel springs, which thoroughly beat it as it ascends. The beating is performed by the middle of the sticks, obviating the risk of tearing the fabric; in hand work, on the contrary, the carpet is struck with the end of the rod used, and this is liable to start the warp. When the carpet passes near the top of the machine, it is operated upon by 56 corn brooms of large size, which revolve rapidly on a shaft, and sweep the carpet as it moves by them slowly, on its way over another roller at the top of the machine, whence it passes to another cylinder and is wound up. If necessary, the carpet can be run back again over the four rollers, and so on. It takes two men to watch the machine and engine. The flail-like sticks that beat the carpet are acted upon by cast-iron flyers, and a number of taut ropes that react.

CARS. See "Rolling Stock" of Railroads.

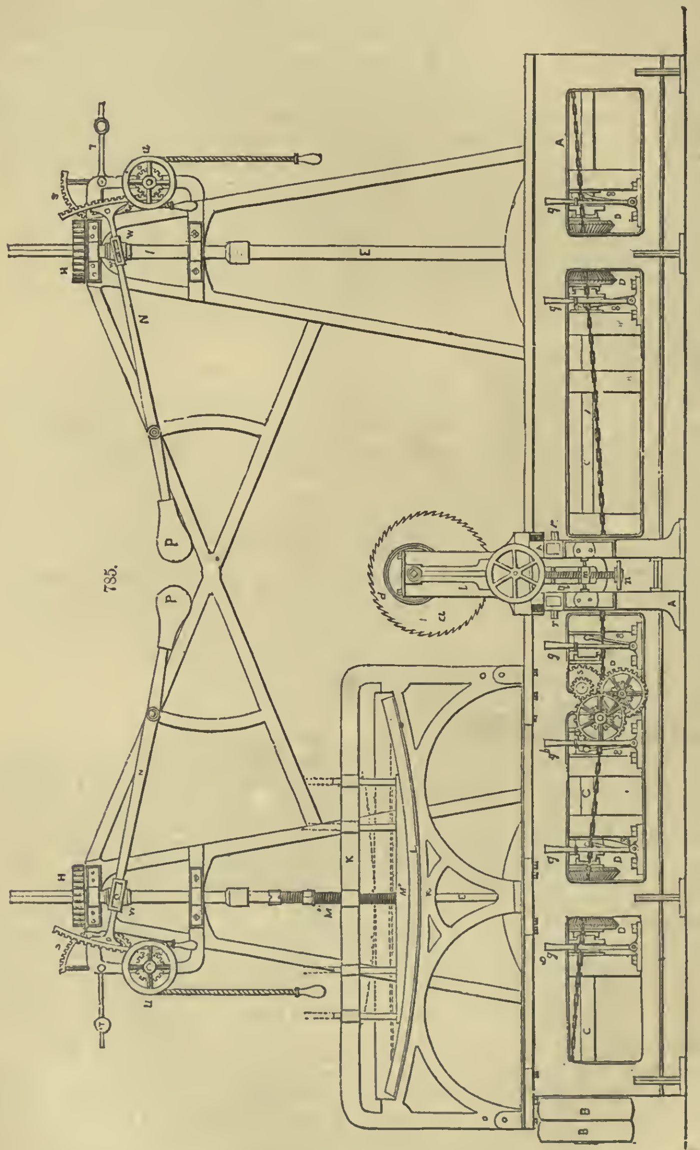
CASE HARDENING. See Tempering.

CASK-MAKING MACHINERY—Rosenborg and Montgomery's *patent*. The patent of Messrs. Rosenborg and Montgomery comprehends a number of processes or mechanical arrangements relating to cask-making, all of which are more or less new and valuable. First, there is a method of sawing wood into pieces or blanks suitable for staves; second, a method of converting these blanks into staves; third, one for combining the staves into casks; and fourth, an apparatus for drilling the holes or sockets in the beads of casks for the reception of the dowels necessary for keeping the parts together. It is the machine comprehended under the second of these heads which has particularly struck us for its ingenuity, and which we here propose to describe. A simple statement of the problem of which it is the practical solution will suffice to convey to the reader a clear idea of the difficulties which the inventors had to overcome. The problem was this:—To take any given number of flat rectangular staves, and so shape the whole at one operation that when built up together into a cask, they shall every one have the exact bevel, bulge, and taper, which is requisite for the formation of the cask. The new machinery by which Messrs. Rosenborg and Montgomery have accomplished this rare combination of difficult achievements is represented in the accompanying figures, of which the following is their own description:

Fig. 4005 represents a front elevation, Fig. 4006 a back elevation, Fig. 4007 an end view, and Fig. 4008 a cross section of this machine. A is the framework; B B the loose and fast-driving pulleys on the main-shaft C; D D bevel-wheels which run loose on the shaft; E E vertical shafts which revolve at right angles to the main-shaft C, and are put in motion by bevel-wheels F F. G and H are spur-wheels which communicate motion to the vertical shafts I I at the front of the machine; K is a frame which slides on the framework A, and carries the blank which is to be formed into a stave. M^1 is a pressing-block, which is made of a convex form on its under surface, corresponding exactly with the interior curve of the intended stave. M^2 is a screw which is passed through the top bar of the frame K, and acts upon the block M^1; N is a lever centred at n, which has a toothed segment O on one end, and a counter-weight P on the other. Q is a pinion which works into the toothed segment O; R (see Fig. 4007, the end view of the machine) is another pinion on the same shaft as Q, which works into another toothed segment S, and thereby gives motion to the tumbler T. U is a cord-wheel, by means

* Bourne & Emery, 139 and 144 Bank street.

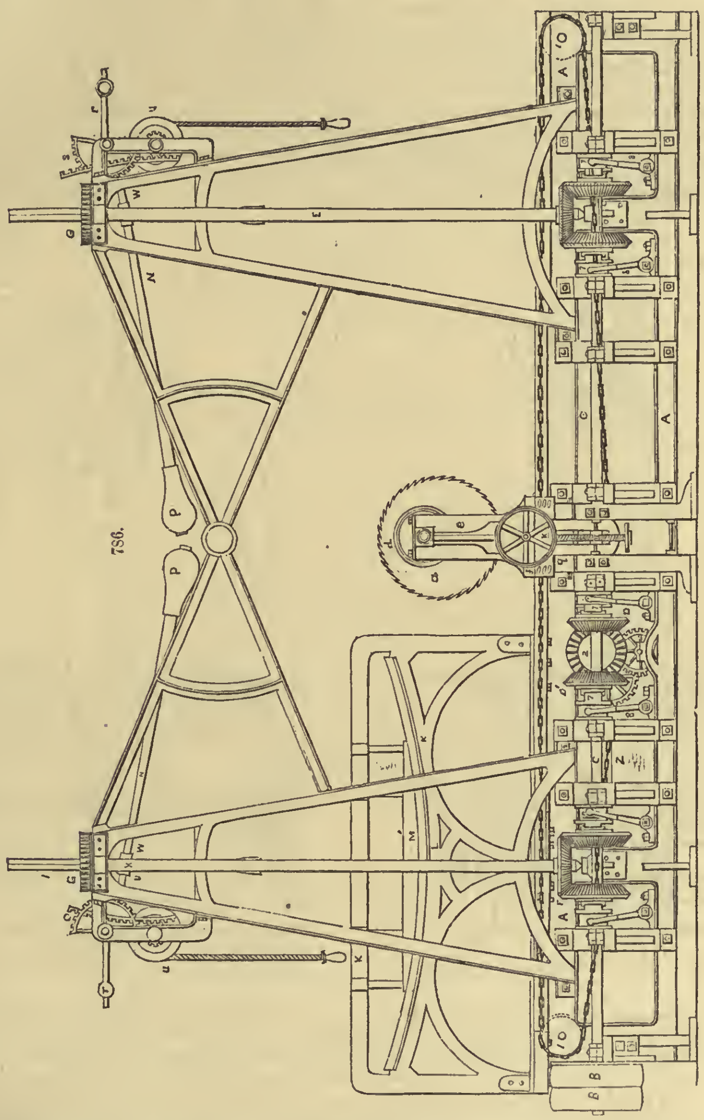
of which motion is given to the toothed segment O and lever N, and also to the tumbler T. V is a loose socket on the vertical shaft I, which socket is kept in its place by means of two collars W W, and has two pins projecting from it at right angles, which work through slots in the eye-piece X of the lever N, which eye-piece fits on to the shaft I. Y is a drum which carries the chain Z over the rollers 1, and being fastened to the sliding-frame K, gives motion to the same. The chain-drum Y receives its motion through the bevel-wheel 2, which works into the bevel-wheels D^1 D^1 on the main-shaft C on the other end of the shaft which carries the bevel-wheel 2 is a pinion 3, which works into the spur wheel 4, to which spur-wheel is attached the pinion 5, which works into the spur-wheel 6 on the shaft



735.

of the chain-drum Y. 7 7 are clutch-boxes which slide on keys on the main-shaft C, and are worked by forked levers 8 8, which again are actuated by the handles 9 9, as seen in the front view of the machine, Fig. 4005. *a a* are circular saws which are fixed to the shafts *b b*, to which shafts motion is given by the strap-pulleys; *c d* are loose strap-pulleys on the same shafts *b b*. The shafts *b b* are mounted in frames *e e*, which are made to slide on the plates *f* by means of V-champs; *g g* are screws by which sliding motion is given to the frames *e*, the screws working in the nuts *h* affixed to the frames *e e*. The spindles of the screws *g g* are mounted on the plates *f f*, and carry at their outer ends hand-wheels *i i*; *k k* are swivel-joints fastened underneath the plates *f f*; *l l* are screws, the upper and plain ends of

which work into the swivels $k\ k$, and are so kept in their places by means of pins which fit into circular grooves cut in the ends thereof. The screws $l\ l$ are also tapped through a swivel-nut m, which has its bearings in plummer-blocks attached to the frame A, and have hand-wheels $n\ n$ at their lower ends. The plates $f\ f$ have lugs $o\ o$ fastened on their inner ends, which lugs work upon shafts $p\ p$, and so form centres for the circular motion of the plates $f\ f$. The plates $f\ f$ are provided also underneath with guides $q\ q$, which work tight in the framework A. The guides $q\ q$ have two screws $r\ r$ tapped into them on each side, which work through slots $s\ s$ in the framework A. The machine is worked in the following manner:

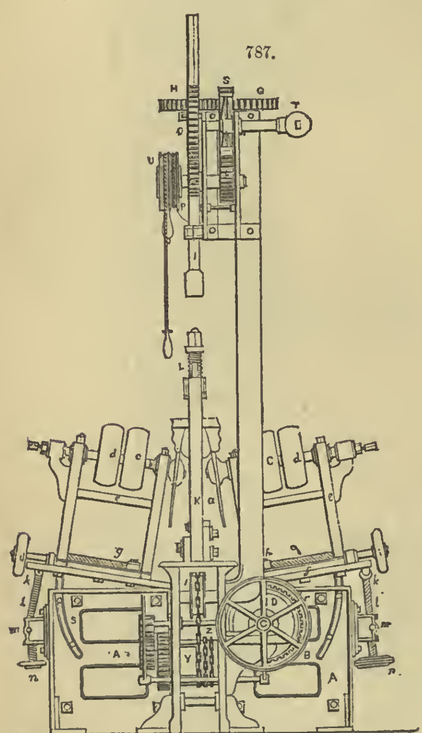


786.

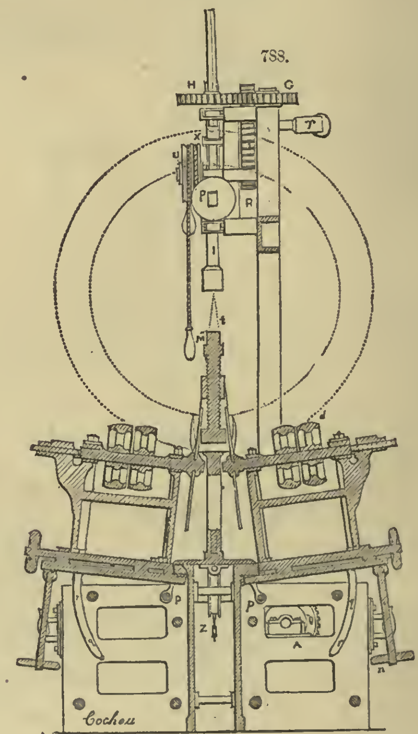
The sliding-frame K being placed at one end of the machine, so that the screw M^2 is in the same vertical line with the shaft I, the pressing-block M^1 being raised close under the top of the frame K, (see dotted lines in Fig. 4005,) the blank required to be shaped into a stave is placed in the frame K. The handle 9^a is moved towards the left, so as to couple the clutch-box 7 with one of the bevel-wheels D. Motion being communicated to the vertical shaft I, in the front of the machine the man takes hold of the cord-handle nearest to the shaft I, and turns the cord-wheel U. By doing so, the vertical shaft I will be lowered down upon the square part of the screw M^2, (the socket of the vertical shaft I fitting over the square top of the screw,) and the tumbler T being moved over to the other side, will keep the shaft I close upon the screw M^2. The screw will now turn round, and thereby bring the pressing-block M^1 down upon the blank piece of wood, and by the motion being continued will press it down in a

curved position close against the bed of the frame K. The wood will now have the shape given to it which it is required to possess when put into its place as a stave in the formation of a cask. When the blank has thus been bent, the same handle 9^4 is moved towards the right, whereby the clutch-box 7 is disengaged from the bevel-wheel D. The motion of the screw is thus stopped, and the workman, by taking hold of the corded handle farthest from the shaft I, causes the cord-wheel U to turn round, by means of which the shaft I is disengaged from the screw M^2, and raised to its former position. The workman now takes hold of the handle 9^5, which couples the chain motion, and by moving that handle so as to bring the corresponding clutch-box into geer, the chain-drum Y will turn round, by means of which the slide K will be put in motion. The circular saws *a a*, being always in motion when this machine is at work, the blank will now be brought into contact with them, and both the sides of the blank will thereby be cut as the slide continues to move betwixt the saws *a a*. When the slide K arrives at the other end of the machine, the handle 9^5 for the chain-coupling is moved by the workman, so as to detach the clutch-box from the bevel-wheel D, and thereby stop the motion of the slide, which will now be in the same position at this end of the machine as it was before at the other end, that is to say, the screw M^2 will be in the same line with the vertical shaft I at this end of the machine. One of the handles 9^3 is now moved by the workman putting the shaft I at this end of the machine in motion in the reverse direction, which being done, the workman takes hold of the corded handle nearest to the shaft I, and by twining round the cord-wheel U, causes the shaft I to descend upon the screw M^2, and thereby puts that screw in motion, which causes the pressing-block M^1 to rise up under the top of the frame

787.



788.



K. The workman now stops the motion of the shaft I, but he does not disengage that shaft from the screw M^2. The stave, being now completed, is removed from the frame K, a fresh blank put in, and the preceding operation repeated, but in the reverse direction of the machine. In order to enable the workman to vary the width of the cut staves, and also to enable him to alter the position of the saws to cut the various bevels required for different-sized casks, the saws are adjusted in the following manner:—Having determined upon the required width of the stave, he moves the hand-wheels *i i*, and by means of the screw *g g*, adjusts the frames *e e*, and the saws *a a*, to the requisite distance from the central line of the framework K. Having done this, he moves round the hand-wheels *n n*, on the screws *l l*, and thereby causes the outer ends of the plates *f f* to rise or fall, in order to place the saws *a a* in a position to form the radii, or nearly so, of the circle of the cask to be made, (see the dotted lines *t t*, Fig. 4008) He now tightens the bolts *r r* on both sides of the guides *q q*, outside the frame A, whereby the angular position of the plates *f f* is secured. With such modifications as will readily suggest themselves to a competent workman, the blank in its longitudinally curved state may be submitted to a circular saw-bench, to a planing or other cutting machine, or to suitable cutting-tools, in order to produce a stave with the bevel bulge and taper requisite for its formation into a cask; a stave may thus be formed either by machine or hand-power, and one or both sides may be completed in one operation.

The improved machinery of Messrs. Rosenborg and Montgomery has not been as yet many months in operation, but already a very considerable number of casks of nearly all descriptions have been manufactured by them; viz., oil-butts for the fisheries, water-butts for emigrants, rum puncheons, sherry pipes, hogsheads, and quarter-casks, beer hogsheads, and barrels for exportation and inland trade, spirit puncheons, &c., &c. Of these, some have been sent to the Hudson Bay Company's settlements, some to Spain, to the West Indies, to the coast of Africa, to the East Indies, to Australia, and to New Zealand.

All these casks have given the utmost satisfaction, with the exception of a very few of those first put together, before the machinery was in perfect working order. Certainly casks cannot be made by hand to equal those which were turned out the other day. The mathematical correctness with which the staves are shaped (or "jointed," as the coopers call it) by these machines, gives much greater strength and tightness to the casks than ever has been witnessed before. The hand-cooper's *art*, in giving form to the stave, is a very difficult one, and requires long practice. He works entirely by measure of the eye; but however well instructed he may have been—however expert he may have become in hitting angles—still he cuts away to a certain extent at random, and it is therefore impossible that he can attain to that accuracy which is necessary to make a stave *a perfect part of a cask.* Besides, casks of different shapes and sizes require staves of different forms, depending upon the greater or lesser "bilge" and length, by which the curvature of the lines of the staves must be determined. Another most difficult and important matter to be attended to is *the bevelling of the edges.* As the cask varies in diameter from the middle or highest point of the bilge to the end or "head," so must the bevel of the edges of each stave vary accordingly, in order to produce a good or "tight joint," or to make the stave fit well in its place. It is no doubt this latter circumstance which has presented to inventors hitherto the principal difficulty in the way of constructing machines for jointing staves. By the machinery of Messrs. Rosenborg and Montgomery, the curvature of the lines, as well as the varied bevel of the edges, are given to the staves with unerring correctness, whatever may be the shapes and sizes of the casks.

CAST-IRON. See Iron.

CASTINGS, *how to make fine.* See Details of Engines, and Casting and Founding.

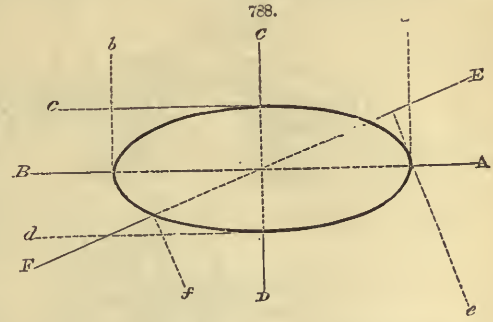
CASTING AND FOUNDING. We are indebted to the fusibility of the metals for the power of giving them, with great facility and perfection, any required form, by pouring them, whilst in the fluid state, into moulds of various kinds, of which the castings become, in general, the exact counterparts. This property is of great value.

Some few objects are cast in open moulds, so that the upper surface of the fluid metal assumes the horizontal position the same as other liquids, as in casting ingots, flat plates, and some few other objects; but in general the metals are cast in close moulds, so that it becomes necessary to provide one or more apertures or *ingates* for pouring in the metal, and for allowing the escape of the air which previously filled the moulds.

When these moulds are made of metal, they must be sufficiently hot not to chill or solidify the fluid metal before it has time to adapt itself thoroughly to every part of the mould; and when the moulds are made of earthy matters, although moisture is essential to their formation, little or none should remain at the time they are filled.

The earthen moulds must be also sufficiently pervious to air, that any vapor or gases which may be formed, either at the moment of pouring in the metal or during its solidification, may have free vent to escape; otherwise, if these gases are rapidly formed, there is great danger of the metal being driven out of the mould with a violent explosion, or when more slowly formed and locked up without sufficient freedom for escape, the casting will be said to be *blown*, as some of the bubbles of air will displace the fluid metal and render it spongy or porous. It not unfrequently happens that castings which appear externally good and sound, are full of hidden defects, because the surface being first cooled, the bubbles of air will attempt to break their way through the central and still soft parts of the casting.

788.



The explanatory diagram, Fig. 788, is intended to elucidate some of the circumstances concerning the construction of moulds, which in the greater number of cases are made only in two parts, but in other cases are divided into several. The figure to be moulded is supposed to be a rod of elliptical section, the mould for which might be divided into two parts through the line A B, because no part of the figure projects beyond the lines *a b*, drawn from the margin of the model at right angles to the line of division, and in which direction the half of the mould would be removed or *lifted;* the model could be afterwards drawn out from the second half of the mould in a similar manner.

The mould could be also parted upon the line C D, because in that direction likewise, no part of the model extends beyond the lines *c d*, which show the direction in which the mould would be then lifted.

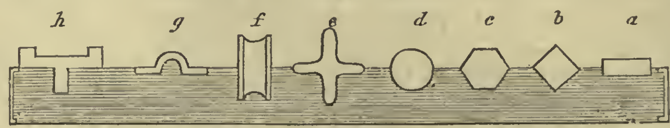
The mould, however complex, could be also parted either upon A B or upon C D, provided no part of the model outstepped the rectangle formed by the dotted lines *b c*, or was undercut.

But, considering the figure 788 to be turned bottom upwards, and with the line E F horizontal, the

removal of the entire half of the mould upon the lines *c f* would be impossible, because in raising the mould perpendicularly to E F, that portion of the mould situated within the one perpendicular *e*, would catch against the overhanging part of the oval towards A. Were the mould of metal, and therefore rigid, it would be entirely locked fast, or it would not "*deliver;*" were the mould of sand, and therefore yielding, it would break and leave behind that part between A and E which caused the obstruction. Consequently, in such a case, the mould would be made with a small loose part between A and E, so that when the principal portion, from A to F, had been lifted perpendicularly or in the direction of the line *e*, the small undercut piece A to E might be withdrawn *sidewise*, on which account it would be designated by the iron-founder a *drawback*, by the brass-founder a *false core.*

All the patterns in the mould, Fig. 789, could be extracted from each half of the mould, because none of them encroach beyond the perpendicular line, or that in which the mould is lifted; *a* and *b* could be laid in exactly upon the diagonal, or upon one flat side, or partly imbedded; and in like manner *f g h* might be sunk more or less into the mould, their sides being perpendicular; but the patterns

789.



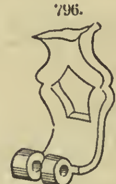
790.

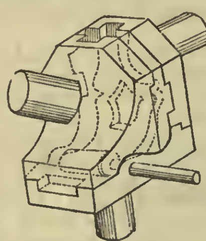
in Fig. 790 being undercut, the division of the mould into two parts *only* would be impracticable, and false cores or subdivisions would be required in the manner represented, the construction of which will be hereafter detailed.

Extending these same views to a more complex object, such as a bust, it will be conceived that the mould must be divided into so many pieces, that none of them will be required to embrace any

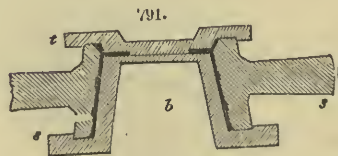
795.

796.

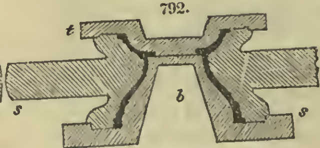




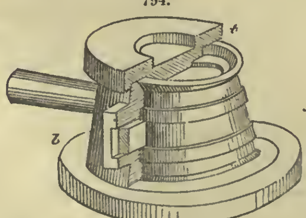
791.



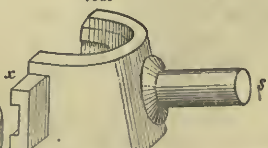
792.



794.



793.



overhanging part of the figure. For instance, were it attempted to mould a human head so that the parting might pass through the central line of the face and down the back: the two halves could not be separated if they were made each in a single piece, as the inner angles of the eyes, the spaces behind the ears, and the curls of the hair would obstruct it, and the head could be only thus moulded

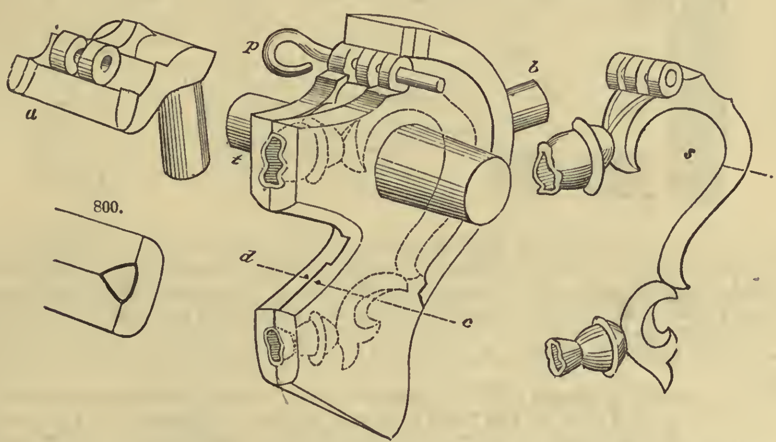
by making false cores or loose pieces at these particular places, in the manner illustrated by the former figures. These, would require to be accurately adapted to the surrounding parts by pins, or contrivances to ensure their retaking their true positions. These remarks, however, are only advanced by way of general illustration, as figure-casting is the most refined part of the art of moulding.

Metal moulds are employed for many works in the easily-fused metals, which are required to be produced in large quantities, and with great similitude and economy: the examination of which moulds will serve to demonstrate many of the points of construction and proceeding. Thus the common bullet-mould is made like a pair of pliers, the jaws of which are conjointly pierced with a hole or passage leading into a spherical cavity; the aperture is equally divided between the two halves of the mould, so that in fact the division is truly upon the diametrical line both of the sphere and the runner, or the largest part of each; otherwise the pliers could not be opened to remove the bullet when cast. Iron shot for great guns are likewise cast in iron moulds, by which they also possess great accuracy of form and size.

Figs. 791 to 794 represent the moulds for casting pewter inkstands. These moulds are a little more complex, and are each made in four parts; the black portions represent the sections of the inkstands to be cast. The moulds each consist of a top-piece or *cap t*, a bottom or *core b*, and two sides or *cottles s s*. In Fig. 794 the one side is removed, in order to expose the castings, and the top-piece *t* is supposed to be sawn through to make the whole more distinct. It will be seen the top and bottom parts have each a rebate like the lid of a snuffbox, which embrace the external edges of the two side-pieces *s s*, and the latter divide, as in the bullet-mould, exactly upon the diametrical line of the inkstand, which in a circular object is, of course, the largest part; the positions of the parts are therefore strictly maintained.

When the mould has been put together, laid upon its side, and filled through *x* the ingate, or as it is technically called, the *tedge*, it is allowed to stand about a minute or two, and then the top *t* is knocked off by one or two light blows of a pewter mallet; the mould is then held in the hand, and the bottom part or core is knocked out of the casting by the edge; lastly, the two sides are pulled asunder by their handles, and the casting is removed from the one in which it happens to stick fast; but it requires cautious handling not to break it. The face of the mould is slightly *coated* with red ochre and white of egg, to prevent the casting adhering to the same, and to give the works a better face. The first few castings are generally spoiled, until in fact the mould becomes properly warmed.

799. 798. 797.



Most of the works made in the very useful material, pewter, are cast in gun-metal moulds, which require much skill in their construction; thus, a pewter tankard, with a hinged cover and spout, consists of six pieces, every one of which requires a different mould. Thus:—

1. The body has a mould in four parts, like that for the inkstand, but it is filled in the erect position through two ingates, which are made through the top-piece *t* of the mould.
2. The bottom requires a mould in two parts, and is poured at the edge.
3. The cover is cast in the same manner; and thus far the moulds are all made in the lathe, in which useful machine these castings are also finished before being soldered together.
4. The spout requires a mould in two parts.
5. The piece, Fig. 796, by which the cover is hinged to the handle, requires a much more complex mould, which divides in four parts, as shown in Fig. 795, and much resembles, except in external form, the remaining mould: namely,
6. For the handle, which mould, like the last, consists of four pieces, fitted together with various ears and projections. They are represented in their relative positions in Fig. 798, with the exception of the piece *a*, Fig. 799, which is detached and shown bottom upwards. Fig. 797 shows the pewter handle separately, with the three knuckles for joining on the cover; and on reference to Fig. 798, of the five parts through which the pin *p* is thrust, the two external pieces belong respectively to the sides *c* and *d* of the mould; the others are parts of the casting, and the two hollows are formed by the two solid knuckles fixed to the detached piece of the mould *a*, Fig. 799. At the time of pouring, the pin *p* serves

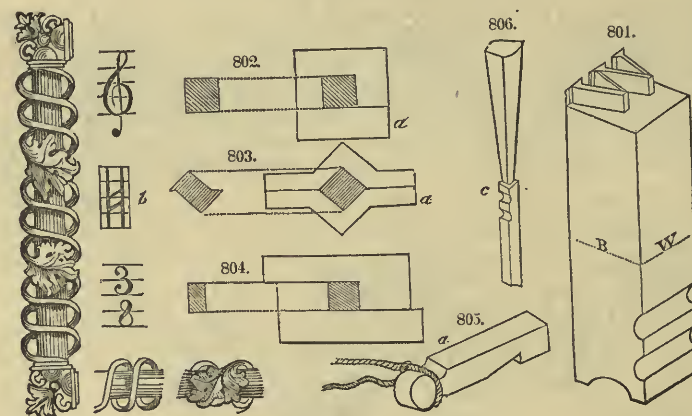
to connect the three parts *a c d* together, and also to form the hole in the casting for the pin of the joint.

Fig. 800 shows the section of the mould upon the dotted line *s*. By this it will be seen the handle is cast hollow, as almost immediately the mould has been filled through *t*, all but the thin external shell is poured out again, and the weight is reduced to less than half. To extract the handle, the pin *p* is first twisted out; then the joint-piece *a* is removed; next the back-piece *b*; and lastly, the two sides *c d* are pulled asunder.

Tin or pewter bearings for locomotive carriages have been cast in appropriate metal moulds; and such materials are very useful to the mechanist for many temporary purposes, such as collars, bearings, screws, and nuts, either for difficult positions, or where no screw-tap is at hand and the resistance is moderate; in such cases the parts of the machine constitute one portion of the mould, the apertures being closed with moist loam. The processes are most successful when the parts can be made warm and the clay is nearly dry.

The most important, exact, and interesting example of casting in metallic moulds is that of type-founding, the description of which, as well as drawings of the mould, have been repeatedly given; some of the peculiarities only of this art, will be therefore noticed. Each complete set of types consists of five alphabets, A, ᴀ, a, *A*, *a*, besides many other characters, in all about two hundred, and which are required to be most strictly alike in every respect, except in *device* and *width;* the width is the greatest for the W and M, and the least for the i and !. Every required measure of the types, (represented on an enlarged scale in Fig. 801,) is determined by the *mould alone*, and not by any after correction.

TYPE-FOUNDING.



If the moulds for the rectangular shafts of the types were made as in Figs. 802 or 803, the usual forms of square moulds, they would not admit of alteration in width, as shifting *a*, Fig. 802, would produce no change, and Fig. 803 would thereby produce the form *b*. The mould which is used, is made in two L-formed parts, as in Fig. 804; whence it follows that shifting the part *a* to the right or left, increases or decreases the width of the type without interfering with its thickness, or as it is technically called, its *body*, (B, Fig. 801;) the width, W, is adjusted by a piece called the *register*, fixed at the bottom of the mould.

The device is changed by placing across the bottom of the mould one of the two hundred little pieces of copper, Fig. 805, called *matrices*, into which the face of the letter is impressed by very beautifully-formed punches. The length of the letter is determined by a contraction at the upper part of the mould, as shown at *c*, Fig. 806, which represents the type as it leaves the mould; the metal is poured with a *jerk*, to make a sharp impression of the matrix,—the mould, which is held in the left hand, and the ladle in the right, being jerked simultaneously upwards, at the moment of filling the mould, and without which the face of the type would be rounded and quite imperfect. The *breaks c*, or the runners of the types are first broken off, and after a slight correction of the sides, the hollows or channels in the feet are planed out of a whole column of them, fixed between bars of wood, without touching the square shoulders which determine the lengths of the types, and are left as originally cast.

In some types with a large face and much detail, such as the illustrations given above, the motion of the hand is barely sufficient to give the momentum required to throw the metal into the matrix, and produce a clean, sharp impression. A machine is then used, which may be compared to a small forcing-pump, by which the mould is filled with the fluid metal; but from the greater difficulty of allowing the air to escape, such types are in general considerably more unsound in the shaft or body; so that an equal bulk of them only weigh about three-fourths as much as types cast in the ordinary way by hand, and which for general purposes is preferable and more economical.

Some other variations are resorted to in type-founding; sometimes the mould is filled at twice, at other times the faces of the types are *dabbed*, (the *clichée* process;) many of the large types and ornaments are stereotyped, and either soldered to metal bodies, or fixed by nails to those of wood. The music type, and ornamental borders and dashes, display much very curious power of combination.

The *clichée* process is rather stamping than casting. The melted alloy is placed in a *paper* tray, and

stirred with a card until it assumes the pasty condition. The *metal* die, or mould, is then "dabbed" upon the soft metal, as in sealing a letter, but with a little more of sluggish force.

Plaster of Paris Moulds, and Sand Moulds.—Other examples of metallic moulds might be given, but there are far more frequent cases in which one single casting is alone required; or else the number is so small, or the pieces themselves are so large or peculiar, that the construction of metal moulds would be found almost or quite impracticable, even without reference to an equally fatal barrier, the expense.

In making these single copies in the metals of considerable fusibility, plaster of Paris is sometimes employed: thus, after the printer has arranged the loose types into a page, and the requisite corrections have been made, a stereotype, or *solid* type, is taken of the whole as a thin sheet of metal, which serves to be printed from almost as well as the original letters; and its small cost enables the printer to retain it for future use, after the types themselves have served perhaps for a hundred similar regenerations, and are ultimately worn out.

The stereotype-founder takes a copy of the entire mass of type in plaster of Paris; this is dried in an oven, and placed *face downwards* within a cast-iron mould, like a covered box, open at the four top-corners. The mould and plaster-cast are heated to the fusing temperature of the type-metal, and gradually lowered into a pan or bath of the same by means of a crane; the hot fluid metal runs in at the corners of the mould, and raises the inverted plaster, which latter would rise entirely to the surface but for the restraint of the cover of the mould.

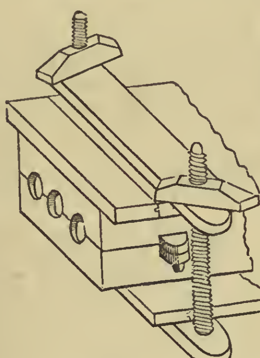
Type-metal is about eleven times as heavy as water; and if the mould be immersed four inches below the surface, it is subjected to a pressure equal to that of a column of water forty-four inches high, or of above two pounds upon every square inch.

The necessity of this arrangement is shown when a few ounces of type-metal are poured from a ladle on the face of the plaster; the metal looks like a dump, almost without any mark of the letters, whereas the stereotype-cast is nearly as sharp as the original type. The immersion fulfils the same end as the jerk of the hand-caster, or of the pump occasionally employed; and the long continuance of the mould in the fluid metal allows ample time for the air to escape in bubbles to the surface; after which the mould is raised and cooled in a vessel of water, and the plaster is mostly destroyed in its removal.

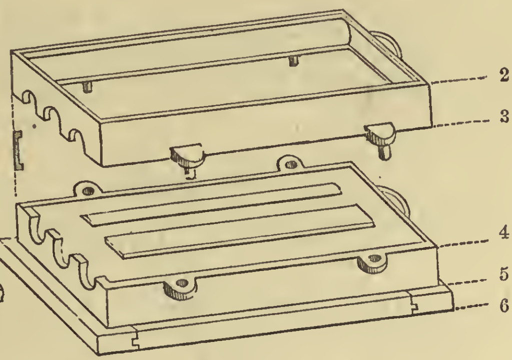
Plaster of Paris, although it may be, and frequently is used for the fusible metals, such as lead, tin, and pewter, cannot be employed alone for iron, copper, brass, and many other metals, the intense melting heats of which would calcine the material, and cause it to crumble; even the soft metals should not be very hot, or they will make the plaster of Paris blister off in flakes or dust. We must therefore seek a substitute better capable of enduring the heat, and likewise susceptible of receiving definite forms; for which purpose damp sand, with a small natural or subsequent admixture of clay or loam, is found to be perfectly adapted.

The moulding-sand cannot, however, be used without external support, and which is given by shallow iron frames, without tops or bottoms, called flasks, represented in Figs. 807 and 808. The bottom part, 4, 5, is supposed to have been rammed full of sand, and to stand upon a flat board, 6. The model of the plain flat bar which is to be cast, is now laid on the surface of the sand, that of the round bar is imbedded half way in the same, and the mould is dusted with dry parting sand.

807.



808.



The top part of the flask 2, 3, is shown still empty, and in the act of being attached to 4, 5 by its pins, which enter corresponding holes in the latter, easily but without shake: 2, 3 is also rammed full of sand, and covered with a top board, 1, not represented to avoid confusion. The mould is now opened, the models are removed, and channels are scooped out from the ends of the cavities left by the models, to the hollows or pouring-holes at the end of the flask; the parts are all replaced in the order 1 to 6, represented in Fig. 808, and the whole are fixed together by screw-clamps, so as to assume the condition of Fig. 807.

The flask is now placed almost perpendicularly beside the pouring-trough, and the metal is poured into it from the crucible; but the flask, if small, is put on the surface of the pouring or spill trough, and propped up with a short bar.

This brief sketch of the entire process of moulding and casting in sand moulds, will be now followed by some remarks in greater detail: first, on the patterns of the objects to be cast; secondly, on the conditions required in the sand; and thirdly, the process of moulding simple and solid bodies. The

section then following will be devoted to moulding cored works and figures, after which a few lines will be given upon the subject of filling the moulds.

Patterns, Moulds, and moulding simple objects.—The perfection of castings depends much on the skill of the pattern-maker, who should thoroughly understand the practice of the moulder, or he is liable to make the patterns in such a manner that they cannot be used, or at any rate be well used.

Straight-grained deal, pine, and mahogany, are the best woods for making patterns, as they stand the best: screws should be used in preference to nails, as alterations are then more easily made in the models; and glue joints, such as dovetails, tenons, and dowels, are also good as regards the after use of the saw and plane for corrections and alterations.

Foundry patterns should be always made a little taper in the parts which enter most deeply into the sand, in order to assist their removal from the same, when their purposes will not be materially interfered with by such tapering. The pattern-maker, therefore, works most of the thicknesses, and the sides or edges, both internal and external, a little out of parallel or square—perhaps as much as about one-sixteenth to one-eighth of an inch in the foot, sometimes much more.

When foundry patterns are exactly parallel, the friction of the sand against their sides is so great when they penetrate deeply, that it requires considerable force to extract them; and which violence tears down the sand, unless the patterns are much knocked about in the mould, to enlarge the space around them. This rough usage frequently injures the patterns, and causes the castings to become irregularly larger than intended, and also defective in point of shape, from the mischief sustained by the moulds; all which evils are much lessened when the patterns are made consistently taper and very smooth.

It must be distinctly and constantly borne in mind, that although patterns require all the methods, care, and skill, of good joinery or cabinet-making, they must not, like such works, be made quite square and parallel, for the reasons stated. Sharp internal angles should in general be also avoided, as they leave a sharp edge or arris in the sand, which is liable to be broken down in the removal of the pattern, or to be washed down on the entry of the metal into the mould. Either the angle of the model should be filled with wood, wax, or putty, or the sharp edges of the sand should be chamfered off with the knife or trowel. Sharp internal angles are very injudicious in respect also to the strength of castings, as they seem to denote where they will be likely to break; and more resemble carpentry than good metallic construction.

Before the patterns reach the founder's hands, all the glue that may have been used in their construction should be carefully scraped off, or it will adhere to and pull down the sand. The best way is to paint or varnish wooden patterns, so as to prevent them from absorbing moisture, as they will then hang to the sand much less, and will retain their forms much better. Whether painted or not, they deliver more freely from the mould when they are well brushed with black-lead, like a stove.

In patterns made in the lathe, exactly the same conditions are required; the parts which enter deeply into the sand should be neither exactly cylindrical nor plane surfaces, but either a little coned, or rounding, as the case may be; and the internal angles should not be turned exactly to their ultimate form, but rather filled in, or rounded, to save the breaking down of the sharp edges of the mould.

Foundry patterns are also made in metal; these are very excellent, as they are permanent; and when very small are less apt to be blown away by the bellows used for removing the loose sand and dust from the moulds. To preserve iron patterns from rusting, and to make them deliver more easily, they should be allowed to get slightly rusty, by lying one night on the damp sand; next, they should be warmed sufficiently to melt bees'-wax, which is then rubbed all over them, and in great part removed, and then polished with a hard brush when cold. Wax is also used by the founder for stopping up any little holes in the wooden patterns; whitening is likewise employed, as a quicker but less careful expedient; and very rough patterns are seared with a hot iron. The good workman, however, leaves no necessity for these corrections, and the perfection of the pattern is well repaid by the superior character of the castings.

Metal patterns frequently require to have holes tapped into them, for receiving screwed wires, by way of handles for lifting them out of the sand; and in like manner, large wooden patterns should have screwed metal plates let into them for the same purpose, or the founder is compelled to drive pointed wires into them, to serve as handles, which is an injurious practice.

The flasks or casting-boxes for containing the sand, are made of various sizes; each side is about 2 to 3 inches deep. They are poured at the edge when placed nearly vertical; but for large brass works the practice of the iron-founder is generally followed, who mostly pours his work horizontally, through a hole in the top, as will be explained. The pins of the flask should fit easily but without shake, or the two halves will shift about and cause a disagreement or slip in the casting. The tools used in making the moulds are few and simple; namely, a sieve, shovel, rammer, strike, mallet, a knife, and two or three loosening wires and little trowels, which it is unnecessary to describe.

The principal materials for making foundry-moulds are very fine sand and loam; they are found mixed in various proportions, so that the respective quantities proper for different uses cannot be well defined; but it is always judicious to employ the least quantity of loam that will suffice.* These materials are seldom used in their new or recent states for brass castings, although more so for iron; and the moulds made of fresh sand are always dried, as will be explained.

The ordinary moulds are made of the old damp sand, and they are generally poured immediately or whilst they are *green;* sometimes they are more or less dried upon the face. The old working sand is considerably less adhesive than the new, and of a dark-brown color; this arises from the brickdust, flour, and charcoal-dust, used in moulding, becoming mixed with the general stock, which therefore requires occasional additions of new sand or loam, so that when slightly moist and pressed firmly in the hand, it may form a moderately hard compact lump.

* The iron and brass founders' sand and loam used in this city are principally obtained from Long Island: and are found in great abundance in almost every state of the Union.

Red brickdust is generally used to make the partings of the mould, or to prevent the damp sand in the separate parts of the flask from adhering together.

The face of the mould which receives the metal, is generally dusted with meal-dust, or waste flour; but in large works, powdered chalk, and also wood or tan ashes, are used, from being cheaper. The moulds for the finest brass castings are faced either with charcoal, loamstone, rottenstone, or a mixture of the same: the moulds are frequently inverted and dried over a dull fire of cork shavings; or when dried, they are smoked over pitch or black resin lighted in an iron ladle.*

The cores or loose internal parts of the moulds for forming holes and recesses, are made of various proportions of new sand, loam, and horse-dung, as will be explained in treating of cored works. They all require to be thoroughly dried, and those containing horse-dung must be well burned at a red heat; this consumes the straw, and makes them porous and of a brick-red.

In making the various moulds, it becomes necessary to pursue a medium course between the conditions best suited to the formation of the mould, and those best suited to filling them with the red-hot metal, without risk of failure or accident. Thus, within certain limits, the more loam and moisture the sand contains, and the more closely it is rammed, the better will be the impression of the model; but at the same time, the moist and impervious condition of the mould would then incur the greater risk of accident, both from the moisture and from the non-escape of the air; therefore the policy, on the score of safety, is to use the sand as dry as practicable, so as to avoid the delay of after-drying, and also to keep the mould porous.

The founder, therefore, compromises the matter by using a little *facing* sand containing rather more loam, for the face of the green moulds for general work; and in those cases where much loam is used, the moulds are *thoroughly* dried by heat, which is not generally necessary with ordinary sand moulds.

The power of conducting heat is considerably less in red-hot iron than in copper and brass, and therefore the moulds for the latter require to be in a drier condition than those which may be used for iron; but in either case the presence of superfluous moisture is always attended with some danger to the individual as well as to the work.†

Another point has also to be considered: as castings contract considerably in cooling, in moulding large and slight works the face of the mould must not be too strongly rammed, nor too much dried, or its strength may exceed that of the red-hot metal, whilst in the act of shrinking. The result would be, that in contracting, the casting would be rent or torn asunder from the restraint of the mould; whereas it should have the preponderance of strength, so as to pull down the face of the sand instead of being itself destroyed. But the exact condition both of the mould and of the melted metal, must be determined by the nature of the object to be cast; matters which can be only referred to with the development of the practice of the foundry, and upon which we shall now commence.

The sand having been prepared, and the appropriate flask and boards selected, the moulder first examines every pattern separately, to determine the most appropriate way of inserting it in the flask, as explained by Fig. 789; also to see that patterns, such as *f* and *h*, therein shown, are smallest at the parts entering the most deeply into the sand, in order that they may *deliver* well. It should also be noticed whether they are perfectly smooth, and that there is no glue hanging about them, which would cause them to adhere and to pull down the moist sand.

The bottom flask, 4 and 5, Fig. 808, is placed on a board not less than an inch or two longer and wider than itself, with the face 4 downwards, and it is filled from the side 5. A small portion of the strong facing-sand is rubbed through a fine sieve; the remainder is thrown in from the trough with the shovel, and the moulder drives the whole moderately hard into the flask, either with a mallet, the handle of the spade, or other rammer; or else he jumps up by aid of the rope suspended from the ceiling, and treads the sand in with his feet. The surface is then struck off level with a straight metal bar or scraper, a little loose sand is sprinkled on the surface, upon which another board is placed, and rubbed down close.

The two boards and the flask contained between them, are then all three turned over together; this requires them to be brought to the front of the moulding-trough, so that the individual may rest his chest against them, and his fore-arms upon the edges of the top board; he then grasps the three together at the back part with his outstretched hands, and thus retained in contact, the whole are quickly turned over upon the front edge of the moulding-trough, and then slid back upon the transverse bearers or *blocks*, to the usual position.

The top board is afterwards taken off; the clean surface of moist sand, then exposed, is well dusted over with red brickdust crushed fine, and contained in a linen bag; the mouth of the bag is held in the right hand, and the bottom corner in the left, and both hands are shaken up and down together, to scatter the dry powder uniformly over the flask; a part of the loose powder is removed with the hand-bellows, and the bottom half of the mould is then ready for receiving the patterns.

The models are next arranged upon the face of the sand at 4, so as to leave space enough to prevent the parts breaking one into the other, and also for the passages by which the metal is to be introduced, and the air allowed to escape. When there are only two or three pieces to be cast, a separate runner is often made to each of them from one of the holes in the end of the flask; when several small patterns are to be moulded, they are arranged on both sides a central runner, or *ridge*, from which small passages

* The gold and silver casters frequently use a lighted link for facing their sand-moulds, and some of the type-founders' metallic moulds are smoked over a lamp: all these modes deposite a fine layer of soot upon the moulds.

† The above is the reason generally assigned for the fact, that the iron-founders may and do use their moulds with safety when sensibly more moist than is admissible for brass and copper castings. It is confirmatory of the fact, that the more dense the mould, the drier it must be; as the sand used by iron-founders is also coarser and therefore more porous than that employed by brass-founders.

lead into every section of the mould. The whole mass when poured has been compared to a great fern-leaf with its leaflets, and is usually called a *spray*.

Those patterns which are cylindrical or thick, are partly sunk in the sand, by scraping out hollow recesses with the bowl of an old copper spoon, and knocking the model into the sand with a mallet, afterwards the general surface is repaired to agreement with the *diametrical line* of the model, or its largest section, as the case may be, by means of a knife or a little piece of sheet steel, something like the worn-out blade of a dessert-knife bent up a little at the end, or else with very small trowels.

After the sand is made good to the edges of the patterns, the brickdust is again shaken over them, so that the patterns may receive a slight share as well as the general surface of the sand. The upper part of the flask 2, 3, is then fitted to the lower, or 4, 5, by the pins, and this half likewise is made up: first a little strong sand is sifted in; it is then filled up from the trough, rammed down, and struck off as before, the dry powder serving to prevent the two halves from sticking together.

In order to open the mould for the extraction of the models, a board is placed on the top of flask 2, 3, and struck smartly at different parts with the mallet; the tool is then laid aside, and the upper part of the flask and its board are lifted up *very gently and quite level;* after which it is inverted on its board, and now each of the inner faces of the mould is exposed. Should it happen that any considerable portion of the mould, say a part as large as a cent, is broken down in one piece, the *cavity* is moistened with the end of the knife, the mould is again carefully closed, and lightly struck before the removal of the patterns; it is probable on the second lifting such piece will be picked up.

The breaks are carefully repaired before the extraction of the patterns, to effect which they are driven slightly sidewise with blows of the mallet, given on a short wire or punch, so as to loosen them by enlarging the space around them; the patterns are then lifted out very carefully with the finger-nails, or sometimes a pointed wire is driven a little way into the pattern to serve as a handle to lift it by:* this process requires some delicacy not to tear away the sand, which accident must be carefully repaired, sometimes by replacing the loose pieces, at other times with a little new sand picked out of any unused part of the mould.

Should the flask only contain one or two objects, the ingate or runner is now scooped out of the sand, so as to lead from the object to the pouring-hole; and when several objects are contained, a large central channel, and lesser passages sidewise, are made as before mentioned. The entrance round about the pouring-hole is smoothed and compressed with the thumb, that it may not break down when the metal is poured; and all the loose sand is carefully blown out of the mould, both parts of which may be placed edgewise for the more convenient application of the bellows, if necessary.

The succeeding processes are to dust the faces of both halves of the mould with meal-dust or waste flour, as explained with regard to the brickdust, and to replace the mould and boards: the whole of them are then carried to the spill-trough, upon the edge of which they are rested whilst the one board is placed exactly level with the end of the flask; but the board on the side from which the crucible will be poured, is placed about two inches below, as in Fig. 807, and the hand-screws are fixed on as shown. The mould is now held mouth downwards, that any sand loosened in the screwing down may be allowed to fall out, and the flask, according to its size, is supported either on the ground or on the surface of the trough by aid of a little bar resting against the clamp: it is now quite ready to be filled, the particulars of which process will be described when the remarks on moulding are concluded.

In works that require the first side, or 3, 4, to be cut away for imbedding the models, it is usual when the second part, or 2, 3, has been made, to destroy the first or *false* side, (which is only hastily made,) and to repeat it in a more careful manner by inverting the lower flask upon 2, 3, proceeding in all other respects as before, by which means a much more accurate and sound mould is produced.

When many copies of the same patterns are required, an *odd side* is prepared; that is, a flask is chosen to which there are two bottom sides, 4, 5. One of these latter is very carefully arranged with all the patterns, but which are only imbedded *barely half way*, so that when 2, 3 is filled, and both are turned over, the whole of the patterns are left in the new side; a second side, 4, 5, is moulded to serve for receiving the metal, as the mould is destroyed every time the metal is poured in. By this plan the trouble of rearranging the patterns for every separate mould is saved, as they are merely replaced in the odd side, and the routine of forming the two working sides is repeated.

Moulding Cored Works.—If the objects to be cast require to be so moulded that when they leave the sand they may contain one or several holes, they are said to be cored, and in such cases, a variety of methods are practised for introducing internal moulds or cores, which shall intercept the flow of the metal, and prevent it from forming one solid mass at those respective parts. For example, the pins inserted in the pewterers' moulds, Figs. 795 and 798, for producing the holes in the joints, are essentially cores. Various other methods are pursued, the three most usual of which are represented in Figs. 809, 810, and 811; the upper figures show the exact sections of the three models or casting patterns; the lower figure represents the two halves of the mould, which are respectively shaded with perpendicular and horizontal lines, the cores are shaded obliquely; and the white open spaces show the hollows to be occupied by the metal when it is poured in.

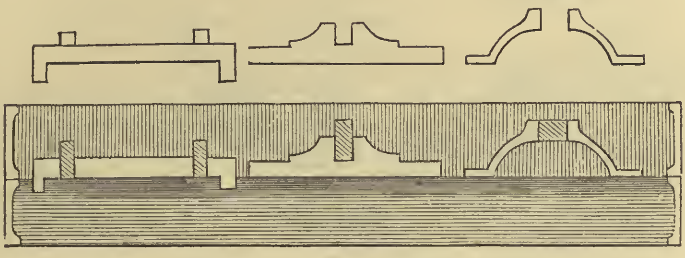
First. Many works are said to deliver their own cores; of such kind is Fig. 809, in which the cavity extends through the model, and exactly represents that which is required in the casting; the hole is either made quite parallel, or a little larger one side than the other, and gradually taper between the two. In some cases, when the hole is sufficiently taper, it delivers its own core as a continuation of the general mass of sand filling the one side of the flask; but in many or most cases, the space in the model is rammed full of strong sand at first, and it is then moulded as if to produce a plain solid casting. Before the mould is finally closed for pouring, the sand core is pushed carefully out of the pattern, and

* A steel wire, pointed and hardened, is convenient as a *picker-out;* and when fixed in the pattern and struck sidewise it serves as a *loosening bar* likewise.

inserted in the mould; to denote its precise position, one side of the core is scored with one or two deep marks in the first instance, which cause similar ridges or guides in the mould.

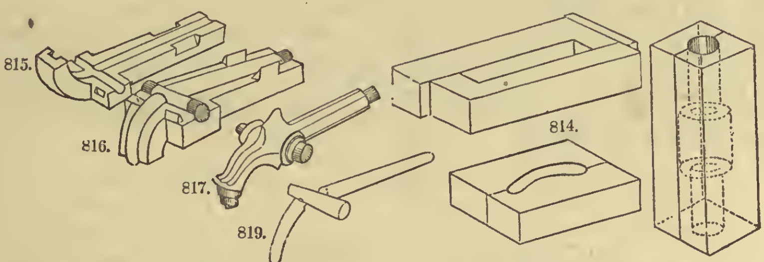
Secondly. When the hole extends only part way through, the hole of the pattern, Fig. 810, is fitted with a solid plug, sawn and filed out of soft unburnt brick, principally sand, (or the common Flanders brick;) the core is made long enough to project about as much as its own diameter, and the work is moulded as if to be cast with a solid pin, instead of a hole. The last step is to extract the filed core, and to insert it into the hollow formed by itself in the flask.

811. 810. 809.



Thirdly. The patterns for iron-work and some others are mostly made with *prints* instead of holes, as in Fig. 811; that is, the pattern-maker places square or round pieces on one or both sides of the pattern, where the square or round holes are respectively required; and the founder has moulds for forming cores of corresponding diameters or sections, and in lengths of about two to twelve inches, short pieces of which are cut off as may be required.

For example, some core-boxes are made like Fig. 812, for cylindrical cores; these divide through the axis, and are kept in position by pins; at the time when they are rammed they are fixed together by wood or iron staples, embracing three sides of the mould, or else by screw-clamps. For straight cores, say one inch wide, twelve inches long, and half-inch thick, the pieces of wood, Fig. 813, are also one inch thick, with an opening between them of twelve inches long and half-inch wide. This core-box is laid on a flat board; it is also held together with clamps, but without pins in the core-box, as the projection at the one end gives the position; it is rammed flush with both sides, and the two parts can be then separated obliquely. If it is preferred to make the cores to the precise lengths instead of cutting them off, this core-box admits of contraction in length, in the manner of the type-mould, Fig. 804; and by placing thin slips between the two halves it may be temporarily increased in width, but not in thickness. Fig. 814 is a similar core-box for a casting with circular mortises; this requires either pins or projections at each end, as it cannot be opened obliquely. Core-boxes are sometimes made of plaster of Paris; wood is much better, and metal the best of all.



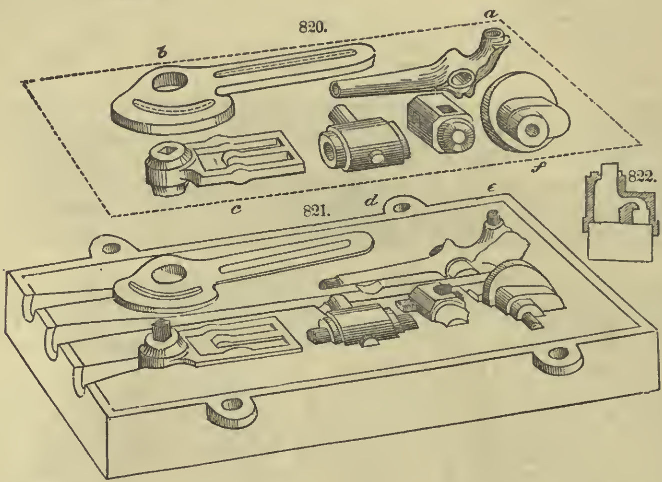
Many works require core-boxes to be made expressly for them; thus the dotted line in Fig. 812 shows an enlargement in the centre for coring a hole of that particular section. Figs. 815 and 816 represent the two halves of a brass or lead core-box suitable to the stop-cock, Fig. 817; and Fig. 819 shows the core itself after its removal from the part 816, in which it is also figured. In 817, the model from which the object is moulded, the shaded parts represent the projections, or *core-prints*, which *imprint* within the mould the places where the extremities of the core, Fig. 819, are supported when placed therein.

The various kinds of core-boxes are rammed full of new sand, sometimes with extra loam; the long cores are strengthened by wires; they are carefully removed from the boxes, and thoroughly dried before use, in the oven prepared for the purpose.*

Fig. 820 represents several examples of coring: in this view the works are represented of their ultimate forms, that is, with the holes in them; in Fig. 821, the models are arranged in the flask, with the runners all prepared, the prints of the cores being in every case shaded for distinction. Thus *a* is the

* Others prefer sand, horse-dung, and a very little loam, for making cores; these are dried, and then well burned, for which purpose they are put into an empty crucible within the fire, the last thing at night, and allowed to remain until the morning. This consumes the small particles of straw, and renders them more porous, in consequence of which the works become sounder from the free escape of air, the necessity of which was adverted to in the earlier part of this subject, and cannot be too much insisted upon.

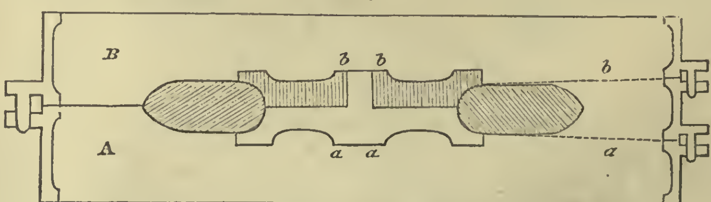
stop-cock, of which explanation has been already given; *b* has a straight and a circular mortise; this pattern *delivers its own core*, in the manner referred to in Fig. 809, as the model is made with mortises like the finished work: *c* only requires a perpendicular square core; *d* a round core parallel with the face of the flask, and in this manner all tubes and sockets are cast, whether of uniform or irregular bore, see Fig. 812; *e* has two rectangular cores crossing each other at right angles; and *f* is the cap of a double-acting pump, the core for which is shown in section by the white part of Fig. 822, the shaded portions being the metal; the great aperture leads to the piston, the two smaller are for valves opening inwards and outwards; this of course requires a metal core-box capable of division in two parts, and made exactly to the particular form.



In addition to the cores used for making holes and mortises, much ingenious contrivance is displayed in the cores employed for other works of every-day occurrence, the undercut parts of which would retain them in the sand but for the employment of these and analogous contrivances. It will now be readily understood that if, in the Fig. 790, the parts shaded obliquely were separate, there would be no difficulty in removing first the upper half of the flask, then the false cores, after which the patterns would be quite free.* By such a method, however, the circular edge of a sheave would require at least three such pieces; but Fig. 823 shows a different way of accomplishing the same thing, when the pattern is made in two parts in the manner represented.

The entire model is first knocked into the side A, the sand is cut away to the inner margin of the pattern which terminates upon the dotted line *a*, and the side A of the mould is then well dusted; a layer of sand is now thrown on, and rammed tolerably firm to form an annular core, which is made exactly level with the inner margin *b* of the pattern, and the core is well dusted; lastly, the side B is put on and rammed as usual. To extract the model, the side B is first lifted, the half pattern *b*, *b*, (which is shaded,) is removed, and the ingate is cut in the side B, to the edge of the pulley; the mould is well dusted with flour and replaced.

823.



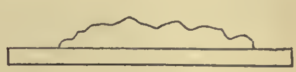
The entire mould is now turned over; A is first removed, then the remaining half pattern *a*, *a*, which must be touched very tenderly or it will break down the core; and the runner (which divides in two branches around the core) is also scooped out in the side A, which is dusted with flour and replaced, ready for pouring. Common patterns not requiring cores, are frequently divided into two parts in the above manner, so that when the mould is opened the pattern may divide and remain half in each side; this lessens the risk of breaking down the mould and the attendant trouble of afterwards repairing it.

Reversing and Figure Casting.—Supposing that an ornament, represented in section in Fig. 824, has been modelled in relief, either in clay or wax upon a flat board, from which a thin casting in brass is wanted without the tablet, the process is called reversing, and is to be accomplished in any of three ways.

* The term *false-core* is employed by the brass-founder to express the same thing as the *drawback* of the iron-founder The former calls every loose piece of the mould not intended for holes, a false-core.

First, an empty flask is placed upon the board, 824, and rammed full of sand; it assumes the appearance of 825; the second part of the flask is attached to 825, and filled to make the part 826, which is called the *back-mould;* some clay is then rolled out to the intended thickness of the casting, with a cylindrical roller running on two slips of wood or on two wires, and a narrow band of this clay is placed on 826, around the figure, that it may separate 825 and 826, exactly to the required distance, ready for receiving the metal.

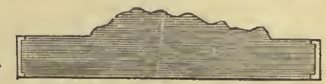
824.



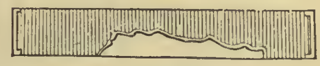
By the second mode, 825 is first made, then 826, and from the latter 827 is moulded, which is a counterpart of 825. A thin sheet of clay is then pressed all over 827, into every cavity, and cut off flush with the plane surface of the mould, by which it assumes the appearance denoted by the double line in 827. After this 826 is destroyed, and made over again in 827, but so much smaller than before as the thickness of the clay *lining;* when the new back-mould 826 is placed in contact with 825, it leaves the required space for the intended casting. This mode is only preferable to the first, when many parts of the work are nearly perpendicular; in which case, if the first mode be adopted, a portion of the back-mould 825, must be pared away at the perpendicular parts, and if incautiously performed there will be a risk of irregularity of thickness, or even of holes in the casting.

825.

826.



827.



The third mode, is to take a casting of 824 in plaster of Paris; when this is thoroughly dry it is oiled, and poured full of a cement of wax, grease, and red ochre, which is poured out again when partially set, leaving a thin crust behind, (as in the pewter handle.) A second, a third, or more layers of wax are thus added until the whole is sufficiently thick, when the wax shell is extracted, and then moulded from in the ordinary manner; the first brass casting is finished and chased to serve as the permanent pattern. The management of the wax requires practice.

In constructing such moulds additional care is given to every part of the work; for example, the sand is sifted much finer, the parting is made with fine charcoal dust, and the facing with charcoal and rottenstone mixed together in about equal parts, the mixture being of a slaty color; sometimes the loamstone, which is found in the pits where clay for making tiles is dug, is used instead of rottenstone. The moulds are well dried in an oven, or over the mouth of the furnace, and the faces are afterwards smoked over a dull fire of cork shavings; this deposites a very fine layer of soot over the face of the mould, which greatly assists the running of the metal; when this additional care is taken the works are known as *fine-castings.*

In casting figures, such as busts, animals, and ornaments consisting of branches and foliage, considerably more skill is required: the originals are generally solid, but the moulds necessarily divide into very many parts. Most persons will have had the opportunity of judging of the complexity of these moulds, from similar works in plaster of Paris, which are frequently purchased by artists and the virtuosi before the seams of the mould are removed.

A glance at these plaster-casts, at the complex and undercut form of many of these ornamental works, and at the explanatory diagram, Fig. 788, will convey some notion of the method to be pursued as well as of the trouble attending them. It is shown, for example, by the diagram just referred to, that all figured works approaching to the circular or elliptical section, require that the mould should be divided into at least three parts, except under most favorable circumstances. In the human figure and quadrupeds, the four limbs and the trunk require at least three parts each, and often many more; it will be easily conceived, therefore, that such moulded works require considerable skill and patience.

Piece after piece of the mould is successively produced, just as in making the core, Fig. 823, every piece embracing only so much of the figure, as in no part to require any core to overhang the line in which it is withdrawn. The side of the mould in which the figure is partly imbedded is first dusted with charcoal, and then the first core is very carefully rammed into the nook, and pared down to the new line of division; the green or wet sand-core is then dusted, and the second core is made, and afterwards dusted, when the moulder proceeds with the third core, and so on; every one being carefully adapted to its neighbor and withdrawn, to see that all is right, before the succeeding core is proceeded with. The relative positions of the cores amongst themselves are readily recognised and maintained by the irregularity of their forms, as in a child's dissected map, or by making a notch or two here and there, which are faithfully copied in the succeeding piece. It is frequently necessary to thrust two or more broken needles through the green cores into the neighboring parts to connect them together, in imitation of the pins in the flasks.

All the parts of the mould are dried in the oven, and the facings are smoked over a cork fire as before explained; the perfection of the casting is augmented by pouring whilst the mould is still slightly *warm,* as otherwise on cooling it has an increased affinity for damp; but the mould when *hot* is more or less filled with aqueous vapor, which is equally prejudicial.

When a figure, such as a bust, is required to be cast hollow from a solid model, it is first moulded exactly as above. The core is now produced as follows: At the foot of the bust a large space, nearly equal in length and bulk to the bust, is cut away in the sand, to serve for fixing the core in the mould, or for the *balance,* as it is called, as the core cannot be propped up at both ends. The entire hollow, that is, for the bust and the balance, is filled with a composition of about one part of plaster of Paris and two of sand or fine brickdust, mixed with a little water and poured in fluid, a few wires being placed amidst the same for additional support.

The mould is now taken to pieces to extract the core, which is then dried, thoroughly burned, and allowed to cool slowly, (which the founder calls *annealing,* from a similar method being employed in

annealing or softening the metals and glass:) the core is then returned to the mould, to see that it has not become distorted. If needful, the fitting around the balance is made good to suit the reduced magnitude of the core, which latter is then so far pared away as to leave room for the thickness of metal; this is frequently regulated by boring holes at many parts of the core with a stop-drill, having a collar to prevent its penetrating beyond the determined depth; the surface of the core is now pared down to the bottoms of the holes, as uniformly as possible. When the mould has been faced, dried, and smoked, the whole is put together for pouring, for which purpose the figure is inverted and filled from the pedestal.

Equestrian and other figures are sometimes cast in two, three, or more pieces, and joined together by solder, screws, or wires; but in all such works the aim of the founder is to leave little or nothing for the finisher or chaser to do.

Some objects which are either exceedingly complex in their form, or soft and flexible in their substance, and which do not therefore admit of being moulded in sand, in the ordinary manner of figure-casting, may be moulded for *a single copy*, provided the originals consist of substances which may be either readily melted or burned into ashes.

A cavity is made in the sand of the moulding-trough, a little larger and longer than the object, or else a wooden box of appropriate size is procured, in the midst of which the wax model may be placed; to the end of the model is added a piece to represent the runner, which will be required for introducing the metal. The composition of one-third plaster of Paris and two-thirds brickdust, mixed with water, the same as for the core of the bust, is then poured in, entirely to surround the model. The mould is first slowly dried; it is then inverted and made warm to allow the wax to run out, after which it is annealed, or burned to redness; and lastly, when cooled, it is buried in sand and filled with metal. The method necessarily throws the chance of success upon a single trial, as the model is destroyed.

Should the face of the casting be required to be particularly smooth, a small quantity of brickdust is washed, (in the manner practised with emery, and to be explained,) and mixed with very fine plaster; a coat of this is brushed over the model, which excludes air-bubbles, the model is quickly placed in its cavity, and the coarser mixture is poured in as before.

The above method exactly corroborates a mode long since described as being suitable to casting copies of small animals or insects, parts of vegetables, and similar objects; these are to be fixed in the centre of a small box, by means of a few threads attached to any convenient parts, one or two wires being added to make air-holes and ingates for the metal. A small quantity of river silt or mud, which had been carefully washed, was first thrown in and spread around the object by swinging the box about; and when partly dry, successive but coarser coats were thrown in, so as ultimately to fill up the box. When it had become thoroughly dry, the wires were first removed from the earthy mould; it was then burned to reduce the object to ashes, and when every particle of the model had been blown out, it was ready to be filled with metal.

Filling the moulds.—Having traced the formation of various kinds of moulds for brass work, we must now return to the furnace to see if the metal is in condition to be poured, which is indicated by the slight wasting of the zinc from its surface with a lambent flame. When this condition is observed, the large cokes are first removed from the mouth of the pot, and a long pair of crucible tongs are thrust down beside the same to embrace it securely, after which a coupler is dropped upon the handles of the tongs; the pot is now lifted out with both hands and carried to the skimming-place, where the loose dross is skimmed off with an iron rod, and the pot is rested upon the spill-trough, against or upon which the flasks are arranged.

The temperature at which the metal is poured must be proportioned to the magnitude of the works; thus large, straggling, and thin castings, require the metal to be very hot, otherwise it will be chilled from coming in contact with the extended surface of sand before having entirely filled the mould: thick massive castings if filled with such hot metal would be *sand-burned*, as the long continuance of the heat would destroy the face of the mould before the metal would be solidified.

The line of policy seems therefore to be, to pour the metals at that period when they shall be sufficiently fluid to fill the moulds perfectly and produce distinct and sharp impressions, but that the metal shall become externally congealed as soon as possible afterwards.

For slight moulds the carbonaceous facings, whether meal-dust, charcoal, or soot, are good, as these substances are bad conductors of heat, and rather aid than otherwise by their ignition; it is also proper to air these moulds for thin works, or slightly warm them before a grate containing a coke fire. But in massive works these precautions are less required, and the facing of common brickdust, which is incombustible and more binding, succeeds better.

The founder therefore fills the moulds having the slightest works first, and gradually proceeds to the heaviest; if needful, he will wait a little to cool the metal, or will effect the same purpose by stirring it with one of the ridges or waste runners, which thereby becomes partially melted. He judges of the temperature of the melted brass principally by the eye, as when out of the furnace and very hot, the surface emits a brilliant bluish white flame, and gives off clouds of the white oxide of zinc, a considerable portion of which floats in the air like snow; the light decreases with the temperature, and but little zinc is then fumed away.

Gun-metal and pot-metal, do not flare away in the manner of brass, the tin and lead being far less volatile than zinc; neither should they be poured so hot or fluid as yellow brass, or they will become sand-burned in a greater degree, or rather the tin and lead will strike to the surface. Gun-metal and the much-used alloys of copper, tin, and zinc, are sometimes mixed at the time of pouring; the alloy of lead and copper is never so treated, but always contains old metal;* and copper is seldom

* When the founder is in doubt as to the quality of the metal, from its containing old metal of unknown character, or that he desires to be very exact, he will either pour a sample from the pot into an ingot mould, or extract a little with a long rod terminating in a spoon heated to redness. The lump is cooled and tried with the file, saw, hammer, or drill, to learn its quality.

cast alone, but a trifling portion of zinc is added to it, otherwise the work becomes nearly full of little air-bubbles throughout its surface.*

Some persons judge of the heat proper for pouring, by applying the skimmer to the surface of the metal, which when very hot has a motion like that of boiling water; this dies away and becomes more languid as the metal cools. Many works are spoiled from being poured too hot, and the management of the heat is much more difficult when the quantity of metal is small.

The mixture and temperature of the metal being found to be proper, it is poured in the manner represented in Fig. 788; the tongs are gradually lowered from the shoulder down the left arm, and the right hand is employed in keeping back the dross from the lip of the melting-pot. A crucible containing the general quantity of 40 or 50 lbs. of metal, can be very conveniently managed by one individual; but for larger quantities, sometimes amounting to one hundred weight, an assistant aids in supporting the crucible, by catching hold of the shoulder of the tongs with a *grunter*, an iron rod bent like a hook.

Whilst the mould is being filled, there is a rushing or hissing sound from the flow of the metal and the escape of the air; the effect is less violent when there are two or more passages, as in heavy pieces, and then the jet can be kept entirely full, which is desirable. Immediately after the mould is filled, there are generally small but harmless explosions of the gases, which escape through the seams of the mould; they ignite from the runners, and burn quietly; but when the metal *blows*, from the after-escape of any confined air, it makes a gurgling, bubbling noise, like the boiling of water, but much louder, and it will sometimes throw the fluid metal out of the runner in three or four separate spirts. This effect, which mostly spoils the castings, is much the most likely to occur with cored works, and with such as are rammed injudiciously hard, without being, like the moulds for fine castings, subsequently well dried.

The moulds are generally opened before the castings are cold, and the founder's duty is ended when he has sawn off the ingates or ridges, and filed away the ragged edges where the metal has entered the seams of the mould; small works are additionally cleaned in a *rumble*, or revolving cask, where they soon scrub each other clean.

Nearly all *small* brass works are poured *vertically*, and the runners must be proportioned to the size of the castings, that they may serve to fill the mould quickly, and supply at the top a mass of still fluid metal, to serve as a *head* or pressure for compressing that which is beneath, to increase the density and soundness of the casting. Most *large* works in brass, and the greater part of those in iron, are moulded and poured *horizontally*, and the process being exactly alike for both metals, we must refer the reader to the following.

Iron-Founders' Flasks, and Sand-moulds.—The process of moulding works in sand is essentially the same both for brass and iron castings; but the very great magnitude of many of the latter give rise to several differences in the methods: it will suffice, however, to advert to the more important points in which the two practices differ, or to those which have not been already noticed; I shall therefore commence with a few remarks upon the flasks and the sand.

In the greater number of cases, the iron-founder moulds and casts his works horizontally, with the flasks lying upon the ground; frequently the top part only is lifted; and in the largest works the lower part of the flask is altogether omitted, such pieces being moulded in the sand constituting the floor of the foundry; in these cases the position of the upper flask is denoted by driving a few iron stakes into the earth, in contact with the internal angles of the *lugs*, or projecting ears of the flasks.

The sand would drop out of such large flasks, if only supported around the margin; they are consequently made with cross-bars, or wooden *stays*, a few inches asunder, which, unless the entire flask is made of wood, are fixed by little fillets cast in the solid with the sides of the iron flasks. A great number of hooks in the form of the letter S, but less crooked at the ends, are driven into the bars, and both the bars and hooks are wetted with thick clay-water, so that the sand becomes entangled amidst them, and is sustained when the flask is lifted. Some flasks require the force of either two or several men, who raise them up by iron pins or handles projecting from the sides of the flask; they are then placed upon one edge, and allowed to rest against any convenient support whilst they are repaired, or they are sustained by a prop.

The very heavy flasks are lifted with the crane, by means of a transverse beam and two long hangers, called *clutches*, which take hold of two gudgeons in the centres of the ends of the flask; it can be then turned round in the slings, just the same as a dressing-glass, to enable it to be repaired.

The modern iron-founders' flasks are entirely of iron, and do not require the wooden stays, as they are made full of cross-ribs nearly as deep as the flask itself, and which divide its entire surface into compartments four or five inches wide, and one to two feet long. On the sides of every compartment are little fillets, sloping opposite ways, so as to lock in the small bodies of sand very effectually. When these top flasks are placed upon middle flasks without ribs, as in moulding thick objects, the two parts are *cottered* or keyed together, by transverse wedges fixed in the steady pins of the flask; lifters or *gaggers* are then placed amidst the sand; these are light T-shaped pieces of iron, wetted and placed head downwards, the tails of which are largest at top, so as to hold themselves in the sand, the same as the keystone of an arch is supported. The gaggers are placed at various parts to combine the sand in the two flasks, and they fulfil the same end as the iron hooks and nails driven into the wooden stays of the old-fashioned flasks.

The bottom flask, or drag, has sometimes plain flat cross-ribs, two inches wide, (like a flat bottom with square holes,) that it may be turned over without a bottom-board; and unless the flasks have swivels for the crane, they have two cast-iron pins at each end, and one or more large wrought-iron handles at each side, by which they may be lifted and turned over by a proportionate number of men.

* The engraved cylinders for calico-printing are required to be of pure copper, and their unsoundness when cast in the usual way was found to be so serious an evil, that it gave rise, in 1819, to Holingrake's patent for casting the metals under pressure.

The sand of the iron-founder is coarser and less adhesive than that used by the brass-founder The parting-sand is the burned sand which is scraped off the castings; it loses its sharp, crystalline character from being exposed to the red heat. The facing-sand is sometimes only about equal parts of coal-dust and charcoal-dust, ground very fine; at other times, either old or new sand is added, and for large, thick works a little road-drift is introduced. All these substances get largely mixed with the sand of the floor, and lessen its binding quality, which is compensated for by occasional additions of new sand, and by using more moisture with the sand, as before extracting the patterns, the iron-founder wets the edges of the sand with a sponge, which has sometimes a nail tied to it to direct the water in a fine stream; for heavy works a watering-pot is used.

The *green-sand moulds* are made as in the brass-foundry, of the ordinary stock of old moist sand; these are often filled as soon as they have been made.

The *dry-sand moulds* are made in the same manner, but with new sand containing its full proportion of loam; these moulds are thoroughly dried in a large oven or stove, and then blackwashed or painted, with thin clay-water containing finely-ground charcoal; this facing is also thoroughly dried before the moulds are poured.

The *loam-moulds*, which are much used for iron-castings, and somewhat also for those of brass, are made of wet loam with a little sand, ground together in a mill to the consistence of mortar; the moulds are made partly after the manner of the bricklayer and plasterer, as will be explained; the loam moulds also are thoroughly dried, blackwashed, and again dried, as from their greater compactness they allow less efficient escape for the vapor or air, and therefore they must be put into the condition not to generate much vapor when they are filled.

Iron moulds are also employed for a small proportional number of works which are then called *chilled castings;* and occasionally the methods of sand-casting and chilling are combined, as in some axletree-boxes, which are moulded from wooden patterns in sand, and are cast upon an iron core. To form the annular recess for oil, a ring of sand, made in an appropriate core-box, is slipped upon the iron mandrel, and is left behind when the latter is driven out of the casting.

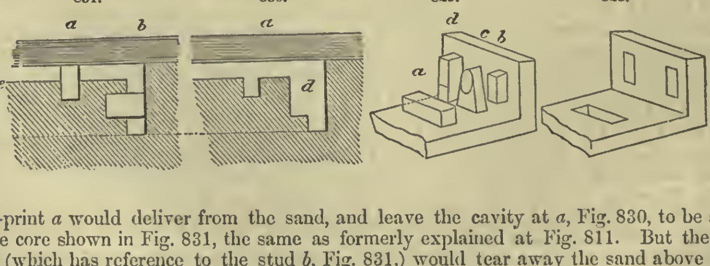
It would be a useless repetition to enter into the details of moulding ordinary iron-works; but from the horizontal position of the flasks, it is necessary that the part of the work which is required to be the soundest, and most free from defects, should be placed downwards, as the metal is more condensed at the lower part, and free from the scoria or *sullage* which sometimes renders the upper surface very rough and full of minute holes. As the flasks almost always lie on the ground, it is also found the most convenient to retain them in contact by placing heavy weights upon them; the foundry should in consequence have an abundant supply of these.

The flasks require to be poured through a hole in the upper half, as seen at *r*, Fig. 837, which hole is formed by placing a wooden *runner-stick* in the top part A, whilst it is being rammed; and a small channel is afterwards cut sidewise into the mould. Sometimes two, three, or even half-a-dozen or more runners are put to one single casting, either when it requires a great weight of metal, or when it is large but slight, as in trellis-work, in which case the metal might cool before filling the mould, if only introduced at one single runner.

When the runners are required to be lofty, either to supply pressure to the metal, or as a reserve to fill up the space left by its contraction in cooling, iron rings of six or eight inches diameter are piled up to the required height, to support the tube of sand contained within them. Small objects that are poured from one hole, are frequently moulded with two runners, that the metal may *flow* through the mould, and that there may be a sufficient supply to meet the shrinkage, and also to supply head or pressure; another advantage also results, as it assists in carrying off the scoria or *sullage*.

The iron-founder employs all the methods of coring explained at pages 246 to 248, and also others of an entirely different kind but little required in brass-works; namely, for lateral holes in the parts of the castings buried beneath the general surface of the mould, and which are explained by the Figs. 828 to 831. Thus, 828 represents the finished casting, 829 the model of the same, 830 the appearance of the bottom flask or drag when the pattern is first removed, and 831 the flask and cores when closed ready for pouring; the moulds are inverted, and the same letters of reference refer to similar parts of all these figures.

831. 830. 829. 828.



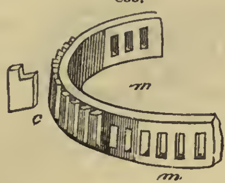
The core-print *a* would deliver from the sand, and leave the cavity at *a*, Fig. 830, to be afterwards filled by the core shown in Fig. 831, the same as formerly explained at Fig. 811. But the core-print *b*, Fig. 829, (which has reference to the stud *b*, Fig. 831,) would tear away the sand above it in withdrawing the pattern; therefore the print *b* should, like *d*, Fig. 829, extend to the face of the pattern, or the parting line, represented by *c*, Fig. 831. This being the case, the pattern would leave the space denoted at *d*, Fig. 830; the core is put down sidewise to the bottom of the recess, and extends entirely across the same; the small open space above is made good with the general surface, as shown by the shade lines in Fig. 831, and this filling in, at the same time fixes the core precisely where denoted by the print *d*, which latter has a mark to show to the moulder where the core is to end. The circular

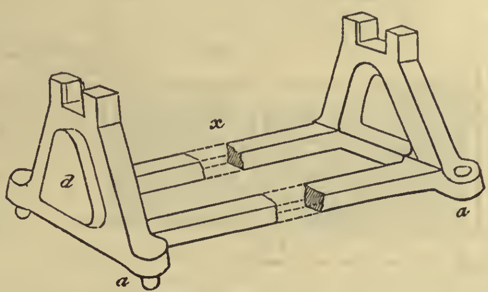
hole requires the core-print shown at *c*, Fig. 829; the cores themselves are made in the core-boxes, 812 and 813, before explained.

Fig. 832 represents the model and core-print, from which the finished casting shown at Fig. 832 might be made from a solid pattern in a two-part flask; it would be inverted, and the parting would be made

832.

833.



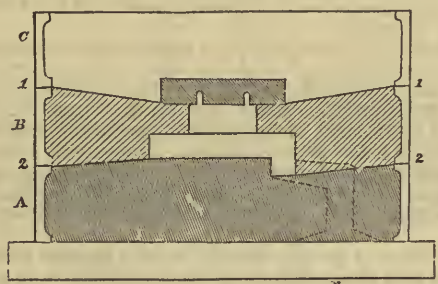


upon the line *x*. The prints for the four holes *a a*, would be placed in the top flask, and those for the great apertures or panels *d*, would be made in a core-box of the express form, and as thick as the pattern and core-print measured together. The core would be deposited edgewise into the core-print, and the upper corners of the mould will be made good, as explained in Fig. 831.

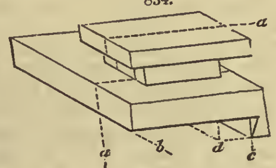
By the same method, a mortise-wheel, or one with spaces around its edge, as at *m m*, Fig. 833, to be filled with wooden cogs, might be made with a series of core-prints, as at *c*, brought up flush with the parting of the mould; if every print were filled with a core such as Fig. 833, made in an appropriate core-box, the matter would be accomplished with great facility and truth.

The iron-founder makes frequent use of flasks which divide in three or four parts; this is done in many cases simply to increase the depth of the contained space; in which case, when wooden flasks were employed, they admitted of being temporarily fixed together by dogs, or large iron staples, driven a little way into the neighboring flasks, but the modern iron flasks are fixed by cotters. The following examples will show the nature of some other uses to which the flasks with several partings are applied.

835.



834.



A casting, such as Fig. 834, which represents the top of a sliding-rest for a lathe, might be moulded in a very deep two-part flask, if the parting were made upon the dotted line *a a;* but there would be very great risk of tearing down the mould in drawing out the pattern; and from the depth, there would be scarcely a possibility of repairing it, and the metal would probably be strained. It would be also possible to mould it with the joining upon the line *b*, provided several cores were employed; but the mode adopted is more convenient than either of these, when the pattern is made in two parts, and the flask in three, as in Fig. 835.

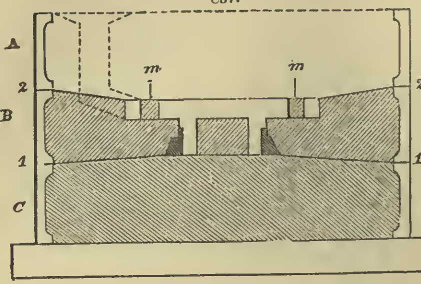
A and B are first united and partly filled with sand, the pattern is knocked in as represented, and the whole well rammed, especially in the groove, the parting being made on the line 1 1, and dusted. C is now put on, filled, and struck off level; a board is put above it, and A B C are all turned over together, A becoming the top.

A is now removed, and the sand is cut away to make the second parting on the line 2 2, after which A is replaced, and the runner-stick is inserted to make the runner *r*. On removing the pattern, the runner-stick *r* is first taken out, A, or the top part of the flask, is lifted off, and the white part of the pattern is drawn out; B, or the middle part, is then lifted, and the last or shaded piece of the pattern is drawn out of the mould, which is now put together again, and poured through *r;* so that the top-surface of the pattern, as seen in both views, becomes the *face,* from being cast downwards, or upon the lowest piece C, of the flask, called the drag.

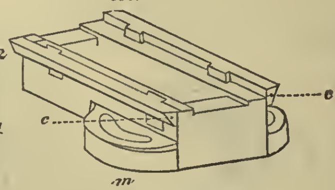
The part *c*, Fig. 834, might be cast with a chamfer in three different ways; although, in small castings, it is more usual to cast it square and plane it out of the solid. First, the pattern might be moulded square, and the top A, after removal, might be worked to the angle by aid of the trowel and a chamfered slip of wood, used as a gage; or secondly, by the employment of a core, the print of which is represented by the dotted lines terminating at the angle *d*, Fig. 834; or thirdly, by having a loose slip on the pattern sliding on the line *c*, Fig. 834, so as to be drawn off when the top A had been lifted

This last method is analogous to that represented in Fig. 836, also intended for a sliding-rest, and which might be cast in a two-part flask, if the two chamfers *c c* were fitted loosely upon slides, as shown; but a three-part flask is more convenient, as explained by Fig. 837, in which the pattern is inverted

837.



836.



The lowest piece C, or the drag, is parted upon the line 1 1, but its sand extends upwards between the two sides of the pattern, as shown by the shade lines. The middle piece B is parted through the line 2 2; and lastly A, the top, is filled up level, the runner-stick at *r* being inserted at the time; A is first lifted, and all the pattern is then removed, excepting the chamfered bars and their slides, which are represented black; this pattern delivers its own cores for the circular mortises *m m*, the sand forming them being a part of that in B, or the middle flask; lastly, B is lifted, and the chamfer-slips are picked off from C. This pattern may consequently be moulded without turning over the flask, and every part of the mould is quite accessible for repair.

The pedestal of the swage-block, is another good example of moulding in a three-part flask. The model is made with the upper fillet loose, also with the sides solid, or without the holes, and the object is moulded as it stands. The top part of the flask opens at the upper moulding, and which latter is then removed from the pattern; the middle flask divides at the plinth or flange, so that when this has been lifted, the pattern also may be withdrawn, leaving a square pedestal of sand, as large as the interior of the model, standing upon the bottom part or drag, as in Fig. 837. The panels are made by means of a core-box, of the kind Fig. 814: the box is exactly as thick as the metal to be cast; and the circular cores are then fixed upon the pedestal of sand by means of a few wires or nails, after which the flask is put together, ready for pouring.

If the casting here referred to, had four fluted columns at the four angles, either with a large cap to each, or with a square entablature connecting the whole of them, the object might be also cast in one piece, if moulded in a three-part flask. After removing the top flask, the entablature and capitals would be first withdrawn, the columns being divided through their *smallest* diameters; the mould would be then turned over, and upon lifting off the drag, or bottom piece, the remainder of the pattern could be drawn, either in one single piece, or if the pillars were loose, the five parts could be more safely extracted; the three-part mould would be put together again, and reversed for pouring. In this general manner, by making either the mould or the pattern, or both, in different pieces, and by the judicious employment of cores and drawbacks, objects apparently the most untractable are cast with very great perfection.

The iron-founders are likewise very dexterous in making castings in some respects different from the patterns from which they are moulded: thus, if the pattern be too long, or that it be temporarily desired to obliterate some few parts, the mould is made of the full size and *stopped-off*, additional sand being worked into the mould, by aid of the trowel and some temporary piece of wood, to represent the imagined termination of the pattern. On the other hand, any simple enlargement or addition is not always added to the pattern, but it is frequently *cut out* of the mould with the trowel, in a similar manner.

Many common works, such as plates, gratings, parts of ordinary stoves, and simple objects, are made to *written* measures, and without patterns, as a few parallel slips of wood to represent the margin of the casting are arranged for the purpose upon a flat body of sand, which is modelled up almost entirely by hand; but for all accurate purposes and for machinery, good and well-made patterns are indispensable, and to some particulars of which a little attention will be now devoted.

Remarks on Patterns for Iron Castings.—The construction of patterns for iron castings requires not only the observance of all the particulars conveyed, but in addition, the large size of the models, the peculiar methods employed in moulding them, and the nearly inflexible nature of the iron castings when produced, call for some other and important considerations; and which should not be entirely overlooked, even in works of comparatively small size, or it may lead to failure and disappointment.

Thus, it becomes necessary to make patterns in some degree larger than the intended iron castings, to allow for their contraction in cooling, which equals from about the ninety-fifth to the ninety-eighth part of their length, or nearly one per cent. This allowance is very easily and correctly managed by the employment of a *contraction-rule*, which is made like a surveyor's rod, but one-eighth of an inch longer in every foot than ordinary standard measure. By the employment of such contraction-rules, every measurement of the pattern is made proportionally larger without any trouble of calculation.

When a wood pattern is made, from which an iron pattern is to be cast, the latter being intended to serve as the permanent foundry pattern, as there are two shrinkages to allow for, a *double* contraction-rule is employed, or one the length of which is one quarter of an inch in excess in every foot. These rules are particularly important in setting out alterations in, or additions to, existing machinery; the

latter is measured with the common rule, and the new patterns are set out, to the same nominal measures, with a single or double contraction-rule as the case may be, the three being made in some respects dissimilar to avoid confusion in their use; the entire neglect of contraction-rules incurs additional trouble and uncertainty.*

Patterns for iron castings are much more frequently divided into several parts than those for brass; for instance, the division into two equal parts, after the manner of Fig. 823, (but without reference to the under-cutting,) is very common, as both the pattern and flask separate when the top part is lifted, and the halves of the pattern can then be drawn out from the halves of the flask with much less risk of tearing down the sand.

Fig. 790, if small, would be moulded as represented, with false cores or drawbacks; but if it were a large fluted column, the iron-founder would employ a solid two-part flask; the shaded parts would together represent the body of sand in the drag, and the pattern would be made in *three* parts, something like a boot-tree. When the top flask had been lifted, the central slice of the pattern, extending from the two upper to the two lower angles, would be withdrawn vertically, and the two outer pieces would be released sidewise. The general rule is to divide the circumference of the pattern into six equal parts, and to let the central slice equal one of them in width.

The figures 835 and 837, representing two parts of a slide-rest, and the pedestal, are some amongst many of the common examples of the division of the patterns; and with which may be associated the numerous subdivisions of the mould instead of the pattern, by the employment of cores, many applications of which have been also explained. All these matters display much interesting and ingenious contrivance, resorted to either to render possible the operation of moulding, or to facilitate its performance.

To lessen the distortion of castings from their unequal contraction in cooling, it is important that the models should be nearly symmetrical. For example, bars or rods of all the sections in Fig. 789 may be expected to remain straight; perhaps *g* is the most uncertain, but if the lower fins of *e* and *h* were removed, their flat surfaces then exposed to the sand would become rounding or convex in length, from the contraction of the upper rib being unopposed by that of a similar piece on the under side. Bars and beams, the sections of which resemble the letter **I**, are of the most favorable kind for general permanence, and also for strength, and large panels may be cut out from their central plates to diminish their weight without materially reducing their stability. They are much used, not only in building, but also in the framing of machinery, which is in a great measure based upon the same general rules.

It is also of great importance, especially in castings of large size, that the *thickness* of the metal should be nearly alike throughout, so that it may cool at all parts in about the same time. Should it happen that one part is set or rigid, whilst another is semi-fluid, or in the act of crystallizing, there is great risk of the one part being altogether torn from the other and producing fracture. Or should the disturbing force be insufficient to break the casting, it may strain the metal nearly to its limit of tenacity or elasticity; so that a force far below that which the casting should properly bear may break it in pieces.

An example of this is seen in wheels with very light arms and heavy rims or bosses. The arms sometimes cool so quickly as to tear themselves away from the still hot rim or nave; or when the arms are solidified without fracture, the contraction of the rim may so compress the spokes endwise as to dish the wheel, (in the manner of an ordinary carriage-wheel,) and thereby strain the casting nearly or quite to the point of fracture. The arms are sometimes curved like the letter **S**, instead of being straight and radial; the contraction then increases their curvature with less risk of accident than to straight arms.† A more elegant way of avoiding the mischief was invented by Mr. Isaac Dodd, of the Horsley Iron Works, by placing the spokes as *tangents* to the central boss, in which case the contraction of the rim makes a small angular change of position in the boss; for the rim in thrusting the spokes inwards, causes the boss to twist round a little way with far less risk of fracture.‡

The destructive irregularity of thick and thin works is partly averted by uncovering the thick parts of the casting, or even cooling them still more hastily, by throwing on water from watering-pots. In wheels this has been done by a hose, the axis of which is concentric with the wheel, the arms being all the time surrounded by the sand to retard their cooling; but it is the most judicious in all patterns, to make the substance for the metal as nearly uniform throughout as circumstances will admit, so as not to require these modes of partial treatment, which often compromise the ultimate strength of the casting.

Another mode sometimes adopted for avoiding the fracture of wheels, from the great dissimilarity of their proportions, is by inserting *wrought-iron arms* in the mould, but they do not always unite kindly with the iron of the rim and the nave. The same inconvenience occurs when iron pins are inserted in the ends of either iron or brass castings, to serve for their attachment to their respective places. In iron castings it frequently produces the effect of chill casting, so as to render the works difficult to be turned or filed at the junction, and there is risk of the casting becoming blown or un-

* The contraction of brass is nearly three-sixteenths of an inch in every foot, but from the small size of brass castings the contraction-rule is less required for them, as the differences may be easily allowed for without it.

Iron castings weigh about fourteen times as much as the ordinary deal and fir patterns from which they are made, that being nearly the ratio of the specific gravities of those materials. All these matters are entered into in the pamphlet, "A New System of Scales of Equal Parts," and the paper "On a Scale of Geometrical Equivalents for Engineering and other Purposes," Lond. and Edin. Philos. Mag., July, 1838, wherein are described numerous applications of scales of equal parts to the purposes of drawing and calculation, and to the comparison and conversion of all kinds of measures, weights, and other quantities.

† It appears to be often desirable to supersede the straight diagonal braces of iron castings by curved lines, which are both more ornamental, and better disposed to yield to compression or extension by a slight alteration in their curvature.

‡ Mr. Dodd had to contend with the shrinking of the *nave*, which was the last to cool; the accidents therefore occurred from the tension, instead of the compression of the spokes; this equally fatal effect was completely remedied by placing the arms as tangents.—*Trans. Soc. of Arts*, vol. li. p. 66.

sound in either case. When the pins are heated before being placed in the mould, they become nearly cold before the metal can be poured, and they also endanger the presence of a little steam or vapor, which is detrimental; therefore they are more generally put in cold, notwithstanding the sudden check they then give to the fluid metal.

The patterns for iron castings of large size are necessarily very expensive, especially those for hollow cylinders and pans, many of which are so large that it would be impossible to find solid pieces of wood from which the patterns could be made; either with sufficient strength for present use, or with the necessary permanence or form for a subsequent period, as they would be almost sure either to break, or to become distorted from the effects of unequal shrinking. Such patterns, therefore, require to be made of a great many thin layers or rings of wood, each consisting of 6, 8, or 12 pieces, like the felloes of wheels, so that in all parts the grain may be nearly in the direction of a tangent.

As they are glued up, every succeeding layer is connected with the former, by glue and wooden pins or dowels, and the whole is afterwards turned to the tubular or hemispherical form, as the case may be. As the castings are generally required to be rather thin, such models are not only very expensive, but also very liable to accident; and besides, it frequently occurs that only one or two castings of a kind may be required, which makes the proportional cost of the patterns excessive.

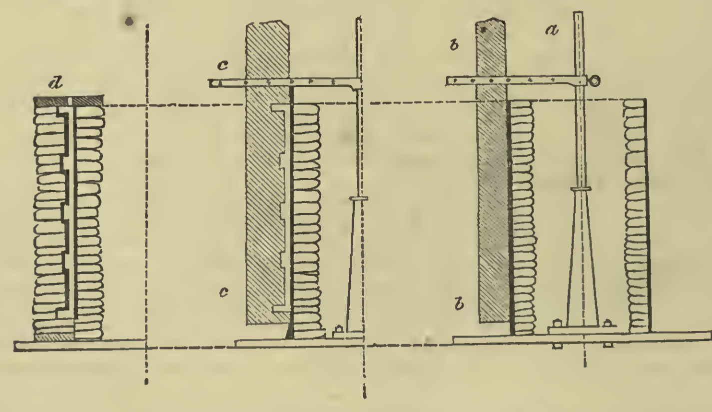
It fortunately happens, however, that this case, which is one of the most costly and uncertain by the employment of ordinary wood or metal patterns, becomes exceedingly manageable by a peculiar and simple application of the art of turning, (the one great centre of the constructive arts, to which these pages are intended immediately and collaterally to apply;) and by which process, or one branch of *loam moulding*, to be explained in the following section, patterns are not generally required.

Loam Moulding.—Figs. 838, 839, and 840, are intended to illustrate this process as regards a steam cylinder. Fig. 838 is the entire section of the mould in its first stage; Figs. 839 and 840 are the half sections of the second and third stages, preparatory to burying the mould in the pit in which it is to be filled.

The inner part of the loam-mould is called the *core* when small, but the *nowel* when large; the outer is called the *case* or the *cope*. Each part is built upon an iron loam-plate, or a ring cast rough on the face, and with four ears by which it may be lifted. The mould is occasionally erected upon four shallow pedestals of bricks for the convenience of making a fire beneath it to dry the loam; at other times it is made upon a low truck upon which it may be wheeled into the loam-stove, which is heated to about the temperature of 300 to 400 degrees Fahrenheit.

A vertical axis *a*, is mounted in any convenient manner, frequently in two holes in the truck itself, or as shown in Fig. 838, in a pedestal or socket erected upon the truck; at other times the axis is mounted in a hole in the loam-plate, and in any bearing attached either to the building, or its roof.

840. 839. 838.



The first step is to fix upon the spindle the templet *b b*, at the distance of the radius of the cylinder, either by one or two *clutches*, with various binding screws. An inner cylinder of brickwork is then built up, plastered by the hands with soft loam, (which is represented black in all the figures,) and scraped into the cylindrical form by the radius board, which is moved round on its axis by a boy. When the surface is smooth and fair it is thoroughly dried, after which it is brushed over with blackwash, and again dried. The charcoal-dust in the blackwash serves as a parting, to prevent the succeeding portions of the loam-mould from adhering to the first.

The templet *c c*, Fig. 839, cut exactly to the external form of the cylinder, is now attached to the axis at the distance from the core required for the thickness of the metal: some additional loam is thrown on to form the *thickness*, which is smoothed in the same careful manner as the centre, after which the templet and spindle are dismounted, and the thickness, which is represented white in Figs. 839 and 840, is also dried and blackwashed.

The ring for the outer case or cope is now laid down, and its position is denoted either by fixed studs or by marks; and the outer case represented in Fig. 840, is built up of bricks and loam, with an inner facing of loam worked very accurately to the turned thickness. The new work or the cope is also thoroughly dried, and afterwards lifted off very carefully by means of the crane and a cross-beam with four chains. This process likewise drags off the thickness, which usually breaks in the removal; its

remains are carefully picked out of the cope, both parts of the mould are repaired, and again blackwashed and dried.

When the cylinder requires *ports* at the ends, or the short tubes with flanges for attaching the steam passages, models of the tubes are worked into the cope, and are afterwards withdrawn; the cores are made in core-boxes, and are partly supported by the outer extremity, and partly upon *grains*, or two little plates of sheet-iron connected by a central wire, the whole being equal to the thickness of the metal at the part. When steam passages are wanted, either along the side, or around the cylinder they are worked up in clay upon the thickness, and duly covered in by the cope; their cores are supported, partly by their loose ends, and partly by grains, which become entirely surrounded by, and fixed in the metal, when it is poured.*

The mould is now put together in a pit sunk in the floor of the foundry, and the two iron plates are screwed together; the surrounding space being rammed hard to prevent the mould from bursting open, but the inner part is left much more loose for the escape of the air. The top edges of the mould are covered over with a *loam-cake*, (which has been previously made and dried,) or a ring three or four inches thick, strengthened with iron bars amidst the clay, the joining being made air-tight by a little cow's hair, and by the pressure of a quantity of iron weights; the loam-cake is generally perforated with many holes, as shown at *d*, for the entry of the metal and the escape of the air. But provision must always be made in casting thin cylinders, boxes, and such like forms, for the breaking up of the core as soon as the metal is set, to prevent the metal *scoring* or rending from its contraction upon a rigid, unyielding centre.†

Large pans, and various other circular works, are moulded precisely in the same way as cylinders, except that curved templets are used, and that towards the conclusion, the apertures through which the spindle passed are filled in and worked by hand to the general surface.

Water-pipes are made much in the same mode, but the cores for these are turned upon an iron tube pierced full of holes, which is laid horizontally across two iron trestles with notches, and is kept in rotation by a winch-handle at the end; there is also a shaper-board or scraper fixed parallel with the axis: this primitive apparatus is called a *founder's lathe*.

The perforated tube (serving as the mandrel) is first wound round with haybands, then covered with loam, and the core is turned, dried, and blackwashed; the thickness is now laid on and also blackwashed, after which the object is moulded in sand. The thickness is next removed from the core, which latter is inserted in the mould, and supported therein by the two prints at the extremities, and by grains with long wires, the positions of which may be seen by the little bosses on the pipe, the metal being there made purposely thicker to avoid any accidental leakage at those parts. When pipes are cast in large quantities, they are moulded from wooden patterns in halves, so that it only becomes necessary to turn the core; and this, when made in the above manner, is sufficiently porous for the escape of the air.

The moulds for crooked pipes and branches are frequently made in halves, upon a flat iron plate. An iron bar or templet of the curve required is fixed down, and a semicircular piece of wood, called a *strickle*, is used for working and smoothing the half core; next a larger strickle is used for laying on the thickness, the two halves are then fixed together by wires, and moulded from in the sand-flask; the thickness is now stripped off the core, which is fixed in the mould by its extremities, and if needful, is supported also upon grains.

By the employment of these means, although the loam-work requires time for the drying, yet with ordinary care an equality of thickness may be maintained, notwithstanding the complexity of the outline, and without the necessity for wooden patterns.

Very many of the large works in brass are also moulded in loam, the management being in most respects exactly the same as for iron, except that in some ornamental works wax is more or less employed, and is melted out of the moulds before the entry of the metal; a very slight view of the methods will serve as a sequel to the subject of brass-founding.

Large bells are turned in almost the same manner as iron cylinders or pans, by means of wooden templets, edged with metal, and shaped to the inner and outer contour of the core and thickness. The inscription and ornaments are either impressed within the cope, the clay of which is partially softened for the purpose, or the ornaments are moulded in wax, and fixed on the clay thickness before making the cope. Less generally the whole exterior face of the bell, or indeed its entire substance, is modelled in wax, and melted out before pouring. In any case, the concluding steps in filling up the apertures where the spindle passed, are to attach a dissected wooden pattern of the central stem and of the six *cannons* or ears by which the bell is slung, which parts are moulded in soft loam; and then, the parts

* There is always some uncertainty of the sound union of the grains, or other pieces of iron, with the cast-metal. Some cast them in iron and file them quite bright; others also tin them, apparently to preserve them from rust, as the tin must be instantly dissipated by the hot metal. Grains should always present clean metallic surfaces, and when used for very thin castings, to prevent them from dropping out, the wires are nicked with a file that they may be keyed in the metal. It is, however, better to avoid the use of grains, which may be generally done by giving the core *sand bearings*, and afterwards plugging up the holes in the casting.

† The largest cylinders, such as those of the Cornish pumping-engines, of 80, 90, and 95 inches bore, and 12 or 14 feet in length, and the blowing cylinders of blast furnaces, sometimes 105 inches bore, are made without the employment of the thickness. The case or cope is built up in the pit, and turned *inside*, with a radius bar, and the core is erected on a plate on the floor, and turned *outside* to a gage; when dried, it is lowered into the other by the crane. The cylinders are cast one foot or upwards longer than required, to serve as a head of metal and make the top edge sound, and thus much is cut off before they are bored.

To enable the mould to resist the great pressure of the lofty column of fluid metal, (equal at the base to near 60 pounds on every square inch,) the core is strengthened by diametrical iron bars entering slightly into the brickwork: the outer cylinder is surrounded at a small distance by iron rings piled one on the other, the interval being rammed with sand; and stays are placed in all directions from the rings to the sides of the pit, which is either lined with brickwork, or when liable to be inundated with water, it is made of iron like a water-tight caisson.

Small cylinders are moulded in sand from wooden models, and only the cores are turned in loam; for cylinders of the smallest size the cores are made of sand in core-boxes, as already explained.

having been dried and replaced, and the iron ring for the clapper inserted, the whole is ready for the pouring-pit. The heaviest bells are moulded within the pit the same as huge cylinders.

Brass guns are also moulded in loam, and in a somewhat peculiar manner; a taper rod of wood, much longer than the gun, is wound round with a peculiar kind of soft rope, upon which the loam is put for making the rough casting-model of the gun, which is turned to a templet; the work is executed over a long fire, to dry it as it proceeds, and the model is made about one-third longer than the gun itself. The model, when dried and blackwashed all over, is covered with a *shell* of loam, not less than three inches thick, secured by iron bands; the shell is also carefully dried; after this the taper bar is cautiously driven out from its small end, the coil of rope is pulled out, and so likewise is every piece of the clay model of the gun.

The parts for the cascable and trunnions, which should have been worked separately upon appropriate wooden models, are then attached to the shell. Should the gun have dolphins, or any other ornamental figures, they are modelled in wax and fixed on the clay model before the shell is formed, and are then melted out to make the required space for the metal.

When all is ready and dried, six, eight, or more of these loam cases, or shells, are sunk perpendicularly in a pit at the mouth of the reverberatory furnace, and the earth is carefully rammed around them; at the same time a vertical runner is made to every mould, to enter either at the bottom or not higher than the trunnion: the upper ends of the runners terminate in the bottom of a long trough or gutter, at the far end of which is a square hole, to receive the excess of metal.

In casting brass guns, tapping the furnace is rather a ceremony, and certainly an imposing sight: the middle and the end of the trough are each stopped by a shovel or gate held across the same; and the runners are all stopped by long iron rods, held by as many men. When all is pronounced to be *ready*, the stopper of the furnace is driven inwards with a long heavy bar swung horizontally by two or three men, and the metal quickly fills the trough; on the word of command, "*number one, draw*," the metal flows into the first mould, and fills it quickly but quietly from the bottom; the mould being open at the top, no air can be accidentally enclosed. Numbers two, three, and four are successively ordered to draw. The first shovel is then removed from the great channel, and now the guns, five to eight or ten, as the case may be, are similarly poured and filled to the level of the trough; after which the last shovel is withdrawn, and the residue of the metal is allowed to run into the square bed or pit prepared for it. The flow of metal from the furnace is regulated by the tapping-bar, the end of which is taper, and is thrust more or less into the mouth of the furnace as required; the trough and runners are thus kept exactly full, which is an important point in most cases of pouring, as it prevents a current of air being carried down along with the metal.

Large bells are poured much in the same manner, except that the runners are at the top, and the metal runs from the great channel, through smaller gutters, to every sunk mould, the stoppers for which are successively drawn. For quantities of brass intermediate between the charge of an ordinary crucible, and such as require the reverberatory furnace, the large ladles or shanks of the iron-founder are used; the contents of four or six crucibles being poured into the shank as quickly as possible, and thence in one stream into the mould.

The author of the article Founding, in the Encyclopedia Metropolitana, minutely describes three ways of casting large hollow statues, which are briefly as follows:

First; a rough model of the figure is made in clay, but somewhat smaller than its intended size; it is covered over with wax, which is modelled to the required form, or the wax is worked up in separate pieces and afterwards attached: various rods or cylinders of wax to make the apertures for the runners and air-holes, are fixed about the figure and led upwards. The whole is now surrounded with a coating of loam and similar materials, the inner portion of which is ground very fine and laid on with a brush, like paint; and the outer part is secured with iron bands. When all has been partially dried, a fire is lighted beneath the grating on which the figure is built, to cause the wax to run out through one or more apertures at the base, which are afterwards stopped, and all is thoroughly dried and secured in the pit, after which the charge of the furnace is let into the cavity left by the wax.

Secondly; the finished figure is modelled in clay, and stuck full of brass pins just flush with its surface, which surface is now scraped away as much as the thickness required in the metal; the reduced figure is now covered with wax mixed with pitch or rosin, which is worked to the original size with all the exactness possible. The other stages are the same as in the foregoing; the metal studs or pins prevent the mould and core from falling together, and they afterwards melt, becoming a part of the metal constituting the figure.

Thirdly; the finished figure is modelled in plaster, and a piece-mould is made around it, the blocks of which consist internally of a layer of sand and loam, 1½ inch thick, and externally of plaster one foot thick. The mould when completed is taken to pieces, dried, and rebuilt in the casting pit; it is now poured full of a composition suitable for the core, the mould is again taken to pieces, the core is dried and scraped to leave room for the metal, and all is then put together for the last time, secured in the pit, and the statue is cast.

The first plan is the most wasteful of metal; the third, the least so, although it is the most costly when the time occupied is also taken into account; but it has the advantage of saving the original work of the artist.

Melting and Pouring Iron.—Iron is usually melted in a blast-furnace, or, as it is more commonly called, a cupola; although the cupola or dome leading to the chimney, from which it would appear to have derived its name, is frequently omitted, the two or three furnaces being often built side by side in the open foundry.

At the basement there is a pedestal of brickwork about 20 to 30 inches high, upon which stands a cast-iron cylinder from 30 to 40 inches diameter, and 5 to 8 feet high; this is lined with road-drift, which contracts its internal diameter to 18 or 24 inches. The furnace is open at the top for the escape of the flame and gases, and for the admission of the charge, consisting of pig-iron, waste or old metal, coke and

lime, in due proportion. The lime acts as a flux, and much assists the fusion; chalk is considered to answer the best, but oyster shells are very commonly used where they are abundant.

At the back of the furnace there are three or four holes one above the other for the blast, which is urged by bellows or by a revolving fan. No crucible is used, and as the fluid metal collects at the bottom of the furnace, the blast-pipe is successively removed to a higher hole, and the lower blast-hole is stopped with sand, which partly fuses and secures the blast-hole very effectually.

The front aperture of the furnace through which the metal is allowed to flow into the ladles or trough, is usually made sufficiently large for the purpose of clearing or raking out rapidly the fuel and slag, as the process is most laborious, owing to the excessive heat. This aperture is closed by a *guard-plate*, fixed on by staples attached to the iron-case of the furnace, in the centre of which plate the tapping-hole is made: during the time the metal is fusing, the tap-hole is closed by sand well rammed in, and this if well done is never found to fail.

Many iron furnaces are made octangular, and in separate parts bound together by hoops, so that in the event of the charge becoming accidentally solidified in the cupola, the latter may be taken to pieces for its removal, and thus avoid the necessity of destroying the furnace. There is frequently a light framing or grating above the furnace, upon which the small cores are placed that require to be dried.

In some foundries the cupolas are built just outside the moulding shop, beneath one or more chimneys or shafts, which carry off the fumes; in such cases the fronts of the furnaces are accessible through an aperture in the foundry wall, with which they are nearly flush; when the furnaces are lofty there is a feeding stage at the back, from which the charge is thrown in.

For heavy iron castings, which sometimes amount to thirty tons and upwards in one piece, reverberatory or air furnaces are also commonly used; the ordinary charge for these is four to six tons of iron, and five or six furnaces are commonly built close together, so that they may be simultaneously tapped in the production of such enormous works.*

For melting iron in the small way, good air-furnaces may be used, and also some of the blacklead furnaces, which are blown with bellows, but this is one of the processes that is not successful upon a limited scale.

Considerable judgment is required in proportioning the *charge* for the iron furnace, which always consists of at least two, and often of half-a-dozen kinds of new pig-iron mixed together, and to which new iron, a small proportion of old cast-iron is usually added. The kinds and quantities used are greatly influenced by local and other circumstances, so that nothing can be said beyond a few general remarks.

When the principal object is to obtain sound castings with a very smooth face, as for ornamental works not afterwards wrought, the soft kinds of iron containing most carbon, which are most fusible and flow easily, are principally used. But such metal would neither possess sufficient hardness, durability, nor strength, for many of the castings employed in the construction of edifices and machinery.

If the cupola contained a little hard pig-iron, but were in great measure filled with old cast-iron, which had been repeatedly melted, and had become successively harder from the loss of carbon at every fusion, such castings would be brittle, and sometimes so hard as scarcely to admit of being cut; these would be equally unfit for the generality of machinery from the opposite causes.

But the same mixture of iron will be found to differ very much according to the size of the objects in which it is cast; iron, which in a plate one-fourth of an inch thick, may be quite brittle and hard, will mostly be of good, soft, and useful quality, in a stout bar or plate of two or three inches thick. Thick castings are necessarily slow in cooling, and are seldom very hard, unless intentionally made so.

Between the extremes, (say three parts of pig-iron to one of old, or three parts of old iron to one of pig-iron,) various qualities may be selected; in castings for machinery the general aim is to obtain a strong, sound, and tough iron; mixtures of this nature which are used for iron ordnance, are called gun-metal amongst the gun-founders.

The fireman, or the individual having the management of the furnace, therefore always employs the scales in mingling the different kinds of iron, according to the magnitude and character of the works to be cast; and until the sorts in use are familiarly known, it is partly a matter of trial, and requires the same attention as the making of alloys properly so considered.†

---

* A few of the modern cupolas greatly exceed the air-furnaces in effect, as they are calculated to contain upwards of twelve tons of melted iron. One of these, at the works of Messrs. Nasmyths, near Manchester, is six feet two inches diameter externally, and lined with Stourbridge bricks. It has three sheet-iron tuyeres, nine inches diameter at the mouth, the blasts from which enter the furnace at three points of the circle, and they may be slid like telescope-tubes to either of the four series of holes, as the furnace becomes gradually filled.

There are three other furnaces progressively smaller, arranged beside the first; all of which may be used separately or in combination, according to circumstances. The blast, which is under corresponding control, is obtained from two revolving fans, five feet diameter, making above 1000 revolutions per minute.

Messrs. Acramans, of Bristol, have likewise enormous cupola power; they have a series of four cupolas, in which collectively from forty to forty-five tons of iron may be melted at one time.

In some cupolas the top is contracted by a cone made of iron plate; in Yates's patent, a brick trunk is built upon the cupola, with narrow arches crossing the trunk at right angles: this economizes the heat by causing the flame and gaseous matters to be retarded, from pursuing a serpentine course in their escape.

† When the management of cast-iron was less efficiently understood, it was occasionally alloyed with five or six per cent. of shreds of copper, thrown into the ladle full of iron to produce a close, sound, strong metal, suitable to three-throw cranks for pumping machinery, and other purposes. It is said that ten per cent. of copper renders cast-iron malleable, and that alloyed with copper or tin it is less disposed to *rust:* all these alloys may be now viewed as matters of experiment alone.

It is much to be regretted that no protection has yet been found to prevent the conversion of cast-iron into plumbago, or the carburet of iron, from long immersion in sea-water, or the water of copper-mines, sewers, and other places. This, which is a most serious inconvenience in dock-works, sea-walls, and mines, arises, says Dr. Faraday, from the circumstance that the protoxide of iron, formed beneath salt-water, is soluble, and becomes washed away, thus robbing the original mass of its iron; whereas the peroxide, or ordinary rust formed by exposure to the air, is insoluble, and serves partly as a

When enough iron is melted, (the common charge being two and a half to four cwt., but sometimes above twelve tons,) the cupola is tapped in front, at a hole close to the bottom, which allows the whole contents to run out, either into ladles, or, in very large works, into channels leading directly to the moulds.*

In pouring iron, the means of conveying the melted metal to the flasks, differ with the quantity. One man will carry from fifty to seventy pounds in a hand-ladle; three to five men will carry from two to four cwt. in a double hand-ladle, or a *shank;* larger quantities, amounting sometimes from three to six tons, are carried in the crane-ladle. These all possess one feature in common, namely, their handles or pivots are placed but slightly above the centre of gravity of the ladles; they may therefore be tilted very readily, as their fluid contents, in obeying the law of gravitation, are almost neutral in the operation of tilting, which they scarcely assist or retard, unless by mismanagement the ladle is over-filled, and thus rendered top-heavy.

All these ladles are coated with a thin layer of loam, and every time before use, they are brushed over with blackwash, and carefully dried. The hand-ladle has a handle three or four feet long, with a *crutch* or cross-piece at the end, which is mostly held in the left hand; frequently the contents of half a dozen or more hand-ladles are poured simultaneously into the same flask. The shank has a single handle on the one side, and one made in two branches at the other, and together they measure six to eight feet in length; the tilting is completely under the command of the one or two men at the double handle.

The crane-ladle is carried from the furnace to the mould by the swinging and traversing motions of the crane, which is similar to those used at the iron-forges, &c., and in very large foundries, the plan of the building is divided into imaginary squares with a crane in the centre of every square, so that the ladle is walked from one to the other, even to the far end of the shop, with great facility and expedition.

The *bail*, or handle of the crane-ladle, is fixed in its perpendicular position by the *guard*, a simple bolt which prevents the ladle from being overset by accident until it has reached its destination. Two long handles, terminating in forked branches, are now fitted by their square sockets upon the swivels or pivots of the crane-ladle, and secured by transverse keys, after which the guard is withdrawn; and then two men at the ladle, two others at the crane, and one to skim the dross from the lip of the ladle, commonly suffice to manage two or three tons and upwards of fluid iron, with great ease and dexterity.†

The observations offered on page 250, respecting the temperature of the metal suitable to different brass works, might be here in a great measure repeated; namely, that the smallest castings require very hot metal, and a gradually lower temperature is more suitable to works progressively heavier, to avoid their becoming sand-burned or rough on the face, from the partial destruction of the mould.

When cast-iron is very hot, the metal scintillates most beautifully, far more vividly than a mass of wrought-iron raised above the welding heat; as the metal cools, the sparks become intermittent, and at last the metal remains entirely quiet, excepting a multitude of lines vibrating in all directions, as if the surface were covered with thousands of wire-worms in great activity; this effect lessens until the metal solidifies. The softest iron shows most of this play of lines, or is said to *break* the best.

Iron castings are generally much heavier than those of brass, and the melting heat of the metal being considerably higher, the quantity of gas generated is very much greater; additional care is consequently required to provide for its escape, or the explosions are much more violent. The sand is punctured at many places with a fine wire, before the removal of the patterns; sometimes also more coarsely as soon as the metal has become solidified. The gases issuing from the filled moulds are often lighted, either by the red-hot skimmer, or by a torch of straw with which the moulds are flogged: this lessens the accumulation of gas and the consequent risk of accident.

The pouring of very large objects in *open* moulds, such as plates, beams, and girders, is a very beautiful and grand sight. The metal is led from the furnace, through a gutter lined with sand, into a large trough or *sow*, the end of which is closed with a *shuttle;* when the sow is full, the shuttle is raised; this allows the metal to flow very quickly into the mould, but enables it to be kept back should it be unnecessarily hot; the castings made in open moulds are generally covered up with sand as soon as the metal is set.

The above, and the casting of smaller objects, such as flat plates in open moulds, may appear amongst the most certain modes of procuring sound castings; but unless the air be well *drawn* from the lower surfaces, they will become honey-combed or full of air-bubbles. This defect is avoided by making the sand-bed sufficiently porous, and pricking it with many holes just below the surface, to serve as horizontal *air*-drains.‡

---

defence to the metal beneath. When first raised from the sea-water, the plumbago becomes exceedingly hot from the action of the atmosphere; it may be cut with a knife like an ordinary pencil.—Minutes of Conversation, Inst. Civ. Engineers, 8th Feb. 1842.

* The furnace is not unfrequently tapped whilst the charge of metal is being melted, and in such cases when the required quantity has been removed into the ladles, the fireman restops the tap-hole by a conical plug of clay on the end of a wooden bar; the process is called *botting*, and requires a dexterous hand, or the whole contents of the furnace may escape.

† Mr. Nasmyth has added to the pivot of the large crane-handle, a tangent-screw and worm-wheel, by which it may be gradually tilted by one man standing directly in front at any convenient distance; and another man skims the metal by a kind of throttle-valve coated with clay, which sweeps into the lip of the ladle, and keeps back the sullage: the axis of the skimmer is continued as a long rod, at right angles to the first, and also terminating in a cross. By these arrangements any precise quantity of metal can be delivered, and the risk of accident scarcely exists.

‡ In casting lead, tin, &c. on a flat metallic plate, the formation of air-bubbles is lessened by placing a sheet of dry paper on the plate; it appears to keep down any little bubbles of air or vapor, and to provide a thin channel for their escape.

But the most perfect example of a porous mould is that invented by Lord Rosse, to avoid the formation of air-bubbles in those speculums which are cast in open moulds. The plate, or bed of the mould, consists of a great number of slips of hoop-iron placed edgewise and in contact; they are screwed tight within a frame, and are then turned in a

A far greater number of works are cast in *close* moulds, and in the horizontal position; the proportionate quantity of metal is carried to them in ladles: skimmers are held to the lips of the moulds at the time of pouring, to keep back all the sullage or dross. The number, position, and height of the runners, are determined by circumstances; generally not less than two apertures are provided, the first for the entry of the metal, the second for the escape of the air, and to allow the metal to *flow through* the mould and carry off the sullage.

Sometimes in heavy castings, in addition to the runners, one or more large heads or *feeds* are made at the upper part, to supply fluid iron as the metal shrinks in the act of solidifying; and in some such cases the feed is *pumped*, by moving an iron rod up and down in the feed to keep the metal in motion, so that for a time the metal may freely enter and the air escape, to increase the general soundness of the mass. The pumping should, however, be discontinued the moment the metal begins to stiffen and clog the iron rod, or in other words to crystallize, otherwise mischief instead of benefit will accrue.

Works which are required to be particularly sound, as some cylinders, pipes, shafts, and plungers, are cast vertically; the moulds are sunk in the earth, and well rammed to enable them to withstand the great pressure of the fluid column, without becoming strained or bursting open. Such objects are moulded and poured with a head, or an additional portion about one-third the length of the finished casting, as mentioned in respect to brass guns.

In pouring cylinders of tolerably large size, the metal is conducted from the sow through two sunk passages with side branches, entering the mould in the direction of tangents about one-third from the bottom; these keep the metal in circulation, and assist the rise of the sullage. Cylinders are also poured through holes in the loam-cake, other apertures being always provided in it for the escape of the air. Beneath the iron plate upon which the mould is built, is placed a central mass of haybands, in order that the air may have free passage to collect, and then to escape upwards to the surface of the earth, through one, two, three, or more internal or external tubes, as the case may be. The thick cylinders for hydrostatic presses are closed at one end, and those cast with the mouth downwards require an air-tube bent at each end, to lead from the core beneath the casting to the surface of the earth; the gas drives out in a stream, and is immediately ignited like a great torch: others prefer casting them with the mouth upwards, in order that less risk may exist of locking up air within the casting.

For the very heaviest works, the three or four furnaces are usually tapped at the same moment; the stream from every one is conducted through a sand-trough, and they all unite in one great trunk leading to the mould.

In pouring some of the largest cylinders, the trough is led entirely round the top of the loam-mould; and from the circular channel, sometimes as many as thirty runners, every one of which is stopped by a shovel held by a man or a boy, descend to the mould, and as many air-holes are made between the ingates. When the foreman sees that all the furnaces are in full run, and that the channels are well supplied, he gives the word, "*up shovels;*" they rise at the instant, and allow the molten stream to deposite itself in its temporary resting-place.

At the time the cylinder is poured, all the precautions explained in the note, p. 257, are necessary to give the mould sufficient strength to resist the pressure of the fluid metal; but as soon as it becomes set, the conditions are altered, and this resistance must be removed from the inner surface, that the cylinder may shrink, in cooling, without restraint or fracture. Accordingly, after three or four hours' time, all the diametrical iron stays are knocked away by a vertical weight or monkey, and men descend by iron ladders into the cylinder, to break down the brick core. The heat is so terrific, that they can only endure it for a minute or so at a time, but still the precaution is imperative: and even in comparatively small castings of hollow objects, such as cylinders, pans, and boxes, it is desirable to break down the cores, to prevent the castings from *scoring* or breaking.

Although some iron castings employed for bridges, girders, and even for machinery, require the enormous quantities of iron referred to, on the other hand this useful metal is employed for exceedingly light and beautiful castings, abundant examples of which may be seen in the Berlin ornaments and chains.* The links of most of the Berlin chains are connected with wrought-iron wire, but Figs. 841, 842, represent a chain made entirely by the process of casting.

---

lathe to the required curve; by this arrangement interstices exist at nearly every point through which the air may escape downwards.

Speculum metal is perhaps the most untractable of any of the alloys, and it serves to illustrate in a most striking manner many of the effects that occur in castings generally. Small speculums are cast in sand; as soon as they are set, the sand-core is pushed out of the aperture, in such as are intended for Gregorian telescopes, to enable them to contract without fracture, and the red-hot disk is surrounded by ignited wood-ashes or any very bad conductor, to delay the cooling.

These precautions entirely fail with large speculums, as their margins solidify the first, and from the absence of ductility, the central parts tear away in the act of contraction, and the mass becomes rent or flawed. Lord Rosse considered this fracture would be avoided by cooling the speculums in *uniform layers* from below upwards, or as it were in infinitely thin laminæ, and he therefore first employed iron moulds which were cooled by a stream of water projected against their under surfaces; this partially answered with small speculums, but with those of 18 inches diameter it almost always failed, as the mould cracked before the metal was congealed. A general source of failure was the non-escape of air; this caused the lower surface to be full of air-bubbles, which it was tedious to grind out.

The plan ultimately adopted was the porous hoop-iron mould, with a marginal ring of sand; the mould was heated to about 212° F.; it was filled very quickly, and the moment the metal was solidified, it was drawn into an annealing oven previously heated to about the same temperature as the casting; so that for small reflectors of nine inches diameter, the cooling might be extended over about three days, and for large ones of thirty-six inches diameter, over about fourteen days; with these precautions the process was uniformly successful.—*See* Trans. Royal Soc., 1840, pp. 510, 11. The whole of the paper "On the Reflecting Telescope," pp. 503 to 527, is quite a study for those interested in the construction of telescopes, and possesses nearly the same interest for the general mechanist.

* We have seen some of these gems of art in the condition in which they left the moulder's hands, and also a portion of the sand employed: notwithstanding the minute size of the castings, some of them are quite hollow, as if stamped out of thin steel metal.

Professor Ehrenberg says, that the iron employed for them is made from a bog-iron ore, and that the sand is a kind of tripoli, also containing iron: both are entirely constituted of various kinds of animalcules, several of which are found,

Its length is 4 feet 10 inches, it consists of about 180 links, and weighs 1$\frac{5}{8}$ oz. avoirdupois. It was thus made; the larger links *a a* were first cast separately; a solid model of the chain about eight inches long, with core prints, as in fig. 842, was then moulded; the links *a*, previously smoked to prevent the adhe-

sion of the metal, were first laid in the mould, and afterwards the sand-cores *b b*, and a separate runner was made to every one of the small links *c c*, so as to unite the whole when poured.

CEMENT. See Mortar.

CENTRES. See Bridges.

CENTRE OF GRAVITY. The forces with which all bodies tend to fall to the earth may be considered *parallel;* hence, every body may be considered as acted on by a system of parallel forces, whose resultant may be found; and these forces, in all positions of the body, act on the same points in the same vertical direction. There is, therefore, in every body a point, through which the resultant always passes, in whatever position it is placed. This point is called the *centre of gravity* of the body. The centre of gravity of a uniform cylinder or prism is in its axis, and at the middle of its length; of a right cone or pyramid it is also in the axis, but at one-fourth of the height from the base.

To ascertain mechanically the position of the centre of gravity of a body (Figs. 843, 844). Suspend the body by a string from the point Q (fig. 843), and let Q R be the direction of the line when plumb; now the only forces by which the body is acted on are the weights of its different parts and the tension of the string; the former may be replaced by their resultant. Since the body is in equilibrium, the resultant and the tension must act in opposite directions, and in the same straight line Q R. But as the resultant must always pass through the centre of gravity, the centre of gravity must be in the line Q. R. Mark the direction Q R, and suspend from another point P. The centre of gravity, by similar reasoning, must be

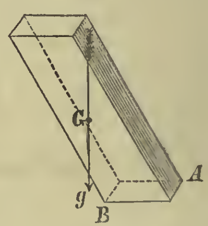

Fig. 846.

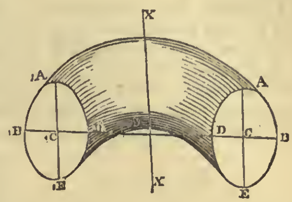
in the line P M, and can only be, therefore, at the intersection C of the two lines. Or, balance the body upon the edge of a bench till it be just on the point of falling off; then mark a line along it by the edge of the bench; do the same in another position of the body, and the centre of gravity in the body will be in a line and perpendicular to the point of intersection. The centre of gravity of a straight line lies in its middle. For bodies whose points are regular and the substance homogeneous, the centre of gravity is determined by certain geometrical rules. The centre of gravity of a cylinder is evidently the middle of its axis; and whenever a body possesses a *centre of figure*, *i. e.* a point so situated that every plane which can be conceived to pass through it must bisect the body, this point is the centre of gravity (supposing the body to be of uniform density). Moreover, whenever a body has an *axis* of figure, that is, a *line*, every plane passing through which bisects the body, then the centre of gravity must be somewhere in that line. Consequently, when the body has more than one such axis, the centre must be found at their intersection. Every *pyramid* or *cone* has its centre of gravity at $\frac{1}{4}$ of its height, from the base,—every *paraboloid* at $\frac{1}{3}$ of its height,—every *hemisphere* or *hemispheroid* at $\frac{3}{8}$,—a *hemicylinder* at ·4244 of its radius from the axis of the cylinder. To find the distance of the centre of gravity of any *segment* of a *disc* or *cylinder*, from the axis, divide the cube of the chord by 12 times the area of the segment. To find the same in a *sector*, multiply twice the chord by the radius and divide by three times the arc. The centre of gravity is not necessarily *in the body*, but may be in some adjoining space. This is obviously the case with a *ring*, an *empty box*, and, in general, any hollow vessel.

Centrobaryc theorem, or *Method of Guldinus.* These centres of gravity of lines or surfaces (which can be found approximately by experiments on thin wires or plates) afford an easy means of solving certain useful problems in mensuration, the solution of which deductively (or by pure mathematics) would be extremely difficult, if not impossible. For instance, any *solid of revolution*, however complex or irregu

lar its outline, may have both its solidity and its superficial contents found by the following very simple methods. Let 847 be the solid, and ABDE its half sections, or that plane figure which, in revolving round the line AE as an axis, would require a space equal and similar to the solid—or, as it is commonly expressed, would *generate the solid.* Cut out this figure in some thin substance of uniform thickness, and by suspending it as above described, find its centre of gravity, which we will suppose to be C. Now the volume of this solid is equal to the product of the area ABED + into the circumference described by the point C, (which circumference will of course be found by applying the well-known multiplier, 3·14159, &c. to twice the distance of C from the axis *c*. Again, to find the *surface* of the solid or of any portion of it, as formed by the revolution of the whole or any portion of the curve ABED, bend a wire into the form of that portion required. Find its centre of gravity, then the surface generated by the revolution = its length + the path described by its centre of gravity. A body, when placed on a horizontal plane, will fall over unless the vertical line passing through its centre of gravity fall within the base; thus in Fig. 845, the body will stand firmly, whereas in Fig. 846 it must manifestly tumble over Persons who carry loads adjust their position so that the common centre of gravity of the load and of the body shall fall within the area bounded by their feet. The lower the centre of gravity, and the more extended the base, the more stable the position of the body, and the more difficult to be overturned.



CHAIN, in surveying, is a lineal measure, consisting of a certain number of iron links, usually 100, serving to take the dimensions of fields, &c.: at every tenth link is usually fastened a small brass plate, with a figure engraved upon it, or else, cut into different shapes, to show how many links it is from one end of the chain.

CHAIN CABLE. Iron cables were first proposed as a substitute for hempen cables by Mr. Slater in 1808, but they were first employed by Capt. Brown of the W. I. Service, in 1811. It was at first supposed by the inventor, that a certain degree of elasticity must be given to the chain cable, so that a sudden strain should not break it. With this view the links of the chain were twisted about half way round, so that when the strain took place, the links by yielding a little, or partly untwisting, might produce an effect somewhat similar to the natural elasticity of hemp. It is found, however, that when a certain length is let out, the weight of the long catenary curve affords an elastic tension, or play to the ship, under the pressure of the wind. The dead strain upon the anchor is thus reduced, and sudden strains upon the flukes or arms, thus in a great measure obviated. The best iron cables are chains made of links, bound and braced by rods across the middle. It is found that the ends of the links wear out much quicker than the sides, and they are therefore made considerably stouter at the ends than in the middle. Mr. Hawkes, iron manufacturer, patented an invention in 1828, for thickening the ends of the links at the point where the greatest friction, and wear takes place. The improved links are formed from cylindrical bars, formed either by rolling, swageing, or stamping with projections or swells placed at such distances on the bar, as to come exactly opposite each other when the bar is turned into a link, by which means the ends are made thicker than the sides. The best form of links is an oval with a broad headed stay in the middle, to prevent it from collapsing or shutting up, under a heavy strain. Another advantage of this stay is, that it prevents the different links from entering each other, and thereby entangling the cable.

As it is frequently necessary to sever the cable, provision is made for the purpose, by means of a bolt and shackle at every one or two fathoms, so that by striking out the bolt the cable is parted with ease. See Proving Machine.

The accompanying is a table of the breaking proof of chain cables, and of the iron used in their construction.

CHAIRS. See RAILROADS.

CHARCOAL. See IRON.

CHIMNEYS. See BOILERS.

CHISELS. See CUTTING TOOLS.

CHRONOMETERS. See WATCHES.

CHAIN PUMP. A machine for raising water; it consists of a series of pistons or round plates of metal, set at certain and regular intervals on an endless chain, which nearly fit the calibre of the tubes in which they work. Putting the chain in motion, supposing the bottom of it to dip into the water of a well, each piston will enclose above it a certain quantity of water, and bear this water to the top, where it overflows into a cistern prepared to receive it.

CHAMFER. An edge or arris, taken off equally on the two sides which form it, leaves what is called a chamfered edge. If taken off more on one side than the other, it is said to be splayed or bevelled.

CIRCULAR SAWS. See SAWS.

CIRCULAR SAW *for Cutting Veneers.* The object of this machine is to cut up logs of fine wood into slices or leaves for purposes of veneering. From ten to sixteen of these slices may be cut from an inch of wood; and considering that the logs are from 9 to 36 inches broad, some idea may be formed of the nicety of the operation, and of the steadiness and rigidity of parts required in the machine for the efficient discharge of its functions.

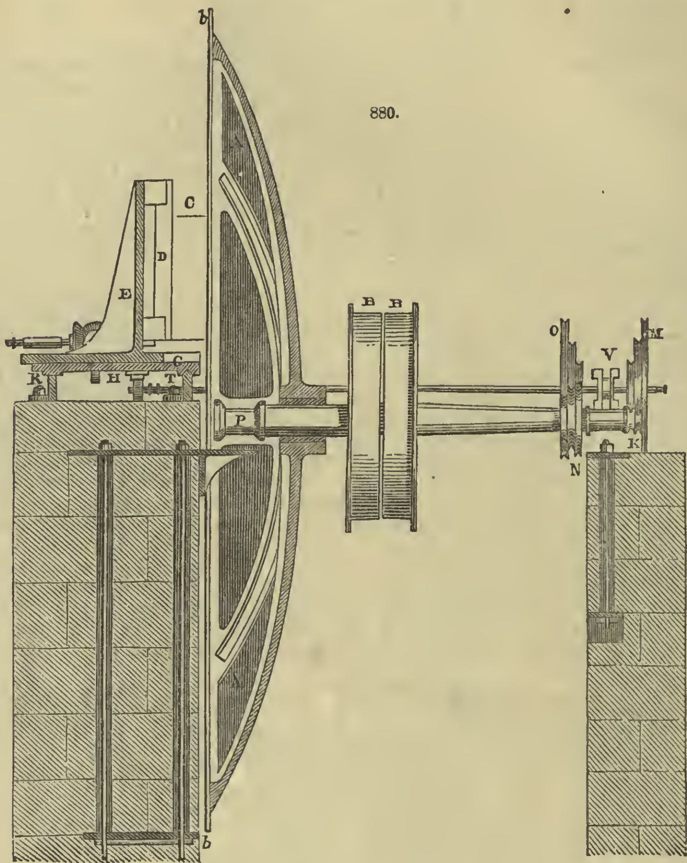
The principal feature of the machine is a circular saw, marked *bb* in the cuts, which is built in segments upon a strong, rigid, cast-iron frame A, which, it will be observed from the sections and the plan, consists of a series of arms radiating from a central eye, dished in form, like an ordinary carriage-

wheel, and flanged on the hollow side, to secure rigidity; these arms terminate in a broad, flat ring, upon which the segments of the saw are fastened by means of short countersunk screws, as exhibited in Fig. 882. The saw-frame, as it may be termed, is hung upon a strong shaft P, which runs in bearings located on wall-plates, secured to a foundation by holding-down bolts. Upon the same shaft are hung the driving-pulleys B B, whence the motion of the machine is derived.

While the axis of the saw-frame remains stationary during the operation of the machine, the log of wood C, which is being cut up, is urged forward against the saw by a gradual progressive motion, being fixed for the purpose on a sliding carriage D E G, moved by a self-acting apparatus.

First of all, the carriage runs upon two parallel rails T R, bedded on two longitudinal square tim-

880.



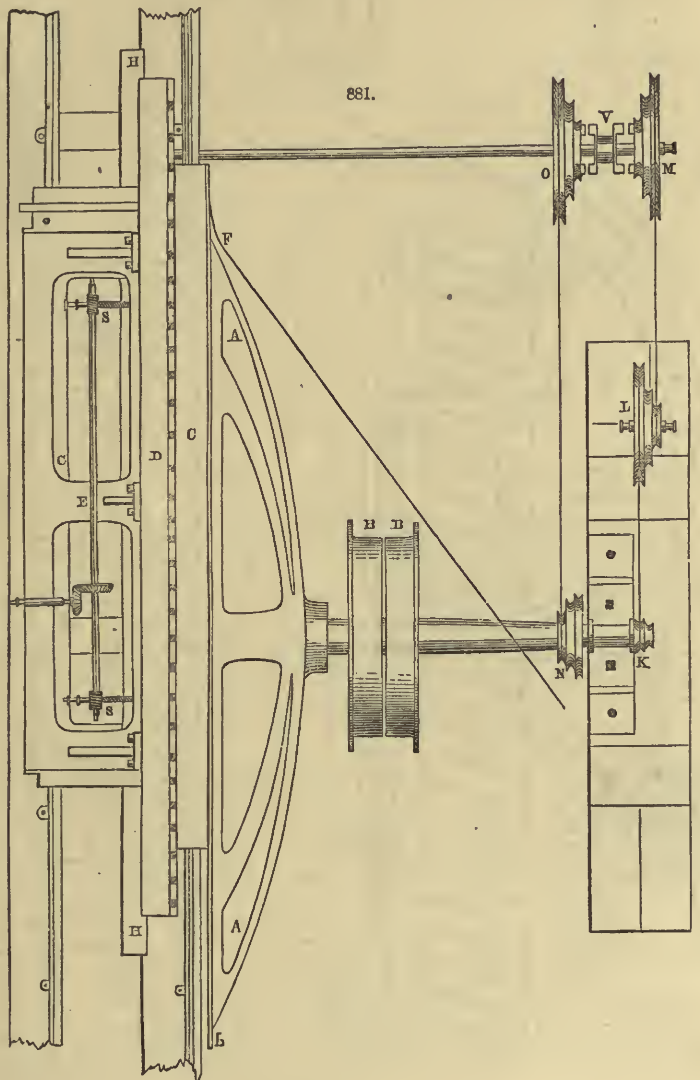
bers, and firmly bolted down to them. The lower part of the carriage G, slides on these rails at three surfaces of contact on each rail, as may be seen in Fig. 882. The upper part of the carriage E is held down to the part G by means of dovetail bevel surfaces, where a broad piece of metal is introduced between the snug cast on the end of the piece G and the bevel edge of the piece E, and bolted down to G, thereby holding down the piece E to G—admitting also of a transverse sliding motion of the piece E; (see Fig. 882.) From the piece E, three flanged arms are erected, to which is bolted the timber frame D, on which is immediately sustained the log C. The frame D consists of two longitudinal square timbers, the lower one of which, as shown in Fig. 880, rests upon short flanges projecting from the faces of the arms of the piece E, and is thus prevented from sliding down; these timbers are connected by a series of spars, checked at both ends into the timbers. The spars are finished flush on their exterior surface, on which they receive the log C, which adheres to them by means of a film of glue interposed. The spars are set at an inclination backwards, as they are thus more directly in the line in which the strain comes upon them.

The self-acting motion for moving the sliding carriage, and thereby feeding the saw, is driven from the main shaft. A rack H fixed on the under side of the carriage, is driven by a pinion on the end of the horizontal shaft T, Fig. 880, upon which the triple-grooved pulleys M O run loose, ready to be catched alternately by the sliding-clutch V. The pulleys M are driven by the pulleys K on the end of the main shaft, the motion being reduced by means of the intermediate pulleys L. The pulleys O are driven directly by the pulleys N on the main shaft. The pulleys K L M are those which feed the saw, the band K L crossing itself, and L M being an open band. The pulleys N O reverse the motion

of the log-frame, and carry back the log to prepare it for a succeeding cut. Three different speeds are provided in these pulleys.

The motion for feeding the saw transversely—that is, for shifting the log in the direction of its breadth, in setting it for another cut—is effected by the screws S S, the bearings of which are fixed on the sole G, and their screwed parts working in nuts fixed on the piece E. On these screws, worm-wheels are fixed, driven by worms on a horizontal shaft, which again is driven by hand, by means of a pair of small meter wheels—all which is represented in the plan, Fig. 881. The lateral motion of the piece E is directed by the bevel surfaces between which it is confined.

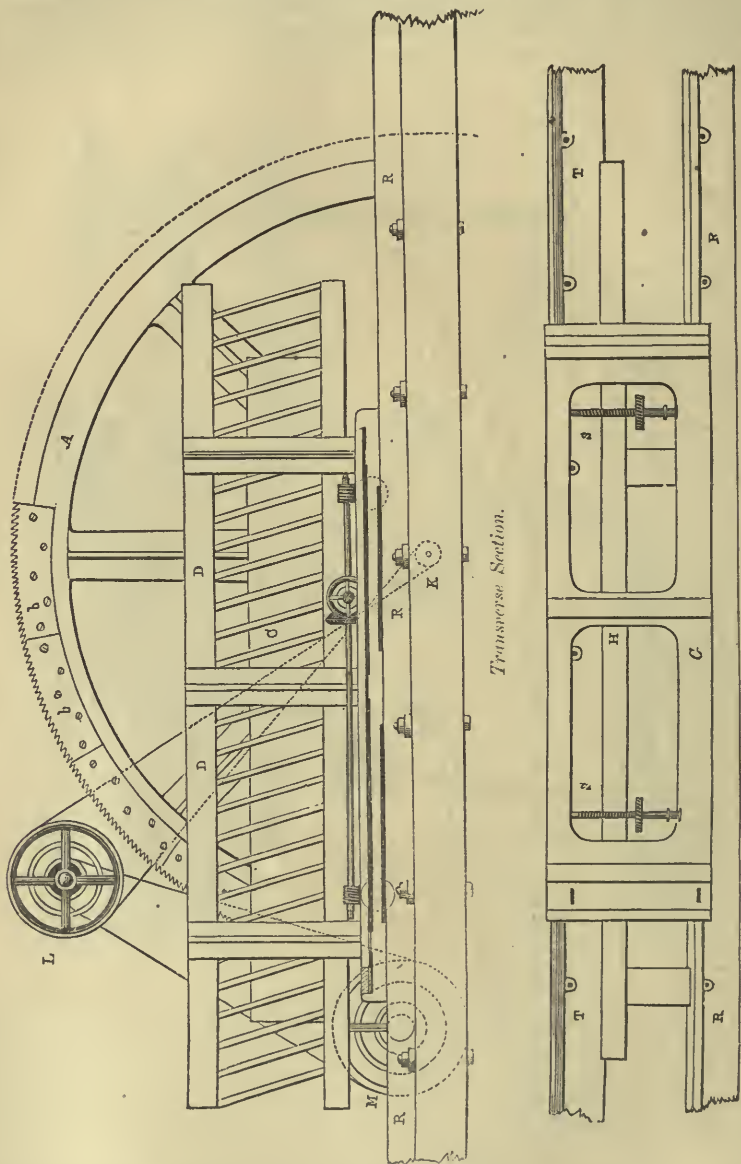
881.



Action of the Machine.—The log being fixed to the frame D E, and the end of it adjusted in contact with the edge of the saw, by means of the longitudinal and transverse sliding-surfaces already described, the clutch V is geered with the pulleys M, the driving-bands being shifted to the proper speeds. The driving-belt is then shifted to the driving-pulley B, and the saw is caused to revolve at a high speed, the self-acting motion at the same time urging forward the log. The veneer, as it separates, glides off the back of the saw-frame, as shown at F in Fig. 881, and, when cut off, is carried away. The clutch V is then reversed into geer with the pulleys O: thus the motion of the sliding-carriage is reversed, and the log is returned to its first position in front of the saw. The clutch is then entirely disengaged, and the transverse motion is applied to the frame D E, by which the log is shifted in front of the saw, in readiness for the next cut. The clutch V is now engaged with the pulleys M, and the process is repeated as already described.

The speed at which the saw is driven is about 180 revolutions per minute, which with a diameter of twelve feet, gives a velocity of 6784 feet in that unit of time. The feed-motion for that velocity is about ¾ inch for every revolution of the saw, making 11¼ feet per minute of veneer cut. The feed-motion is, however, modified according to the quality of the log under operation: often it does not exceed a half of that stated; and in some mills the velocity of the saw is also less.

882.



Transverse Section.

Plan of the Lower Carriage.

Lateral References.—A, the saw-frame, with the saw *b b* attached to it.
B B, the fast and loose pulleys on the saw-frame shaft.
C, the log which is to be cut into veneers.
D, the timber-frame to which the log is attached.
E, the cast-iron frame to which D is bolted, which slides laterally under dovetail surfaces.
F, the veneer as it comes from the saw, gliding off the saw-frame.
G, the lower part of the sliding-carriage, which slides longitudinally on rails laid on timbers.
H, the rack attached to the sliding-carriage, and driven by a pinion on the shaft of the feeding apparatus.

K, grooved pulleys on the end of the main shaft, for driving the feed-motion.

L, intermediate pulleys, driven by the pulleys K.

M, pulleys loose on the pinion shaft, driven by the pulleys L.

N, pulleys on the main shaft, for reversing the motion of the log.

O, pulleys loose on the pinion shaft, driven by the pulleys N.

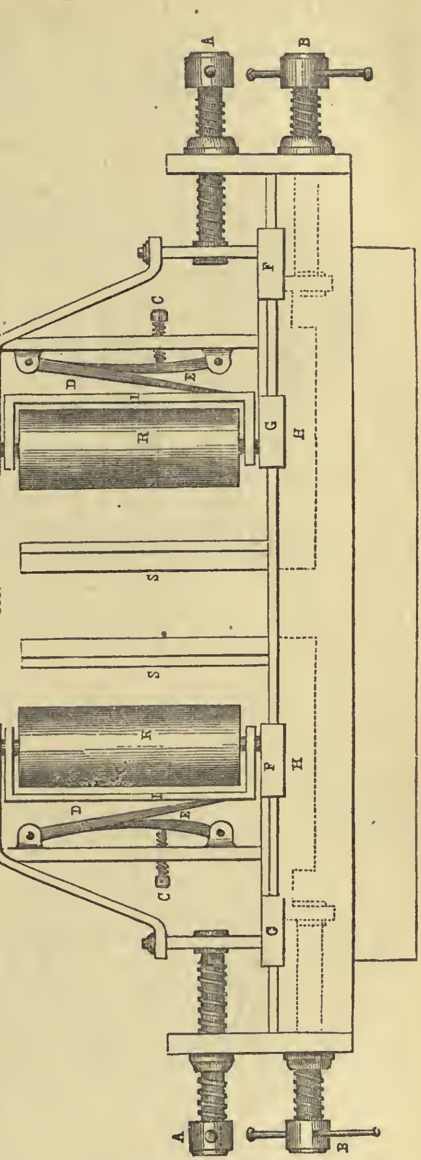
P, the saw-frame shaft.

R T, longitudinal slides on which the sliding-frame is moved.

S, screw and wheel motion for shifting the log-frame laterally.

V, the clutch carried round with the shaft on which it slides, so that it may be put in geer with the loose pulleys M O, alternately.

Saw-mill Rollers for Planks.—Fig. 883 represents an arrangement for steadying the planks or logs as they are moved forward in saw-mills.



883.

A A, are adjusting-screws, working in nuts fixed on the frame of the machine, for setting the roller-frame against the logs.

B B, are adjusting-screws for setting the plank-frame H S.

C C, pinching-screws, acting by the intervention of levers upon the rollers.

D D, levers jointed to the roller-frame, transmitting the pressure of the screws C C to the rollers.

E E, spring-levers intermediate between the screws C and the levers D.

F G, F G, the soles of the roller-frames, guided in their traverse motion by dovetail surfaces upon H H.

H H, the plank-frames, into the ends of which are inserted the screws B B.

I I, clutch-frames, through which the journals of the rollers pass; they transmit the pressure of the levers D D to the rollers.

R R, the rollers which press the planks against the uprights S S, and steady their motion; the ends of their journals move in grooves in the framing F G, F G.

S S, uprights rising from the plank-frames H H, against which the planks are held by the rollers.

CLOTHING BOILERS AND CYLINDERS, *saving fuel from.* See MANAGEMENT OF ENGINES.

CLOTH-SHEARING MACHINE. Invented by Milton D. Whipple, of Lowell, Mass., for shearing cotton cloth, or preparing it for being printed.

Fig. 884 denotes a top view of the machine; Fig. 885 is an elevation of one side of it; Fig. 886 is an elevation of the other side of it; Fig. 887 is a central vertical and longitudinal section of it; Fig. 888 is an elevation of the front end; and Fig. 889 is an elevation of the rear end.

The machine to be described is calculated to remove from the surface of calico or cotton cloth the furze, nap, knots, or other matters which are usually taken off by the process of picking by hand, and singeing by hot rolls or plates, or the flame of gas.

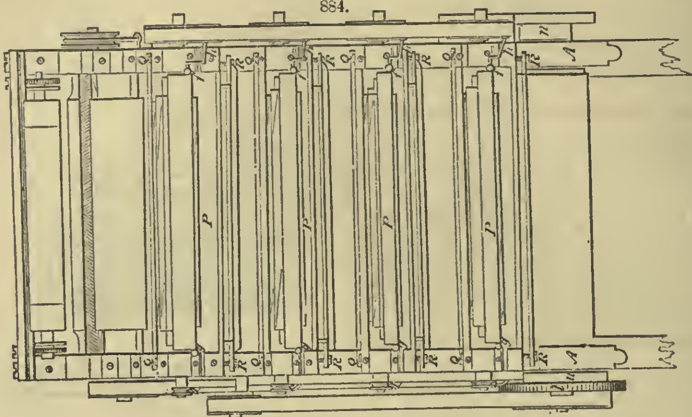
Mr. Whipple does not confine his invention to the shearing of cotton cloth alone, as it may often be used to good advantage on many other thin cloths, such as mouslin de laine, for instance.

In the drawing, A denotes the frame-work of the machine constructed of iron, wood, or any other suitable material; B is the driving-shaft extending across the frame, and made to run in proper boxes; C is a fast pulley, and D a loose pulley arranged on the shaft, motion being given to said shaft by the belt, from the driving power being made to operate on the fast pulley; E F G H are four series of revolving helical shearing-cutters applied to, or arranged respectively on horizontal shafts I K L M, whose journals are supported in boxes N N N, &c. Beneath each of these series of cutters is one of a series of blades or horizontal knives O O O, &c., which is attached to a head-piece or holder P. The ends of the said head-piece have adjusting-screws Q R, Q R, applied to them in such manner as to admit of the correct adjustment of the holder P, and blade O, with respect to the rotating helical cutters over and in advance of them. At some distance in front of each of the blades O O, is a rule or ledge S, whose

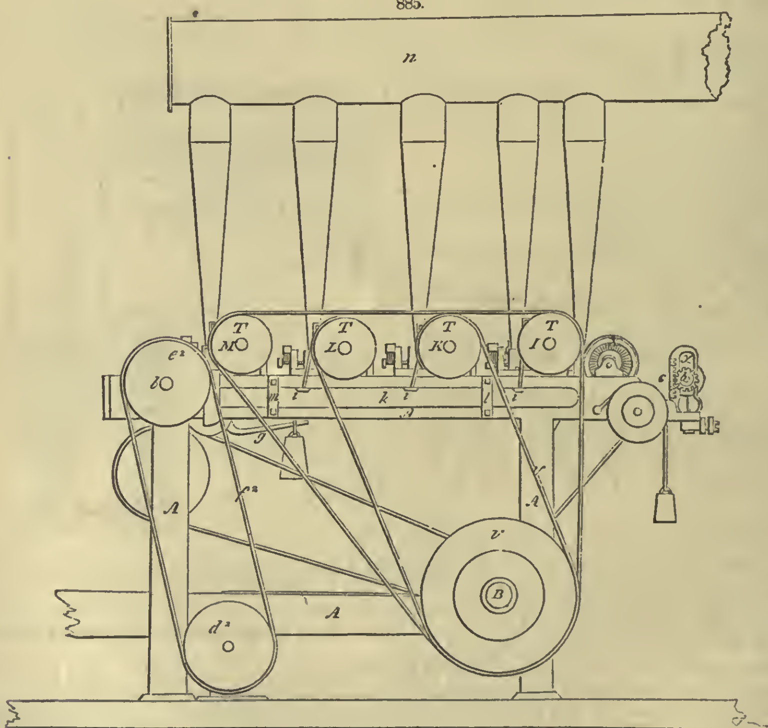
upper edge is placed somewhat above the under surface of the knife or blade O; the position of said rule S, and the top of it with respect to the cutters and blades, being as seen in the drawings. Each of the series of revolving cutters has a pulley T fixed on it. There is a driving-pulley V on the driving-shaft. A belt V passes around the said pulley V, and the two middle pulleys T T, as seen in Fig. 885. It is by means of the said pulleys and belts, that the several series of helical cutters are put in revolution.

A cylindrical brush X is placed in advance of the first rule S, and so as to bear against the cloth Y

884.



885.



as it passes from the under surface of a friction-roll on cylinder Z to the top of the first rule S; the said brush is revolved by a belt, which passes around two pulleys b c, the former of which is fixed on the driving-shaft, and the latter on the shaft of the brush x. In the rear of each blade O, and between it and the rule or ledge S, directly in rear of it, is a long transverse horizontal brush z, which rests on the cloth, and removes any superfluous lint, and lays the nap of the cloth as it passes underneath in the proper direction to be acted upon by the cutters in rear of it; e and f are a pair of drawing-rollers arranged at the rear end of the machine, as seen in Fig. 887. The lower one has its journals sustained

in boxes, applied to the ends of two weighted levers *g*, H, by the action of which it is pressed against or towards the upper roller.

The upper roller has a geer-wheel *i* fixed on its shaft; the said geer-wheel is made to engage with a toothed pinion K fixed on a shaft *i;* on said shaft *i* is a pulley *m*, around which a band *n* passes to a pulley O fixed on the driving-shaft. By means of the pulley, belt, and geers, the upper drawing-roller receives the motion.

A stretching-bar P is arranged at the front end of the machine, and directly over the roller *z*. The upper edge or surface of the bar has grooves or flutes made diagonally across it, those on the side of the centre of the bar being caused to run in a direction opposite to those on the other, as seen in the figures, the object of this bar being to stretch the cloth in lateral directions.

When the cloth first enters the machine, it passes over a cylindrical rocking-bar *q*, (see Fig. 888,) which is supported, so as to rock or vibrate laterally on a post *r*, made to rise upwards from a transverse bar S. From the centre part of each end of the bar, one of two rods or journals *i u* projects, as seen in Fig. 890, which denotes a vertical and longitudinal section of the bar, and parts connected with it. On each of the journals one of two pulleys *v w* is placed, and revolves; each of said pulleys being of a diameter corresponding to that of the cylindric bar *q*. The external curved surfaces of the pulleys are made rough by having sand-paper, or sand or emery glued to them, and each of said pulleys has a neck or hollow shaft *x* extending from it, and through a vertical groove *y*, made in one of two plates or standards *z a*. A small geer-wheel *b* is fixed on each hollow shaft *x;* the said geer-wheel being made to engage with a vertical toothed rack *c*, affixed to the standard, as seen in Figs. 885 and 886. The peculiar object of the said rocking-bar and mechanism applied to it, is to cause the cloth, as it rises up from the pile on the floor, to be delivered centrally upon the front series of helical cutters; or in other words, so that one of its selvages shall be at the same distance from the adjacent end of the series of cutters as the opposite selvage is from the end thereof adjacent to it.

The length of the rocking-bar is made equal to, or somewhat greater than the width of the piece of cloth: when the piece is drawn through the machine by the action of the drawing-rollers, it is made to pass over the rocking-bar. If either selvage or edge of the piece, while so in motion, should happen to project at any time beyond the contiguous end of the rocking-bar, and upon the surface of the adjacent pulley *v* or *w*, it will cause said pulley to turn on its journal; the consequence of which will be, that the toothed pinion *b* will be made to revolve by it; which motion of the pinion will cause it, by its connection with the rack into which it goes, to rise upwards and tilt the rocking-bar into an inclination to the horizon, thereby inducing the cloth to move laterally on the rocking-bar, or towards the pulley at its opposite end. Should it by chance run over the last pulley, a contrary action will occur, and the rocking-bar will be tilted in an opposite direction, and so as to induce the cloth to slide or move towards the other pulley. The apparatus is thus self-acting, and operates with all the desired regularity and precision to introduce the cloth centrally into the machine.

Directly over each of the series E F G H of revolving helical cutters is an oiling apparatus, which consists of a strip of cloth *d*, affixed to a long bar *e*, whose ends have journals which are supported and move in the tops of posts or standards *f* G. One of the journals of each of the bars e^1 e^1, &c., has an arm *h* extending downwards from it, and passing through one of a series of staples *i i*, &c., driven into a long slide-bar K.

This slide-bar is sustained by bearings *l m*, fastened to the side of the frame A, and its rear end rests against a cam *n*, fixed on the shaft of the upper driving-roller. The said cam during part of its rotation forces the slide-bar forward, and longitudinally, in such manner as to move all the arms *h h* simultaneously, and thereby cause all the strips of cloth to rise above their respective series of cutters. The retraction of the bar may be effected by a spring properly applied to it, the said retraction causing all the strips of cloth to descend upon the cutters. Each strip being saturated with oil, will, when it is carried in contact with the knives or cutters, lubricate their edges.

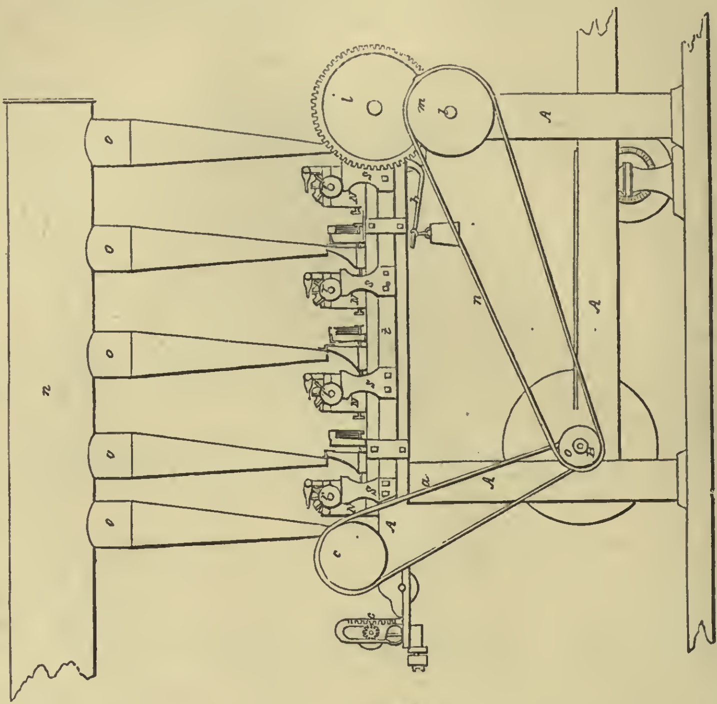
The next portion of the machine to be described is that by which the lint and extraneous matter, removed from the surface of the cloth by the helical cutters, are taken from the machine. For this purpose is placed above the frame A, a large pipe or hollow cylinder or vessel *n*, one end of which should be stopped up while the other should connect with an air-exhausting apparatus of some proper kind.

From this pipe others, O O, &c., extend downwards, and open respectively in vertical, triangular, or other proper-shaped vessels P P, each of which is placed respectively just in rear of the cutters and rotary brush, and is open at bottom, and shaped and made as seen in the drawings.

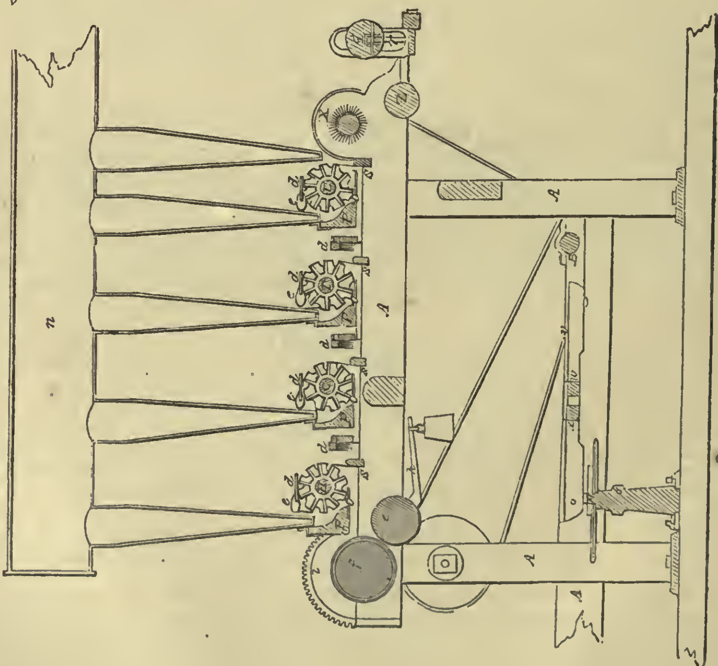
Each of the bars to which the blades O O, &c., are attached is curved upwards, as seen at *q*, so as to direct the lint and the conductors P P. Now when air is drawn out of the pipe *n* by the exhausting apparatus, an atmospheric current will rush up each of the vessels and pipes extending downwards from it. In the passages of said currents into the adjutages of the conductors P P, and through the same, and pipe O, they will carry with them the lint and extraneous matters removed by the cutters and rotary brush.

In order that the cutters may perform their operation on the cloth in a proper manner, a reciprocating lateral movement as well as a rotary movement may be given to them: this is effected in the following manner.

On each cutter-shaft is a grooved pulley r^1, into the groove of which the upper end of one of four vertical plates S S, &c., is inserted, the said plates being secured to a horizontal slide-bar *t*, which is arranged and operated by a cam, and a retracting spring, in substantially the same manner as is the slide-bar K, hereinbefore described. The upper end of each of the plates S is bent out of parallelism with the side of the frame A, as seen in Fig. 884. Now when a reciprocating rectilinear movement in a longitudinal direction is imparted to the slide-bar *v*, and plates S S, the pressure of the plates on the slides of the grooves of the pulleys *r r*, &c., will cause the various series of cutters during their revolutions to move back and forward laterally.

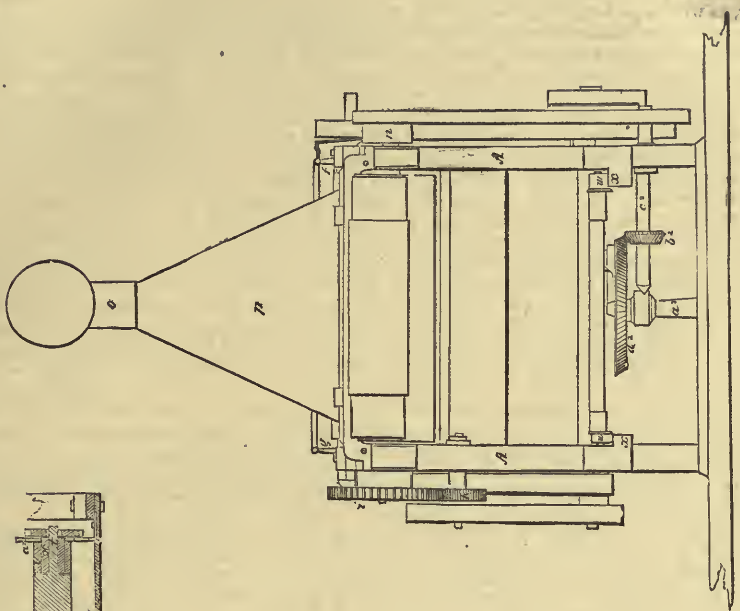


886.

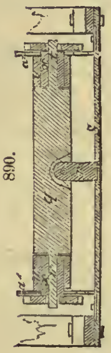


887.

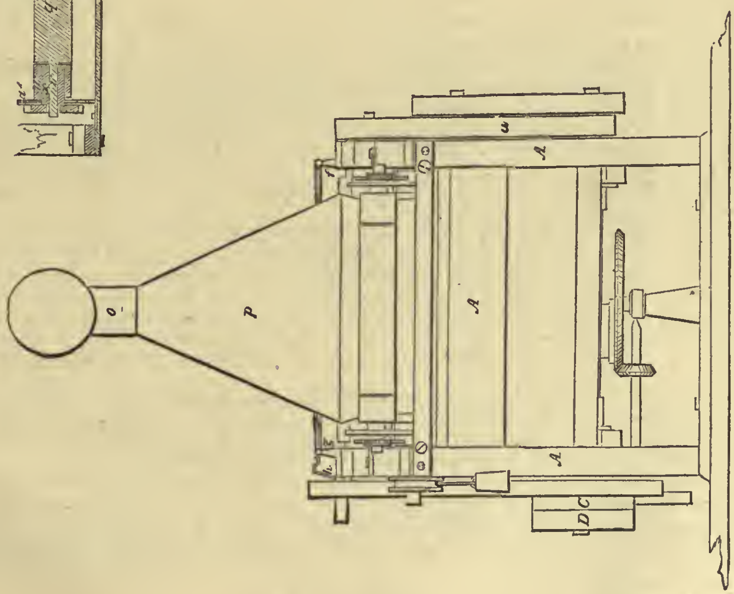
888.



890.



889.



Two straight bars d^2 e^2 are arranged at the front end of, and transversely across the machine, and parallel to one another; one of them, viz. d^2, being fixed firmly in position while the other is made adjustable, or has adjusting-screws or other proper contrivances applied to it for the purpose of regulating its distance from the other bar.

The cloth is passed and moves between these bars, they being adjusted at such a small distance asunder, as will be just sufficient to allow the cloth to pass between them, while no knot or picker-wires or other extraneous substances which would be likely to injure the cutters, present themselves in the cloth.

When such matters exist on the cloth, and are carried in contact with the bars, they will either be removed by the draft on the cloth, or they will stop the motion of the cloth until they can be removed by an attendant.

The next and last portion of the machine to be described is the folding apparatus, which consists of a platform V, supported on two rails X X, by four or any other suitable number of wheels W W. The said platform or carriage should have a reciprocating rectilinear motion imparted to it in a longitudinal direction by suitable mechanism. That employed is as follows:

The carriage has a long plate of metal W secured transversely to its under side; through the plate a long slot X is cut, into which one end of a crank J is inserted, the crank being made to project from the top of a vertical shaft z, which turns in proper bearings of a post or standard a^3, supported on the floor on which the machine rests. On the shaft is a bevelled geer a^2, which engages with a bevelled pinion b^2, which is fixed on a horizontal shaft c^2, which has a pulley d^2 secured to its outer end around this pulley, and a pulley e^2 fixed on the shaft of the upper draw-roller to the carriage V, by said pulleys e^2, d^2, belt f^2, shaft c^2, geers b^2, a^2, and crank y and slot x acting together. The constant fore and back movements of the carriage causes the cloth, as it passes from between the draw-rollers, to be laid on it in regular folds. The manner in which the cloth is passed through the mechanism is seen in b 3 at Fig. 887.

It has been found from experience that the cloth is much better sheared when subject to the action of several series of rotating helical cutters, arranged and operating together as above, than it is when successively subjected to the action of one revolving series of such cutters.

The process of shearing, besides being performed much quicker by two or more series of rotary cutters and their adjuncts, as above specified, is more easily performed, and with less liability of injury to the texture or thread of the cloth.

By reference to the drawing, it will be seen that the position of the top edge of each of the ledges S, with regard to the bottom of the cutters or cutting-blade O, is such that the cloth, after passing over the top of said ledge, is by the ledge borne up against the under side or edge of the blade O, and so that the fur or nap which is to be removed is carried against the edge of the plate, and is cut off by the action of the revolving cutters. Consequently, should there be any knots, motes, or foreign substances projecting from the upper surface of the cloth, they will be removed by the upper surface and blade, and without injury to the cloth.

If the cloth passed directly over a ledge or rest placed under the cutters, as in machines for shearing broadcloths, cassimeres, &c., or thick and long-napped cloths of like character, it would be constantly liable to be cut into strips or otherwise injured.

By doing away with the rest, the cloth has the opportunity of falling, moving, or springing away from the blade when any very large knot or extraneous substance is presented to it and the cutters. The manner in which the cloth is borne against the under surface of each of the blades O, viz. by means of a ledge or rule S, or any equivalent in rear of each blade, we may dispense with the swing-bar which is used in the machine of Courlier to bring the cloth up to the blade, it being subject to the same objections as in the rest.

The machine of Courlier is described at page 8 of Traité Théorique et Pratique de l'impression des Tissus, par J. Persoz, tome deuxieme, Paris, 1846.

Mr. Whipple claims for his invention the manner of supporting the cloth during the performance of the cutting operation, viz. by the under side of the blade O of each of the series of cutters in combination with two ledges S S, or other mechanical equivalents whose upper edges shall be arranged in a plane with or a little above the said blade; the same enabling him not only to dispense with a rest such as in common shearing machines, but with the swing-bar used in the machine of Courlier.

He also claims the combination of two or more series of helical cutters E F G H, blades O O, &c., guide-rules S S, &c., and drawing-rollers as arranged, and operating together substantially as above specified.

Mr. Whipple also claims the apparatus by which the cloth is received at the front end of the machine, and caused to pass centrally into it or towards the cutters. Said apparatus being a combination of a rocking-bar, two pulleys, and two great pinions and racks or any mechanical substitute, the whole being arranged and made to operate together substantially as described.

Mr. Whipple further claims in the machine's combinations with the shearing machinery, the apparatus arranged over it for the purpose of removing the lint by upward currents of air as described; and the reciprocating carriage or moving platform for folding the cloth, in combination with the shearing machinery, the same being arranged and made to operate substantially as above explained; and the set of parallel bars d^2, e^2, as combined with and applied to the shearing mechanism in manner and for the purpose before described.

COAL. Charcoal will be found treated of in the article Iron.

* *Brown Coal* includes all that coal which does not form coke, and is younger, or of a more recent formation than bituminous coal or anthracite. As good fuel can be had abundantly, at reasonable, and even low prices all over the United States, there is no inducement to use this inferior mineral. All of it, which is either found in bogs, in alluvium, or in tertiary rock, is generally very impure, brittle and damp,

* Overmann's Metallurgy.

and with very few exceptions, perfectly useless in its raw state for any of the operations we have under consideration.

Bituminous Coal. Under this class we range all that mineral coal which forms coke; that is, it swells up on being exposed to heat, burns with a bright flame, blazes, and, after the flame disappears, there remains a spongy, porous mass—coke,—which burns without flame like charcoal. We also range under this class of coal the Nova Scotia coal,—the Frostburg coal of Maryland,—Richmond, Virginia, coal,—some North Carolina coal,—the coal of all the western fields belonging to the Mississippi valley,—the coal in Oregon and in California. There are, indeed, coal beds in these localities which are closely allied to either anthracite or brown coal, but we confine our classification to that kind which alters its form on being exposed to heat. The only points which claim our attention, are the chemical composition and the form of the coal.

In its composition we find chiefly carbon, oxygen, hydrogen, nitrogen, sulphur, and ashes, with a little water, which has been absorbed by the crevices. The following table shows the comparative composition of various sorts of mineral fuel.

Table showing the Composition of

	Carbon.	Hydrogen.	Oxygen and Nitrogen.	Ashes.
Turf	58·09	5·93	31·37	4·61
Brown coal	71·71	4·85	21·67	1·77
Hard bituminous coal	82·92	6·49	10·86	0·13
Cannel coal	83·75	5 66	8·04	2·55
Coking or backing coal	87·95	5·24	5·41	1·40
Anthracite	91·98	3·92	3 16	0 94

Quantity of Heat. The most important point, and one which has a direct bearing upon the value of coal, is the quantity of heat, which it can evolve in combustion. If we assume that the quantity of ashes is equal in the four substances mentioned below; that is, 5 per cent. in each, and suppose further, that pine charcoal furnishes 100 parts of heat,—the following table shows the quantity of heat which must be liberated in their perfect combustion.

Kind of coal.	Carbon.	Hydrogen.	Water.	Quantity of heat.
Brown coal	69	3	23	78
Coking coal	75	4	16	87
do	78	4	13	90
Anthracite	85	3	7	94
Pure Carbon	100	–	–	100

Quality of Heat.—The degree of heat which may be produced by coal of the above composition, on the supposition that pure carbon produces 4420°, is, in the first 3890°; in the second 3945°; in the third 3999°; and in the fourth 4142°. These results imply, of course, perfect combustion; that is—neither too much, nor too little oxygen is present. But this is practically almost an impossibility; therefore, these degrees of heat never can be realized, although the quantity may be.

If one ton of pure carbon is considered to be worth one dollar, the same weight of anthracite is worth 94 cents, that of soft, or bituminous coal, from 85 to 90 cents, and that of brown coal only 78 cents. In the valuation of coal we must consider the quantity of ashes as well as the quantity of water. The loss of heat occasioned by water does not depend merely upon the quantity; it is occasioned also by the conversion of it into steam; whereas the loss of heat from ashes is in direct proportion to their quantity, although not, perhaps, in all cases. The ashes of mineral coal consist generally of silex, clay, gypsum, iron pyrites, oxide of iron, lime, magnesia, and often chlorine and iodine.

Anthracite. This is the most important of all the class of mineral fuel, for metallurgical operations in this country, although not in other parts of the world. Pennsylvania anthracite is not only abundantly distributed in the eastern part of that State, but its great purity, and solid form, adapt it particularly to the use of the smelter and operator in metals. The chemical composition of anthracite is similar to charcoal, from which it differs chiefly in its form, being very hard and compact, and in the greater quantity of ashes which it contains. It is, like charcoal, unaltered in form after exposure to the strongest heat; even after passing through a blast furnace, it has equally as sharp edges, and is in form exactly as it was before. The following table presents the composition of some of the anthracite of Pennsylvania.

	Composition.			
Locality.	Carbon.	Volatile matter.	Ashes.	Specific gravity.
Lehigh coal, Summit mines,	88·50	7·50	4·00	——
Schuylkill coal, Tamaqua mines,	92·07	5 03	2 90	1.57
Pottsville,	94·10	1·40	4·50	1·50
Pinegrove,	79·57	7·15	3·28	1·54
Wilkesbarre, Luzerne Co.	88·90	7·68	3·49	1 40
Carbondale, " "	90·23	7·07	2 70	1·40

The ultimate analysis of anthracite shows it to be composed of 90·45 carbon, 2·43 hydrogen, 2·45 oxygen, some nitrogen, and 4·67 ashes. Another specimen of Pennsylvania anthracite was composed of

94·1 carbon, 2·39 hydrogen, 87 nitrogen. 1·33 oxygen, and 1·3 ashes. The ashes generally consist, like those of bituminous coal, of silex, alumina, oxide of iron, and chlorides, which generally evaporate and condense on cold objects in the form of while films. Some of this coal contains considerable quantities of sulphur, which is chiefly found in the fine parts and slack, in consequence of the coal having been broken into lumps of uniform size before use, and, because the sulphureous parts are the most brittle and slaty.

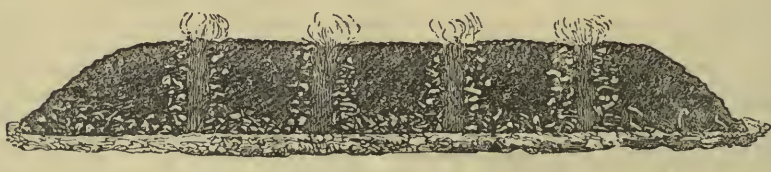
Anthracite is not so inflammable as either dry wood or bituminous coal, but it may be made to burn quite as vividly as either, by exposing it to a strong draught, or in a large mass, to the action of air. This absence of flame in this coal, arises chiefly from the lack of solid, heated particles in the gases, and as transparent hot gas does not radiate heat, no matter what may be its temperature, it has been found that the anthracite flame does not heat the hearth of a reverberatory so well and so quick, as bituminous coal or flaming wood. This evil can be remedied by applying a blast under the grate of a furnace. Thus fine particles of coal are carried over by the hot gases, and the flame so formed radiates heat as well as that of any other fuel. It is manifest, that the pressure of blast, or the force of the current of air, which is to tear loose these particles of coal, must be in proportion to the refractory nature of the coal. If the draft is too strrong these particles will be too large, and therefore be deposited on the hearth where the current has not sufficient strength to keep them suspended; their effect is thus lost. If the particles are extremely small and the furnaces so constructed as to retain a lively current, their subsidence is prevented. A large grate is, in this instance, more suitable to form a good substantial flame than a small one, for a gentle draught in it will produce only small particles, while a strong blast tears off large ones which are of little use. Sometimes the ashes which are formed by anthracite and deposited in the flues, or on the hearth, are a cause of objection. This evil, if it cannot be entirely obviated, can at least be greatly modified by increasing the surface of the grate.

COCKS. See Faucets.

* Coking of Coal. An essential condition in forming coke is that the coal, on being heated, swells and changes into irregular spongy masses, which adhere intimately together. This operation is designed to expel sulphur and hydrogen, and form a coal which is not altered by heat. The sulphur cannot be entirely separated from coke, or from carbon, no matter how high the heat may be; neither can all the hydrogen be removed from carbon by simply heating the compound. If oxygen is admitted to these combinations, both sulphur and hydrogen may be almost entirely expelled, that is, provided the oxygen is not introduced under too high or too low a heat.

Coking in the open air. When coal abounds in sulphur, as well as bitumen and water, the best mode of coking it is in rows or clamps; that is, in a long pit or heap, a section of which is represented in Fig. 891. The length of such a heap may be from 20 to 100 feet, or, in fact, it may have any length;

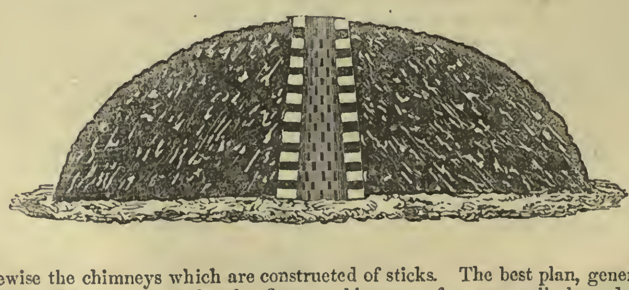
891.



but its width must not exceed from 6 to 12 feet. If the coal is very impure the heaps must be narrow, but if it is hard and pure, it may be charred in wide rows.

In a row, such as is represented above, the coarse coal forms the skeleton of the heap inside, and at distances of 8 or 12 feet, a kind of chimney is constructed with it. If coal coarse enough for the purpose cannot be had, a flue is constructed of loose fire-brick on the floor, over the whole length; this forms an air channel. Chimneys are erected of bricks in the proper places, as shown in Fig. 892. Sometimes, especially where wood is cheap, a longitudinal channel, and also cross channels are formed

892.



with it, and likewise the chimneys which are constructed of sticks. The best plan, generally, is to form air-channels through the bottom and also the flues or chimneys, of coarse well-charred coke; these do not swell; they hold good fire, and cause no loss—for what is burned in one kind of coal is saved in the other; besides, this method furnishes the best coke. One of these long heaps of coal is from 3 to 5 feet high, according to the kind of coal; it consists of coarse coal, covered by small coal and, at last, by slack.

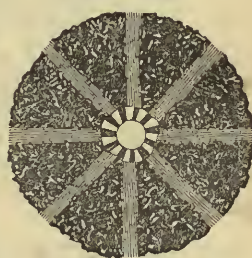
* Overmann's Metallurgy

Fire of wood or burning coke is applied to the foot of the pile, at such distances as will secure a uniform distribution of it and in the very vicinity of the flues which lead to the chimneys, as these are most suitable to conduct it into the interior. One end of a pile may be kindled, burn and even be finished while the other end is building; thus coke may be formed in a short time. The collier must aim to conduct the fire into the interior as quickly as possible, and heat from within outwards; in fact this operation must be done on the same principle as in charring wood. But, since stone coal is less valuable than wood, and as a higher heat is required to drive off impurities, and also more fresh air, and moisture to expel sulphur; the burning coal must necessarily be worked more openly, and under a more brisk heat, than wood. When the fire is well spread through the interior of the pile, and its progress is safe, the sides of the row are covered by coke-dust, but the base and top are kept free, so as to admit of a lively combustion and a strong heat. In fact, a large quantity of air, and if possible damp air, is required at this time to pass through the coal, if good coke is expected to be made. After the lapse of 24 hours, more or less, the heat is well distributed and the flames on the comb of the pile disappear, and hot invisible gases only escape. The pile is now closely covered with coke-dust, and left to cool: this requires another 24 hours, so that in two days' time, the coke is burned and ready to be drawn.

Coarse coal fresh from the mines is best suited for this mode of coking. It should be adopted in all cases where the coal is impure, and a good article is required; for, by no other method than this, can so good coke be obtained. Other modes will furnish more coke from the same amount of coal; but good coal is required to make coke strong and pure, such as is suitable for iron smelt furnaces. The foregoing method cannot be used when the coal is fine, that is, when it consists mostly of slack coal, because such coal is too close and does not admit of the passage of air sufficiently to form good coke. It is often charred by mixing it with small wood, chips, or bushes bound in faggots, but this is expensive, and where wood is scarce cannot be resorted to. The coal then is charred in large heaps, or pits, like wood. Such a pit may be from 20 to 25 feet in diameter, and from 3 to 8 feet high, according to the quality of the coal.

A strong chimney of fire-brick is erected in the centre, affording many flues which lead to the interior of the mass. It is built very open and without mortar. On the floor there should be a series of channels in a radial direction, as shown in Fig. 893. These are formed of coarse coal, or, which is better still, of large lumps of coke, so as to be always open. Flues of fire-brick do answer the purpose, but are not so favorable to the quality of coke as coke channels. These and the floor are covered with the coarsest coal which the mine affords, and when it is exhausted fine coal is spread over them to a height of 2 feet or more, according to its quality. Fire is now applied to the flues at the circumference, and urged to a uniform and lively state. A dense smoke issues at first from the top of the chimney. This soon ceases, and a white flame of carburetted hydrogen takes its place. Within two or three hours, the smoke and some fire appears at or near the top of the coal, which indicates that the fire is well spread in the interior. The remainder of fresh small coal is now gradually thrown on, but in such a manner that the heat is not checked. Some smoke ought to issue from the coal at all times, besides the flame from the chimney. Coal is therefore thrown on gradually, to the height which may be desired, so that the heat follows to the top as the mass increases. When all the coal is put on, the fire is permitted to break through, and show its white flames at the surface. Those places which are hottest, and where the white flame ceases, are covered by coke-dust; meantime other places which do not work so lively, or are behind, are urged by running an iron bar into the heap so as to make draught-holes, thus securing a more lively combustion. When all the coal is thus heated uniformly to the top, the heap is covered by coke-dust. At the foot the air is still admitted for some hours, so as to heat the heap thoroughly. When the inflammable gas ceases to appear at the chimney, the cover of dust is extended to the foot of the heap, but the chimney is still kept open for some time. Finally it is closed at the top by a slab or a cast-iron plate. The dust-cover when a white heat is perceptible below is well secured by throwing dust around it. All the vents on the surface are now covered closely, and the earth increased so as to prevent all access of air to the interior. Three days, and often four or five, are required thus to char a heap of coal. This manner of proceeding applies to slack coal. There is no advantage in charring coarse coal in heaps: it is coked cheaper and better in rows.

Fig. 393



When the coal abounds in sulphur, the heap is opened in places before it is cool, by means of a crowbar, and water is thrown upon the coke although still red hot. Thus a large quantity of sulphur may be expelled, which will be manifest by a strong smell of sulphuretted hydrogen. The effects of this mode of driving off sulphur on the other qualities of the coke are somewhat doubtful; for it invariably has a tendency to weaken the coke and cause it to be spongy and friable. It requires, therefore, a strong coke, which has been produced by a strong heat, to resist the weakening influence of water.

The quantity of coke produced from coal varies according to the quality of the coal, and the mode of operation. It is not often that more than 50 to 55 per cent. by weight is obtained in rows; although coal which does not contain much hydrogen or water, may reach 60 and even 65 per cent. The yield in heaps is somewhat better, and can be brought, by close attention, to 60 or 70 per cent. The coke from coal generally amounts to more by measurement than the quantity of coal that is burned; this varies from 100 to 125 bushels of coke from 100 bushels of coal; it is not often less than 110 bushels.

The coke yard ought to be level throughout, and dug, or ploughed over, so as to remove all stones and damp places within two feet of the surface, and uniformly covered by a loose and light soil. This yard is surrounded by a ditch, into which rain and spring water flows, and which ought constantly to contain some water, which may be at hand when needed, and also moisten the ground. The object of

this is to impart by these means a certain degree of dampness, but not too much, to the whole yard. In the course of the operation the yard is covered by coke dust, which, when mixed with soil, is very suitable to retain moisture; but the presence of water around the yard, enables us always to obtain damp dust by digging. A damp coke yard possesses great advantages for driving off sulphur from coal. This substance adheres tenaciously to carbon, and no degree of heat can expel it; not even with the assistance of fresh air. The best method, therefore, to desulphuret coal is found to consist in highly heated steam. Consequently, if coal is heated on a damp ground, steam is generated, which, in passing through the hot coal, is decomposed and carries off sulphur. If the heat is too high, or too low, these means ar as ineffectual as any others; it is difficult to hit the exact point. If moisture is always present it wil act at the proper time. When the coal is at the highest heat, no vapors will issue; the ground is dry, and none are needed.

The principles involved in making coke are exactly the same as in charring wood, with the exception that coke is less combustible than charcoal and less care and attention is required to obtain good results. The fire should always work from the interior to the exterior, and the more this is attended to, the better will be the yield. When coal is very impure, or fine, it is necessary to work with less cover, in order to make quality, but this is always accompanied by a loss. Sometimes the flues are formed by erecting poles, of 10 or 12 inches in diameter, after the coal is thrown around them, and before the fire is applied they are withdrawn. This mode of forming flues is only applicable where the coal is coarse and does not bake too much. But in such cases no flues at all are needed; the coarse coal, when piled openly, forms sufficient spaces for draught. When coal is very bituminous, and swells considerably, it must be set with large spaces, and good safe flues; and, in order to insure good work, it is coked without any cover of coke dust.

Coking in ovens. This method is resorted to, in order to obtain more coke, work slack coal and save labor; but coke made in ovens is never so free from sulphur as that charred in the open air.

The varieties of form in coke ovens are innumerable. In Fig. 894, is represented a vertical section of a coke oven such as is mostly in use in the western States, and other regions where coke is made. It is generally built against a hill-side, and is accessible, at the top where the aperture is, by a road, so that the wagons may deposit their loads of coal most conveniently to it. The form of the interior of the oven resembles that of a common baker's oven, only it is round as represented in the plan, Fig. 895. The hearth is from 10 to 12 feet in diameter, and has a door 2 feet in width on one side. The arch is in its centre or highest point, about 3½ or 4 feet above the bottom, and about 18 inches or 2 feet in its span. The opening in its centre is from 20 to 24 inches in diameter. The entire hearth, both the bottom and arch, is constructed of fire-brick; the rough walls around these may be either of common brick, or rough or dressed stones. Two or more ovens are generally built together, as shown in Fig. 896. This arrangement saves labor, because there is always more than one hand required; and two or three hands may quite as well tend as many ovens.

Fig. 894.

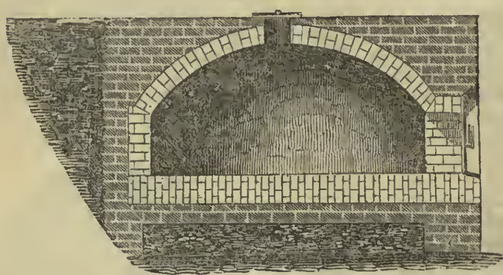


Fig. 895.

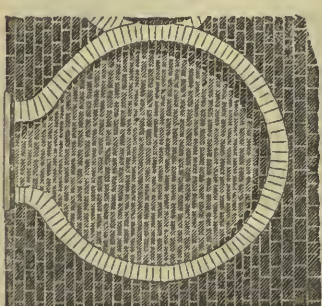


The manner of using these ovens is extremely simple. If one is cold, which is always the case when new, or on Monday mornings, a quantity of wood is first spread over the hearth, and kindled; meantime some lump coal is added. This fire is then continued briskly, until the arch and sides are red hot. The ashes are either removed, or drawn towards the door by means of a long hook, or left where they are, in case no harm is done to the coke. When the oven is hot, the coal is thrown in at the top, and spread uniformly over the hearth, by another hand at the side door. The height of coal upon the bottom, depends on the kind of coke which is to be made; if it is to be close and heavy, the stratum is from 16 to 20 inches thick; and only 12 or 14 inches if it is to be pure, in which case the coke is more spongy. When all the coal, which varies from two to three tons at a time, is charged, the door is shut, either by means of a cast-iron plate, or by fire-brick. A few small apertures, however, are left open for the access of a little air, which are stopped as soon as the heat inside is strong enough to drive off the volatile matter. From the aperture in the centre of the roof, a thick dense smoke at first issues which is soon supplanted by a bright flame. It is not good to increase the heat too rapidly by throwing in the coal too fast; there is no need of haste in charging, for nothing is gained by it; on the contrary, loss may ensue. When the coke is thoroughly heated, which takes about 15 or 16 hours, the flame ceases at the top, and all the openings in the door and at the top are closed; still a few small crevices may be open which admit a little air. This causes the heat to become intense, and then the coke draws together, and forms a more close and compact body. This last heat, which requires about two hours, settles the coke. All crevices and joints are then carefully closed, and the oven left for some hours to cool. One heat requires from 20 to 22

hours, and when all things work well, an oven must be heated and discharged in 24 hours. This, however, depends very much on the quantity of coal which is charged. A high stratum requires a disproportionally longer time for charring than a low one; when, therefore, the object is to make much coke and work cheap, it is not advisable to put too much coal into the oven.

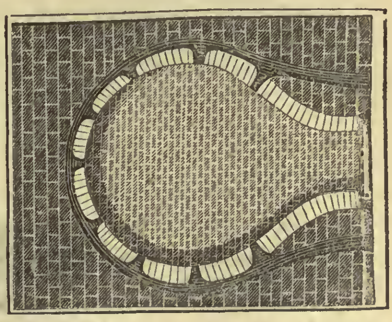
896.

The discharging or drawing of the coke ought to be done while the oven is red hot. It must be done quickly, so as not to lose too much by combustion, and also not to cool the oven, in order that fresh coal may inflame at once when it is charged. The door is opened, but the cast-iron plate which shuts the top is not removed. As the coke forms a solid cake, which is often very strong, a long heavy iron bar is driven in at the bottom, by which the cake is broken, so as to form pieces of a limited size. The coke, when thus drawn from the furnace, is dropped on the ground, and the hot mass sprinkled with water by means of a watering pot and syringe. This damping of the hot coke, cools it for removal, and in the mean time causes some of the sulphur to evaporate. When the hot coke is removed, fresh coal is immediately thrown into the oven, provided it is not too hot; for an unnecessary loss of coke is the consequence of a decomposition of the coal too rapidly.

Ovens do not furnish the cheapest coke, and of course not the best kind. Their superiority over coking in an open yard, consists in working slag coal with greater facility than it can be done in the yard. The yield in an oven, in weight and in measure, may be pushed very high, by applying a low heat in coking; 80 per cent. and even 85 per cent. in weight may be obtained, by 150 or 160 bushels, in measure. The coke thus obtained is not strong and heavy, but always spongy; it burns with flame, and is not suitable for smelting, notwithstanding however good it may be, for use in locomotives. Good coke, even if made in ovens, must be silver-gray, crystallized in columns, and shingle like good well-charred charcoal. The coke ovens near and around Pittsburg, Penn., furnish a first-rate article from slack coal. An oven will not furnish much more good coke from a certain weight of coal, than the heap or row in the yard. The average return of good coke formed by a high degree of heat, is from 55 to 65 per cent. in weight, and 100 to 120 per cent in measure.

A certain quantity of air, and if possible moisture, ought to pass through hot coke, as we have shown, in order to purify it. This does not take place in the ovens above described. A little air passes in at the door, but that of course cannot reach the mass of coke. Experiments have been made to introduce air by perforating the bottom; but they have been found to be of little avail, because the coke soon becomes so close as not to admit of its passage. The most successful method of producing good coke in a large quantity, and also for accelerating the work, is the constructing of a channel around the inner wall of the oven, a horizontal section of which is shown in fig. 897.. The air is drawn in at both sides of the door through this channel, which is about 6 inches wide, between the rough-wall and the lining of the oven, and conducted by small apertures into the oven; there may be nine or ten of such flues or tuyeres 2 or 2½ inches wide in the circumference. These air-holes must be above the stratum of coal. A couple of bricks will serve to close the entrances to the main channel when necessary. The operation of this air channel is plain. Whenever it is open, the air furnished by it will cause the gases which escape from the coal to burn, and heat the arch and the top of the coal. By increasing the heat in the oven, it consequently accelerates the operation, and causes a stronger coke to be made. This channel must be used with discretion and judgment, for if it is either opened too soon on the fresh coal, or suffered to remain open too long on the hot coke, it causes waste.

Fig. 897



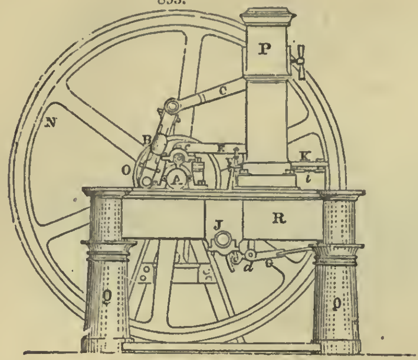
For the formation of good coke, the coal should not be higher than 12 inches, and the highest part of the oven not more than 3½ feet from the bottom. There is little harm done in having the arch only 3 feet high in the centre, and 18 inches around the circumference.

COG-WHEELS. See Geering.

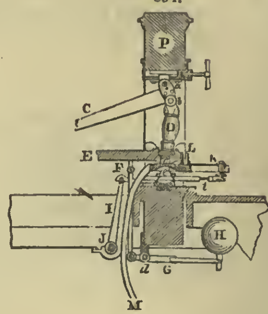
COINING MACHINE. Figs. 893 to 903, are elevations, sections and details of a machine for stamping money, invented by M. Thonnelier, and combines economy with perfection of workmanship, durability of the machine, and safety to the operatives.

The moving power applied to a winch, or rather a steam power, turns a fly-wheel which governs it, and sums up all its powers at the moment the piece is stamped. To the axle of this fly-wheel a spira

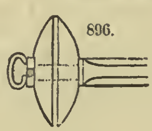
893.



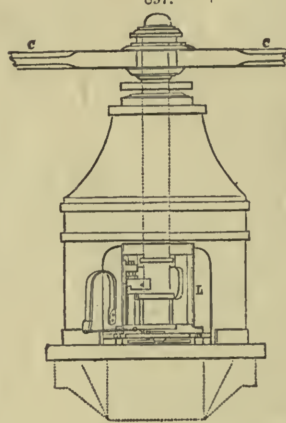
894.



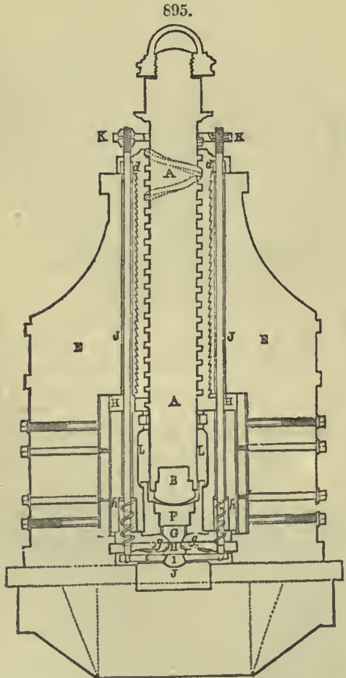
896.



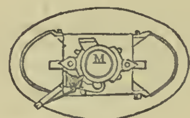
897.



895.



8.



899.

Fig. 893, lateral elevation of the machine.

A, principal axle turned by a winch or moving power.

B, connecting-rod giving to the lever C the movement of the winch adapted to the axle A.

C, lever whose centre of movement is at *a*, in the interior of the cast-iron *f* P; it makes the second cylinder *b* revolve the arc of a circle.

D, a force column of steel. It moves at its lower part, in the box E. Its upper portion is joined to the lever by the intervention of the steel cylinder *b*.

E, a sliding-case leaning against *c*. It is maintained by a double beam F; a lever G, fork-shaped, bearing the two balls H, hold the case against D. The supporter and the lever of the case revolve round an axle in *d*.

I, an iron lever receiving from another lever concealed by the machine, an impulsion transmitted by the eccentric fixed to the plate O of the fly-wheel N; these two levers are fixed to the axle J, which is the means of placing the metal, and of drawing it off when stamped.

i, a lath communicating with the lever I, and destined to raise the point *c* on a level with the side-plate of the ferrule.

e', inferior stamp.

K, placing hand. It has at its extremity an instrument to take the coin off, should it be attached to the superior.

This portion of the machine comprises several pieces; viz. the side-plates of the ferrule; the ferrule, &c.

L, a tube which receives the metal about to be coined.

M, a passage through which the coin passes to fall into the basket.

N, fly-wheel.

O, a cast-iron plate attached to the axle of the fly-wheel.

P, cast-iron case of the machine.

Q Q, four cast-iron columns giving support to the frame of the machine R, likewise made of cast-iron.

curve is adapted to direct the movements of a connecting-rod, which transmits to the moving parts the mechanism of placing and taking off the metal between the stamps, and withdrawing it from the ferrule after the money is stamped.

The power accumulated by the fly-wheel, is transmitted through its axle to a winch, which acts upon two arms joined to each other by a hinge at their extremities, and forming a very obtuse angle, which can be opened or closed a little. When this angle is opened, the two other extremities of the arms or levers become more distant, and as the superior meets a buttress, it is the inferior one which moves; it is properly a funicular lever or mechanical knee. Thus the lower part of the inferior lever is drawn towards a resisting plane, when the angle of the two arms widens, but on the contrary it is carried away from the plane when the angle closes; the movements are produced by the connecting-rod and the winch fixed to the fly-wheel.

The two stamps are placed, the one at the moveable end of the lever, above the metal to be coined; the other is situated beneath, the two planes being parallel.

The pieces to be coined are piled up in an iron cylindrical vessel, and at every turn of the fly-wheel, the nether piece is taken away, and pushed under the press, being contained within a ferrule which limits its circular diameter. When the lever rises, the coin spontaneously leaves the ferrule.

Cylinders.—The principle of this press consists in two cylinders having their axes parallel, and turning in opposite directions.

These cylinders have on their outer surface engraved matrices, smooth and fluted ferrules, as well as ferrules with inscriptions.

Fig. 900 presents a transversal section of the machine perpendicular to the axis of the cylinders.

Fig. 901 is a vertical section made through this axis.

The cylinder A receives the movement of the moving power; its axle has length enough out of the case to have cogs B engaged into the pinion B′, on the axle C. This axle has a fly-wheel C′, and can be set to work by any moving power through the pulleys D D′.

The second cylinder A′ is constructed almost like the first, and of equal diameter, having the same number of matrices.

Two wheels E E′ are connected with one of the extremities of the cylinders in order that they may receive motion.

In the swollen centre of the second cylinder A′, and on its surface, there are excavations to receive the matrices *a*, Fig. 902; they are cylindrical; metallic disks *e* support the matrices, whose distance from the centre, or from the circumference of the cylinder, is thus governed. Buttresses *b* placed on each side of the matrices are inserted into the cylinders, to push the matrices outwards. This forces the iron out; which, when effected, the buttresses are sent back to their original position by the spring *d*. At the central part of the outer surface of the cylinder A, grooves are made to receive the ferrule matrices *a*′, the form of which is hemispherical, Fig. 903, so that they can oscillate through the rotary motion of the cylinders. The plane surface which terminates each matrice, and which is engraved, passes through the centre of the sphere, but the outer circumference of this surface should be somewhat eccentric, to the surface of the sphere.

Pillows can be placed within the groove under the matrices; they are of steel, and can be regulated by a screw. The matrices are by this means secured from oscillations.

Steel springs *e*, Fig. 900, act upon the sloped edges of the ferrule matrices, to forrce back these last to the place they should occupy, as soon as they are no more opposite the matrices *a*.

A tube F, containing the pieces about to be coined, furnishes them to the matrices. The circumference of the second cylinder A is surrounded with steel plates *f*, which have at their centre a cylindrical hole of equal diameter with the matrices *a*; these plates serve to stamp the circumference of the coin. When the cylinders are placed as represented in Fig. 900, the lowest piece in the tube F is in contact with the surface of the plate; as soon as the matrice comes to the orifice of the tube, the piece falls into the vacuum formed by the plate, and comes in contact with the engraved surface of the matrice. The cylinder continuing its rotation brings the metal within reach of the ferrule matrice, and the coin is stamped on both sides at once.

It is then pushed out of the matrice by *b*, assisted by the scraper *g*, which has a counterpoise.

The turning-pieces of the cylinders are received in pillows which allow them no lengthwise displacement; and in order that the matrices may be retained in the same plane, perpendicular to the axis of the cylinders, these are exactly clamped between the two cheek-pieces of the cases which contain their pillows. Wedges pressed by screws *h*, hold the pillows firmly fixed. The coins, as they fall, receive no shock, and are received in a box enclosed within J, the frame-work of the machine.

Such a machine coins more than 100 pieces in a minute, or 60,000 pieces in a day of 10 hours' continual labor. The moving power required is but slight. This press performs its functions without noise, and is not liable to be put out of order; its construction is simple, and it occupies little room. The workman who attends it is perfectly safe during his labor.

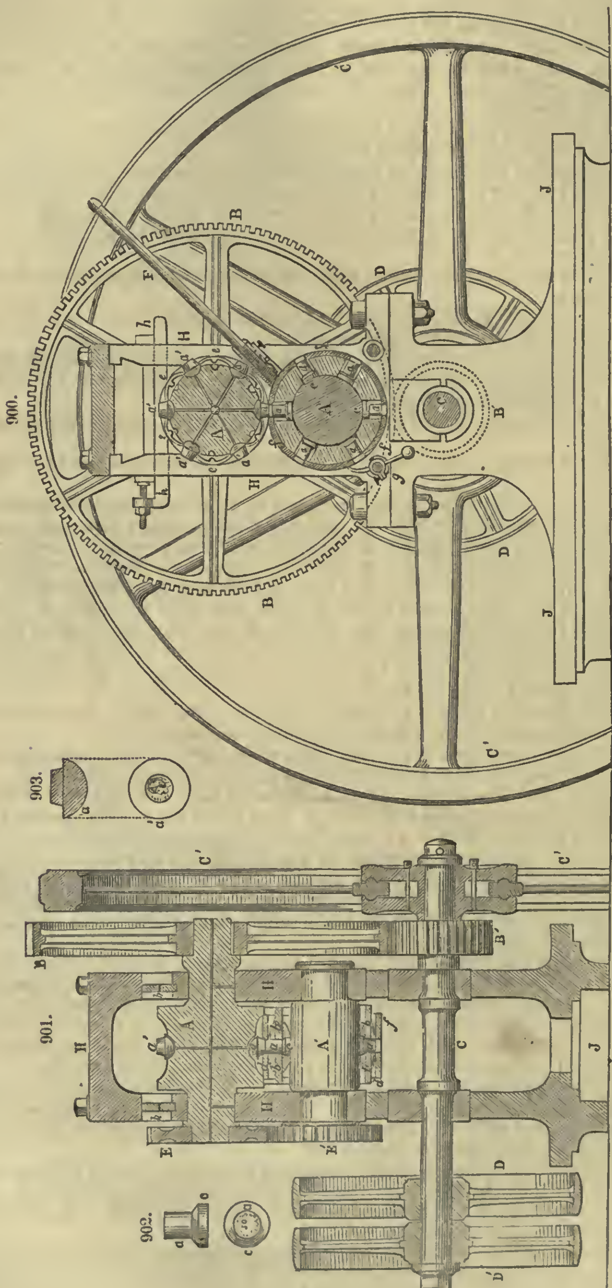
Should any accident or obstacle occur, the machine is so arranged that it stops spontaneously; the fly-wheel C′ is maintained on the axle by a species of break, Fig. 901, which allows it to turn back without turning the axle, when a greater resistance than usual is experienced by the matrices, so that the attendant is made aware of the accident.

New Method proposed by M. Béguin to stamp Money, Medals, and Jewelry.—This consists in placing within the matrices a certain number of steel stamps. These matrices being piled one upon the other, are enclosed in a rectangular box, and made to pass between two cylinders. This pressing is performed rapidly, and many pieces are worked in a short while.

The stamps are placed within the matrices, and are of a slightly conical shape; in order that they may be retained at the same level, a strong plate covers the matrices. A thin plate is interposed between the two matrices, and is pierced with a number of holes equal to that of the stamps; its use

is to keep the pieces to be stamped in connection with the stamps; this plate is made of steel, having its surfaces even, and an equal thickness in all its points.

The system is carefully fixed into a rectangular frame, which is of iron, and holds the different parts so firmly fixed, that they are not deranged while between the rolling cylinders.

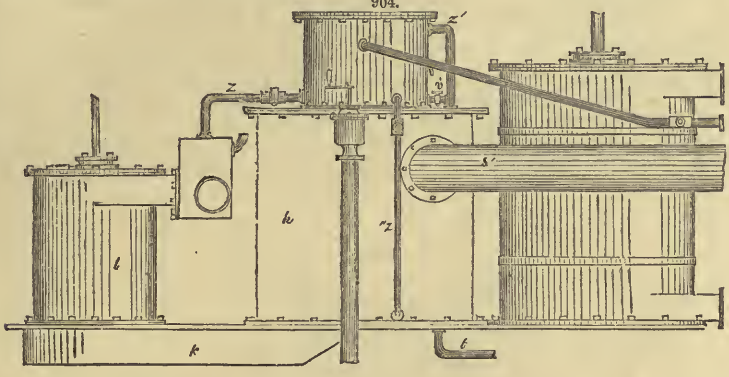


900. 901. 902. 903.

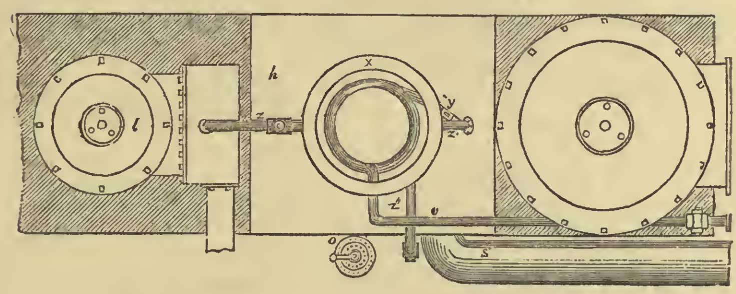
CONDENSER. The usual modes of condensing steam, where it is used as a motive power, are by allowing it to escape into the air; by injecting it into a vessel or vessels which are kept at a low temperature by immersion in cold water, or a current of air, the steam being cooled by contact with the

metal; and by injecting it into vessels in which it is brought in direct contact with a jet of water. In the first instance, the water resulting from the condensation of the steam is lost; in the second, it is retained in the vessel in which it is confined, unmixed with any other substance; in the third, it is retained, but is mixed with the water used for condensing it. Condensing engines are those which employ one or the other of the two last-described plans. In marine engines, or where salt or other impure water is employed for condensing the steam, this latter plan involves the loss of the fresh water resulting therefrom, in a manner well known, and consequently either the boilers must be supplied with bad water, or a supply of pure water must be specially provided. In most cases this cannot be accomplished, as it has been found impossible to carry a sufficient quantity to last for any great length of time.

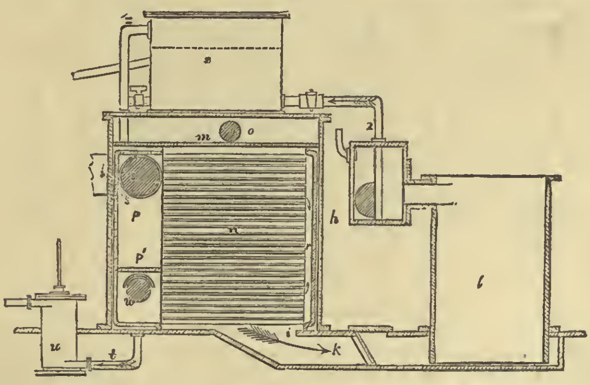
904.



905.



906.



This being the case, attention was early (in the history of the steam engine) given to perfecting the second mode named herein—viz.: the condensing of the steam by radiation in closed metallic vessels, kept submerged in water. In this plan the boilers are to be first filled with pure water; the steam being condensed back to water, is thus caught and returned to the boilers, to be used over and over again; the leakage and waste being supplied from reservoirs provided with an extra quantity, or by distillation. The steam being condensed in vacuo, the external surface of these vessels is thereby subjected to the pressure of the atmosphere, and also to the pressure of a column of water, proportioned to the depth at which they are immersed. In fig. 907 is a view of the usual mode of constructing this kind of condenser: a is a cluster of pipes, (that being the best form to resist pressure,) inserted in two flanges, b;

the ends of the pipes are covered at c by a cap, and at d by the channel in the bed-plate; e is a tank to hold the water for condensing, which flows in and out as indicated; f is the exhaust-pipe for conveying the steam to be condensed; g the air pump. The steam is thus condensed by coming in contact with the cold surface of the metal, the pump, g, maintaining the vacuity of the pipes by removing the water as fast as it accumulates in the channel d, and also any air or other gases Hence the external surfaces of the tubes are subjected to the pressure of the air, and also to that of the column of water in which they are immersed, as before named. This mode of condensing steam has these difficulties to contend with, and which have hitherto been found insuperable. The alternate heating and cooling of the metal pipes, consequent upon the periodical injections of the steam, causes a series of expansions and contractions to be continually going on. In addition to this, the great pressure upon them soon produces fractures in the various joints and seams, which at once destroys the whole operation, as the vacuum can no longer be maintained from the flowing in of the air, and also of the water, which is fatal to the whole operation.

Fig. 907

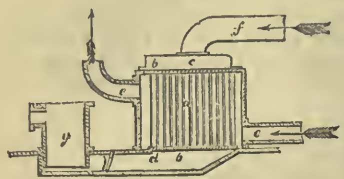


Fig. 904 is a side elevation; fig. 905 is a top view: fig. 906 is a longitudinal section of Pirsson's patent condenser. Figs. 908 and 909 are views showing variations in the construction of the same ap-

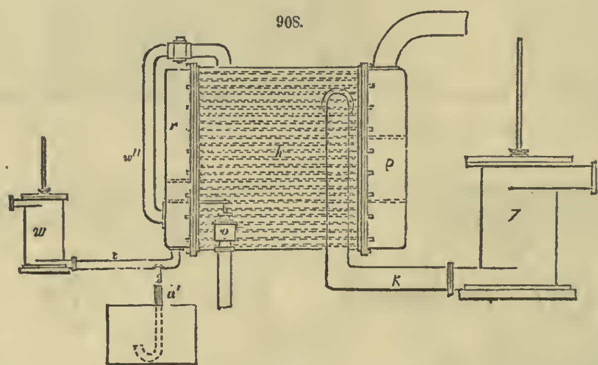
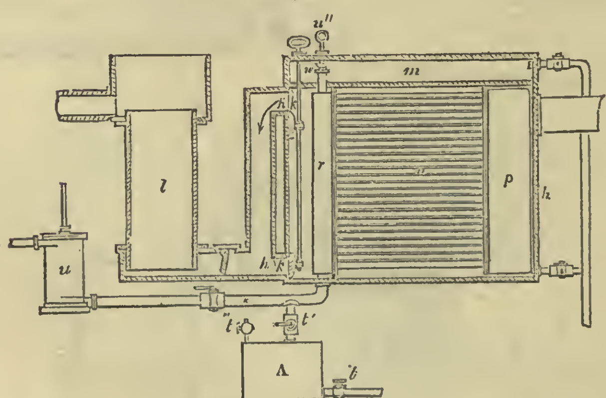
908.



909.



At the letter h, fig. 906, is represented a box or case composed of metal, and of sufficient strength to resist the pressure of the atmosphere, and is also to be made as perfectly air and water-tight as possible. In the under side of the box h, there is an opening i, through which a connection is made by a pipe or channel k, with an air-pump l, of common construction, as shown in section, fig. 906. At m is a perforated plate, on which the condensing water is received, and is for the purpose of dispersing it in a manner well known. A pipe and cock are attached for injecting the water for condensing the steam. Into the box thus constructed, is introduced a radiating condenser, that is to say, a vessel or apparatus in which steam is to be condensed by contact with cold metallic or like surfaces, which is made as follows:—At n, fig. 906, is seen a number of tubes arranged horizontally, their ends being fixed in plates or flanges of metal, having holes perforated to receive them; the ends of the tubes are covered by attaching caps, p and r to these plates, as shown in section, fig. 906. The tubes thus arranged, are in-

troduced within the box h, as shown. In the cap p there is an opening made at s to receive the end of the pipe which conveys the steam to be condensed, which pipe is seen at s'. The steam-pipe s' is bolted to the outside of the box h by a flange, the end passing through and made to enter the cap p, through the hole s as shown. The cap p is divided into two compartments by a partition p', the object of which is to cause the steam to traverse through two sections of pipes. More partitions may be introduced, or any other arrangement may be adopted to insure full and equal distribution of the steam to each pipe. At t is shown a pipe connected with the lower side of the cap p, which passes through the box h, having a tight joint where it comes out. This pipe terminates in a pump u, the use of which is to pump away the water resulting from the condensation of the steam, and which collects in the bottom of the pipes and caps. At w is an opening in the lower division of the cap p, which forms a passage from the pipes to the interior of the box; the use of which will be described more fully. This opening w, is to have a door or valve over it of common construction, which may be opened or closed by a handle from the outside of the box h, the handle working through a stuffing box in h. It is obvious that other forms may be substituted, as sheets of metal, coils of pipe, instead of tubes or pipes.

The operation of this part of the invention is as follows:—The engine being started in the usual manner, the exhaust steam flows through the pipe s', into the cap p, and thence into the cluster of pipes n; at the same time a jet of cold water is admitted through the injection cock o on the perforated plate m, from which it falls in a shower upon the pipes n, and thus, by a well-known law, at once condenses the steam—the water resulting being collected in the bottom of the pipes and caps—the large pump l removing the condensing water as fast as it accumulates from the box h, and maintaining the vacuum, —the smaller pump u removing the water resulting from the condensed steam. In like manner the condensing water is allowed to flow off as fast as discharged from the pump l, but the water taken from the pipes is retained for the feed to the boilers. The use of the aperture w, is for the purpose of maintaining an equal pressure on each side of the pipes, or rather to prevent them from being subjected to any pressure, either internal or external. This can be made apparent as follows:—Supposing the orifice w closed, and cold water admitted in quantity sufficient to condense a part of the steam only, it will be evident that the vacuum in the box h will be better than the vacuum in the pipes, and the difference will be as the volumes of uncondensed steam. Now if we open the door or valve over the aperture w, a portion of the steam in the pipes will at once rush through and extend itself throughout the box h until an equilibrium is produced. So long as the steam is fully condensed, and also the operation of the pumps l and u equal, then, of course, the radiating condenser n will be subjected to the same pressure, both external and internal; or rather, will not be subjected to any, even if the orifice w be kept closed. The use of the opening w, therefore, is to insure the preservation of the equilibrium in cases where the steam is not fully condensed, or where the pumps fail to work equally: the atmospheric pressure being sustained by the box h.

An apparatus for making up any deficiency in the supply of pure water which may arise from leaks and other means of waste. At x, figs. 904, 905, 906, is seen a tank, standing upon the top of the condensing box h (but may be put in any other convenient place). This tank must be air and water-tight, and also capable of sustaining the pressure of the atmosphere. At y, fig 905, a steam-pipe is attached, which may terminate on the inside in a coil or cluster of pipes, or other chamber for holding steam, as shown. The lower end of this coil terminates in a pipe, which passes out through the side of the tank at y', and empties into another pipe as shown. z is a pipe attached to the lower side of the tank x, the opposite end of which terminates in the "hot well" of the air pump l, or other reservoir containing a supply of the water to be evaporated; z' is a pipe attached to the upper side of the tank x; it is bent so as to pass down through the top of the box h, to which it is bolted by a flange, the end terminating so as to discharge into the cap p, of the inside condenser, as shown; z'' is a pipe attached to the tank x near its bottom, by one end, and by the other to the box h, so as to discharge into it. To put this apparatus in operation, the engine is first set in motion, and the condensation of the steam going on, the vacuum of the box h will be communicated through z' to the tank x, the interior of which will consequently be in vacuo. The cock to the pipe z being opened, water from the hot well of the pump l will flow into x by the pressure of the atmosphere; the tank is to be filled sufficiently to cover the coil of pipes, or as seen at the dotted lines. Next, steam is to be admitted through y, the cock y being kept closed (except when it is necessary to draw off the water which may collect from the condensation of steam in this place).

By this means the water in x will be vaporized, the vapor being drawn off as fast as it rises through the pipe z' into the condenser's cap p, and there condensed along with the exhaust steam from the engine, so that it serves to make up for the loss by leakage, &c., of the first supply. As the apparatus is of use only where the water for generating the steam is impure or salt, some mode is required for keeping the tank x clear of the deposit of these impurities, as by evaporation all these must collect in the evaporating vessel, according to laws well known. To remedy this, the evaporating vessel is connected with the box h by a pipe z''—said pipe entering the evaporator near its bottom, and discharging into box h, as shown. A cock or valve is also fitted into said pipe, to regulate the rate of discharge, which takes place by gravity alone, as the two vessels are alike in vacuo. The saturated water will flow through the pipe z'' in the same manner as if x and h were both open vessels. If the supply for waste is to be made up from salt water, as in sea-going steamers, then a certain quantity of this water must be taken out of the tank by this pipe proportionate to the quantity evaporated, and thus the amount fed through the pipe z must be sufficient for both the evaporation and the quantity thus drawn off. The same rule applies to evaporating water containing lime or any other impurity. The water taken off through z'' enters the box h, and is pumped out with the condensing water by the air-pump l.

In fig. 909 is a view of a modification of a condensing apparatus—the same letters referring to the same parts, except where otherwise indicated. This is to show a mode whereby the radiating or surface condenser may be immersed in the condensing water, or showered at pleasure, and exhibits also a

variation whereby the pump removing the water resulting from the condensed steam may be dispensed with.

In this case, when the pipes or other surfaces, n, are immersed in the water, they are subjected to the pressure of the same in a greater or less degree, according to its depth; but they are not subjected to the pressure of the atmosphere in addition, as will be shown. h' h'' represent two openings in h connecting the air-pump l by the channel k. k' k'' are valves for closing the openings h' h'', operated from the outside of the box h, as shown. If the pipes n are to be used submerged, the valve k'' must be closed, and valve k' opened. The condensing water being let on, fills up the box h until the water is on a line with the opening h', and thus the pipes are immersed.

If the pipes are to be showered instead, then k'' must be opened, and the condensing water let on to the plate m, in the manner before described. When this plan is adopted, the aperture for insuring the equilibrium must be placed in such a situation that the condensing water cannot enter the pipes; in fig. 909 it is shown at the pipe w', and w'' is the stop or valve for opening or closing it. The next feature is a method of dispensing with the pump w. A is a tank air and water-tight, and capable of sustaining the pressure of the atmosphere. This is to be connected to t by a pipe, with a valve or cock intermediate, as $t.'$ At t'' is a delivery cock; at t''' is an air cock. The pump u being disconnected, t' is to be opened, and thus communication is made between the tank A and pipes n, as plainly shown—t'' and t''' being closed always when t' is opened. The water from the condensed steam will now descend by its gravity, into A; when A is full, t' must be closed—t'' and t''' opened, which permits the water in A to run out, being collected in reservoirs, from which the boilers are to be fed. As soon as A is empty, close t'' t''', and open t' until again filled, and so on. The periodic opening and closing of these valves or cocks can be easily arranged to be operated by the works themselves.

Fig. 908 exhibits another arrangement, embodying however, the same general principles. The same letters are used to represent similar parts, described in the other figures. The principal variation in the construction of this part of the invention, consists in forming the box h, so that the tubes n shall be inserted in the two opposite sides, as shown in the dotted lines. In that case the caps p and r to cover them, are placed outside. The injection-cock o is placed at the bottom, and the delivery-pipe at the top, so that the pipes are shown as immersed in the water, but may be showered by making the changes before described. w''' represents a pipe forming a communication with the box h, and the interior of the pipes n, for keeping the pressure equal, and is equivalent to the aperture w, in figure 3, or w' in figure 5. Another variation consists in the manner of removing the water of the condensed steam, the same principle being applicable to removing the condensing water also. The pump u being taken off, a pipe a' is substituted which is attached to the cap r, where the water from the condensed steam accumulates. This pipe must have a descent vertically, sufficiently great to cause the column of water to counterbalance the atmospheric pressure (say of 34 feet), and may terminate in a reservoir. By this means the gravity of the water will overcome the vacuum in the pipes, and thus deliver itself without other mechanical aid.

The advantages to be derived from this invention are as follows:

First.—By arranging the radiating or surface condenser, so that it is not subjected to the pressure of the atmosphere. Secondly.—By reason of which arrangement, the apparatus is not so liable to be destroyed by the great pressure it would otherwise have to sustain; therefore durability and safety is increased. Thirdly.—Small leaks and fractures will not affect its operation; the box h being exhausted of air or other uncondensable gases, which are not therefore present to flow through such apertures, and the condensing water will not enter, because there is no external pressure upon the pipes, to force it in; the water falling upon the pipes by gravity alone, its tendency will be to run out rather than in. Thus, where salt or other bad water is used for condensing, no admixture of the pure water of the condensed steam will take place. Fourthly.—Increased safety; as the whole surface condenser might be destroyed in the box h, without impairing the working of the engine, or even arresting its motion. The only change perceivable would be the loss of fresh water, resulting from the condensed steam. This is a most important feature for seagoing steamers.

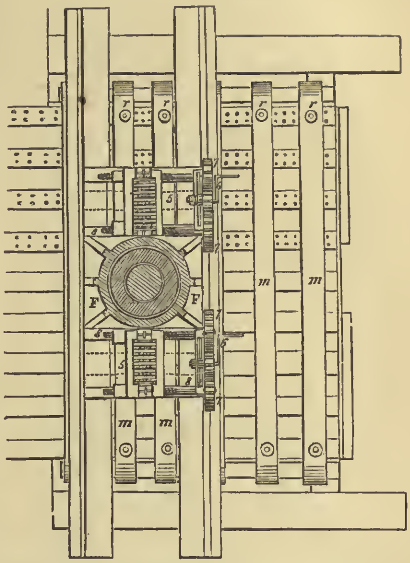
CONWAY TUBULAR BRIDGE. The great engineering event for 1848 is the raising of the Conway Tubular Bridge, and which, after so much fear and anxiety, has been effected with great success. This work derives its importance not so much from its greatness, as from its opening the way for the adoption of a new system of bridge building, whereby the resources of engineering are very much extended. To build a bridge greater than those which have been made before, to make a railway longer than those which have yet been opened, or to construct a more powerful locomotive, is a great work; but it is of much greater importance to execute something entirely new. The engineer who has constructed the greatest lighthouse or the greatest dock in his day, may be overcome by some one else, and then his claim is at an end; whereas, the engineer who extends the resources of his art, has a clear and unique claim to distinction. Mr. Robert Stephenson has the merit of carrying out this system of tubular bridge building, and it will be a special event in his career, beyond the many works of constructive skill he has already produced. The success of the Conway Bridge is none the less important, because it settles the practicability of that greater undertaking, the Menai Tubular Bridge. Thus progress in any one direction leads most certainly to greater exertion; and it is peculiarly necessary to give every encouragement to all attempts, which open a new career for the engineer, and give him greater means of exertion.

We have thus given engravings of the tube and the lifting apparatus, and shall lay before our readers drawings of the ingenious Jacquard machinery, invented by Messrs. Roberts, for punching the plates (See Jacquard Punching Machine.)

The construction, when finished, is to consist of two tubular bridges, formed of wrought-iron plates, each tube being for one line of rails. We shall now confine ourselves to the description of one of the tubes, which was fixed in its place in March, 1847, and is shown in the accompanying engravings

Fig. 907 exhibits a transverse section of one of the tubes and the masonry of the pier, together with the lifting apparatus. Fig. 908 is a side elevation of 19 feet in length of the tube, resting on the masonry, and the lifting apparatus. Fig. 909 is a section through 12 feet in length of the tube, and section of the lifting apparatus. Fig. 910 is a plan of the top of the tube to the extent of 20 feet in length, and plan of the hydraulic press. Fig. 911 is a front view of one end of the suspension girder, and Fig. 912 a side view.

910.



The tube consists of a shell or external casing, *a a*, of wrought-iron plates, from 4 to 8 feet long, and 2 feet wide by half an inch thick in the centre, and five-eighths of an inch thick towards the end of the tube, riveted together to T-angle-iron ribs, placed on both sides of the joints, and angle-gussets at the feet of the ribs to stiffen them; a ceiling, composed of 8 cellular tubes *b*, each 20¼ inches wide, and 21 high; and a floor containing 6 cellular tubes *c*, 27½ inches wide, and 21 inches high. The whole length of the tube is 412 feet, and 22 feet 3½ inches high at the ends, and 25 feet 6 inches high in the centre, including the cellular tubes at the top and bottom, running the whole length, and 14 feet wide to the outside of the side-plates. The upper cells are formed of wrought-iron plates, three-fourths of an inch thick in the middle, and half an inch thick towards the ends of the tube, put together with angle-iron in each angle of the cells; and over the upper joints is riveted a slip of half-inch iron, 4½ inches wide. The lower cells consist of three-quarter-inch iron plates for the divisions, and the top and bottom of two thicknesses of plates, each 12 feet long, 2 feet 4 inches broad, and half an inch thick in the centre, and one-fourth of an inch thick at the ends, and so arranged as to break joint; and a covering plate of half-inch iron, 3 feet long, is placed over every joint on the underside of the tube. The external casing is united to the top and bottom cells by angle-iron, on both the inside and outside of the tube, as shown in Fig. 912.

The ends of the tube, where it rests on the masonry, are strengthened by cast-iron frames *d*, to the extent of 8 feet of the lower cells; 6 cast-iron transverse I-shaped girders *e*, on the floor; 6 similar girders *f*, above; and upright cast-iron stanchions *g*, on each side of the tube, to which are bolted the ends of the girders, top and bottom, and also the cross-lifting girders *h*.

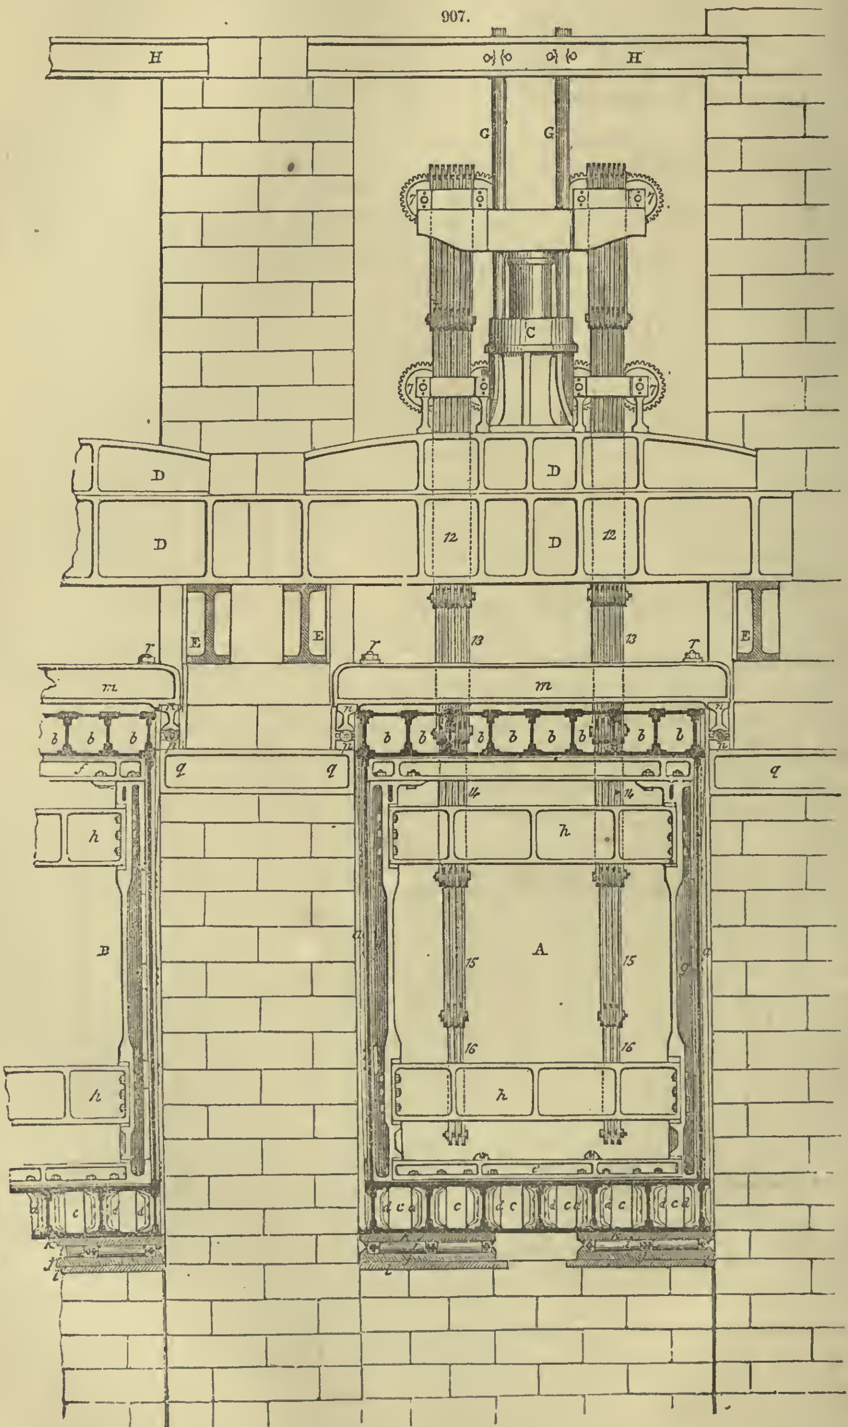
In order to allow of the free expansion and contraction of the tube, the ends rest on 24 pairs of iron rollers *i*, connected together by a wrought-iron frame, and placed between two cast-iron plates *j k*, 12 feet long by 6 feet wide, and 4 inches thick. The lower plate is laid on a flooring of three-inch planks *l*, bedded on the stonework; and the tube is also suspended to 6 cast-iron beams *m*, the ends resting on longitudinal bearers *n*, 12 feet long, with a circular groove on the under side, supported by 12 gun-metal balls *o*, 6 inches diameter, standing upon an iron bed *p*, and supported on the ends of the cast-iron bearers *q*. The tubes are suspended to the beam *m*, by wrought-iron bolts *r*, and spade-pieces riveted on to the sides of the tube, as shown in Figs. 911 and 912.

The lifting apparatus for raising this enormous weight was intrusted by Mr. Stephenson, to Messrs. Easton and Amos, engineers of the Grove, Southwark, to whom great credit is due for the very successful manner the tube was lifted. The machinery consisted of two steam-engines, erected in the recesses B of the corresponding tube, one on each side of the river; and each engine has a horizontal cylinder, 17 inches diameter and 16 inches stroke, with piston-rods working through stuffing-boxes at each end of the cylinder; each piston-rod has a cross-head, and gives motion by side-rods and cranks to two fly-wheels; and the ends of the two piston-rods work two forcing-pumps with plungers, $1\frac{1}{16}$ inch diameter, and 16 inches stroke. These pumps inject the water into the hydraulic press C, shown in the engraving, through the small tube 3.

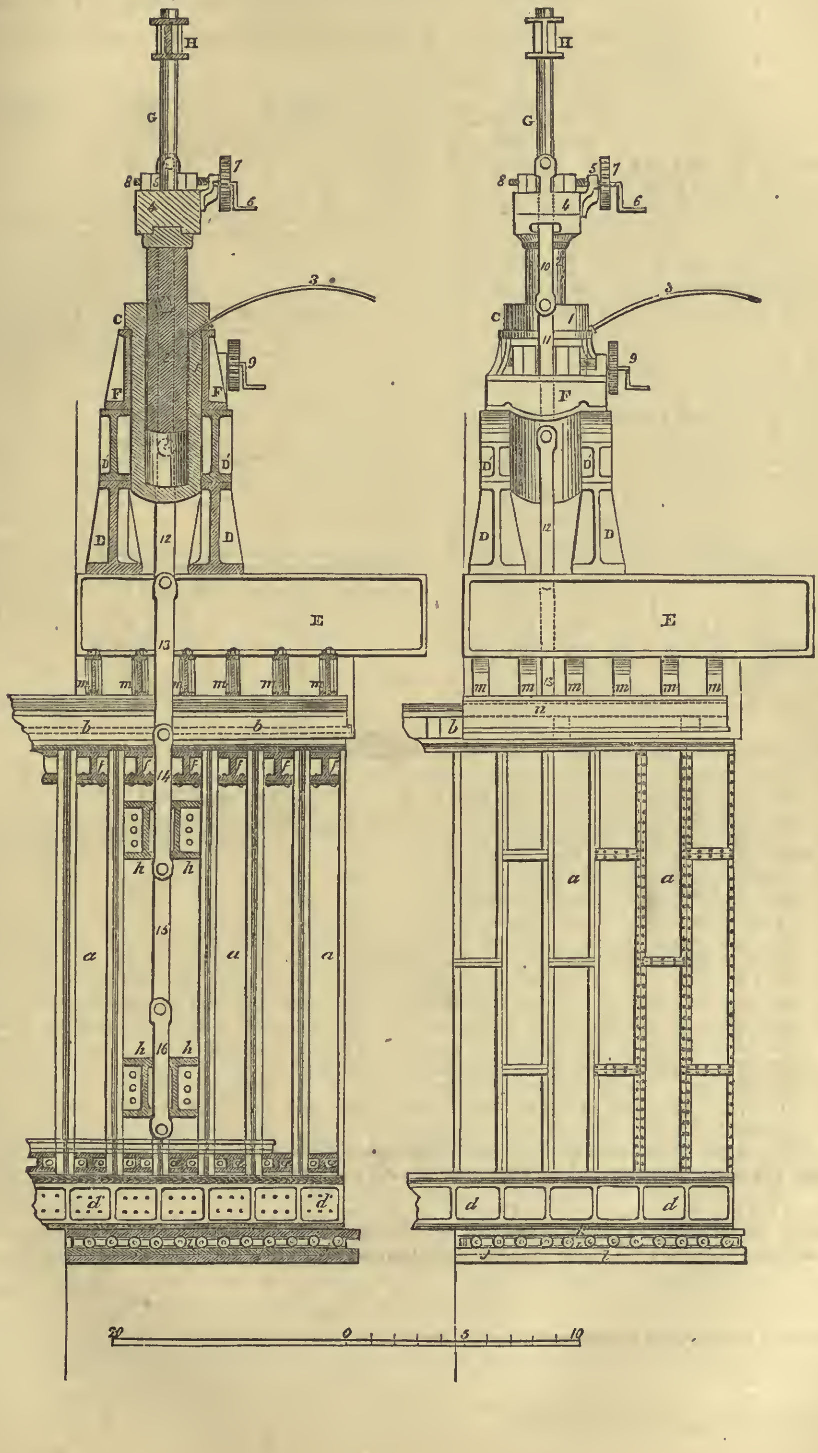
The press was erected on a stage constructed above the level of the top of the tube, and consisted of two cross-girders of cast-iron, each in two heights D, D′, the lower one 4 feet high, and the upper one 2 feet 6 inches high; the ends resting upon cast-iron bearers E, imbedded in the masonry of the piers. Upon the cross-girders was fixed the casing F of the ram, which is 5 feet 2 inches long, by 3 feet 9 inches wide, cast with ribs; and on the top of the cylinder are fixed two vertical guide-rods G, G, 6 inches diameter, passing upwards through the cross-head of the ram, and a cast-iron girder H, nearly at the top of the tower, and 18 feet above the girders D′.

The press consists of a cylinder, 1, firmly fixed in the casing, 37½ inches diameter externally, and 20 inches internally; and the ram 2, 18⅝ inches diameter, with a vacuity nearly seven-eighths of an inch all round, to receive the water injected from the pumps already described, through the tube 3, the orifice of which is three-eighths of an inch diameter; this tube is furnished with a lever-valve close to the cylinder, for safety, in case the pipes should burst. In the event of such a casualty, by an ingenious contrivance the lever-valve would be instantly closed, and the weight supported by the water in the cylinder. On the top of the ram is a cross-head 4, of solid cast-iron, 9 feet 10 inches long, 1 foot 10 inches deep, and 2 feet 4 inches thick, with two apertures, 2 feet 1 inch long, by 1 foot 1½ inch wide, through which the lifting chains pass; and on the top of this cross-head are fixed two clipping vices or clams, 5, 5, each consisting of a pair of wrought-iron jaws, 3 feet long, 11 inches deep, and 6 inches thick,

907.



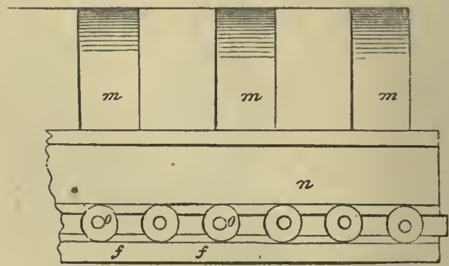
909. 908.



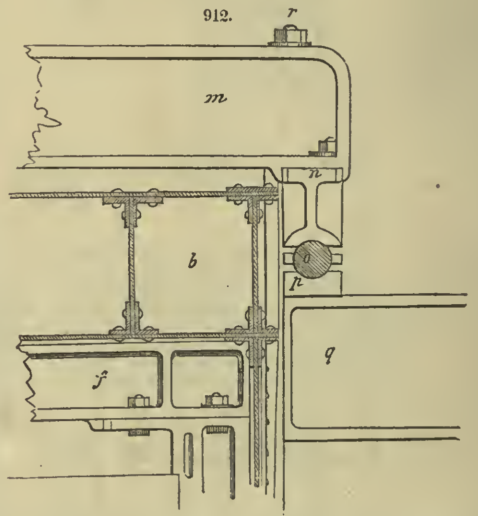
and a winch which turns a small pinion 6, that takes into two cog-wheels 7, 7′, fixed upon the heads of two horizontal screws, (8, 8′, left and right handed,) passing through nuts in the two jaws of the clams Thus it will be perceived, that as the winch is turned, the jaws are made to open or close, for the purpose of clipping the heads of the lifting chains; below these clams are two others 9, 9′, for clipping the heads of the lower links.

The two lifting chains consist of wrought-iron flat bars, in lengths of 6 feet from centre of bolt-eye to centre, and each bar is 7 inches wide and $1\frac{1}{8}$, $1\frac{1}{4}$, and $1\frac{1}{2}$ inch thick, with heads having shoulders fitted to the jaws of the clams. Each chain contained nine links of eight and nine bars alternately, besides the two lower links, each consisting of five and four bars. The heads of the first or upper links passed through the upper lifting clams, fixed on the top of the cross-head of the ram, and there secured by the jaws of the clams being screwed up taut; the second links passed through the lower clam, the jaws of which were left open, and the heads of the two lower links were made to abut against the under side of the lifting girders *g h*. When the pumps were set to work, the ram was lifted 6 feet, its full range; when it had attained this elevation the jaws of the lower clams 9, 9′ were screwed up close and clipped the heads of the third links 11, and there held the chain firm; the jaws of the upper clams were then opened, and the ram lowered down to its original position, when the bars of the top links 10 were removed. When this had been done, the jaws of the upper clams 5, 5′ were again brought under the heads of the second links, and screwed up taut, so as firmly to clip the shoulders of the links, the jaws of the lower vice 9, 9′ opened, and the ram was then set in motion to lift the tube another six feet, when the second links were removed as before described, and the operation repeated as above, until the tube had been lifted the height required, about 22 feet to 24 feet.

911.



912.



The power of the presses may be thus calculated: the area of the ram being equal to 337·64 circular inches, and the force acting upon the plunger equal to 2·14 tons per circular inch, the two being multiplied together give $722\frac{1}{2}$ tons, which is the force of one of the presses, and of the two presses 1445 tons. The actual weight lifted was estimated at 1,300 tons. The quantity of water used for each press is about 66 gallons.

The tube was constructed on a platform erected on the shore of the river, close to where it was to cross; and when finished, six pontoons, something similar to the large coal-lighters on the river Thames, were placed under the tube at low water, and which at high water lifted the tube off the piles upon which the stage was erected. It was then floated to its destination, and placed between the two towers, part of the masonry being left undone until the tube was put into its proper position, and as it was raised the masonry was built up under the tube. The time occupied in raising the tube and building up the masonry occupied four days; the actual space lifted per hour was 13 feet.

COP-SPINNER. *George H. Dodge's Improvements in Machinery for Spinning and Winding Yarn.*—This is a combination of the self-acting mule and throstle, and has many advantages over the common method of spinning, and is equally applicable for filling and warp yarn. In the room usually occupied for 1,000 mule spindles, 1,500 may be placed, which will do the work of 3,000 spindles. It occupies the usual space required for warp spinning, but will spin 50 per cent. more yarn to the spindle than the best ring-bobbin spinning known to us in use, and with a saving of two-fifths of the power. It will spin 100 per cent. more yarn than the flyer spindle, and with one-half the power, compared to the quantity. There is a great saving in expense, by dispensing with bobbins. The spindle is more durable than the common one in use, being tapered to the top; and there being no bobbins or check-pins used, it maintains its balance at any speed required. It is not liable to get out of order. It is much more convenient to piece up the ends when broken, than the bobbin-frame. One cent per spindle is paid for tending warp-frames, and $1\frac{1}{2}$ cent for filling-frames, and twelve dollars extra for doffers, per week. The proprietors, Messrs. John C. Dodge & Sons, of Dodgeville, Attleborough, Mass., have their entire mill upon this method of spinning, and from 29 years' practical experience with other spinning, believe it to be the best in use.

The following table exhibits the comparative product and cost of their old plan of spinning with that of their present improved cop-spinner:—

Bobbin throstles and mules, 4,600 spindles.

1847, 19 weeks product......	25,775 lbs. warp,		......cost, $1,116 69
	23,831¾ " filling,		
1848, " " "	25,974 " warp,		...... " 1,051 78
	24,523 " filling,		
	2)100,103		2)2,168 47
Average, " " "	50,051¾ "		" $1,084 23

Cop-spinner, 2,320 spindles.

1849, 19 weeks product......	32,704 lbs. warp,	
	28,574⅓ " filling,	
	61,278⅓ "	at a cost of $845 50.

The yarn was No. 30, and the average skeins per spindle daily, was seven, no allowance being made for stoppage.

The specification of the patent states, that the peculiar object of the improvements which are applied to a throstle spinning-frame, is to wind the yarn, as fast as twisted, or when properly twisted, upon each of the spindles in a regular or proper shaped cop, which shall have a binding-thread between each two adjacent layers of yarn, in order to prevent the cop from falling apart when removed, or while being removed from the spindle.

Fig. 913 exhibits a front elevation of the improved throstle-frame. Fig. 914 is an end elevation. Fig. 915 is a horizontal section, taken through the axis of the main drum, which drives the spindles and scroll-shaft; the other parts below the plane of the section being represented in top view. Fig. 916 is a rear elevation of the frame, with the exception of those parts of the mechanism which are situated above the tops of the spindles, and which are like those in common use in throstle-frames. Fig. 917 is a vertical section of the scroll-shaft and parts connected with it.

In the several figures, A A denote the cast-iron ends of a throstle-frame; B B are the step-rails of the spindles; C C, the upper bearing rails of the spindles; D D D, &c., are the spindles; E, the main drum by which they are driven; F, on each side of the frame, is the copping or ring-rail; G G, &c., are the guides to the threads in their passage from the front pair of drawing-rollers to the spindles; H is a series of drawing-rollers, such as are in use in other throstle-frames; I is the bobbin-frame or creel; K is the main driving-shaft, from which the drawing-rollers and other parts receive their motions; L is termed the scroll-shaft—it is situated beneath the main shaft, and extends transversely across the machine, and revolves in bearings *a a*, fastened to the step-rails B B. It is also supported by, and revolves in, a third box or bearing *b*, secured to a sustaining bar *c*, ends of which are respectively fastened to one end A of the main frame, and a transverse beam *d* extending from one lower girt *e*, on one side of the frame, to the other *f*.

The scroll-shaft has a reciprocating partial rotary motion imparted to it; it being made to move first in one direction, viz. forwards, with a slow motion, and next in the other direction or backwards, with a much faster one.

A dog or clutch wheel *g* is fixed upon a hollow shaft *h*, made to run loosely upon the scroll-shaft, in the position as seen in Figs. 915 and 917. The said shaft *h* has a worm-geer *i* fixed upon it, which is made to engage with an endless screw or worm *k*, attached to the lower end of a vertical shaft *l*, supported by and made to revolve in suitable bearings. On the upper part of the said shaft *l* is a spur-geer *m* fixed upon it, which is made to engage with, and is turned by a pinion *n*, fixed on another vertical shaft *o*: see Fig. 914. The said shaft *o* turns in proper bearings and has a spur-geer *p* fixed upon it, which geer is made to engage with a spur-geer *q* fixed upon a third vertical shaft *r*, put in motion by two bevelled wheels *s t*, the former of which is placed upon it, and the latter upon the main driving-shaft *k*. Consequently, when the main shaft is put in revolution in the direction denoted by the *arrow u*, in Fig. 914, motion will be given to the clutch or dog wheel *g*, in the direction denoted by the *arrow v*.

The clutch-wheel *g* consists of a circular plate, having a series of projections *w w*, &c., disposed at equal distances, as seen in Fig. 918, which is a side elevation of the dog-wheel, as removed from the scroll-shaft.

The teeth *w w*, &c., project over the periphery of a circular plate *y*, which is fixed upon a hollow tube *b′*, screwed to the scroll-shaft, and has a recess *z* cut in it, (as seen in Fig. 919, which is a side view of the plate *y*,) for the reception of a spring-dog *a′*, the spring of which is secured to the hollow hub *b′*. A bent lever *c′* is made to turn upon a screw-pin *d′*, inserted in the face of the plate *y*. The said lever should be so curved as to rest against the spring of the dog *a′*, and when its outer end is elevated, to press against the spring of the dog, and move it and the dog inwards, or out of one of the spaces *x* of the dog-wheel and into its recess *z*. A standard *e′* is fixed to the side of the frame for the lever *c′* to rest on.

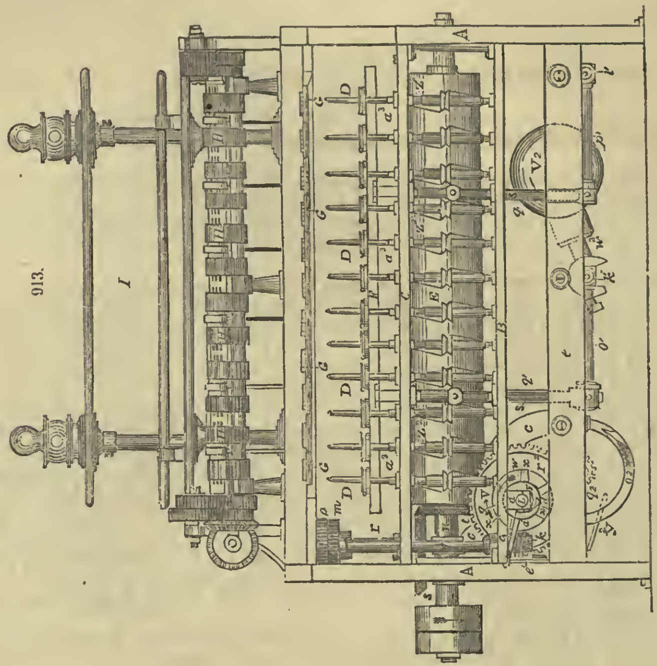
From the above it will be seen, that while the dog remains in any one of the spaces *x x*, &c., of the dog-wheel, the said dog-wheel will be so clutched to the scroll-shaft as to put the shaft in motion when the dog-wheel is rotated. When thus put in motion the shaft will continue to move until the lever *c′* is so borne against the stud *e′* as to press the spring-dog inwards, and out of the space *x*, in which it may happen to be.

The scroll-shaft will be then unclutched from the dog-wheel, and left free to move in an opposite direction, and will drag the spring-dog around with it until it meets the succeeding notch *x*, and springs into it, and by so doing, again clutches the dog-wheel to the scroll-shaft.

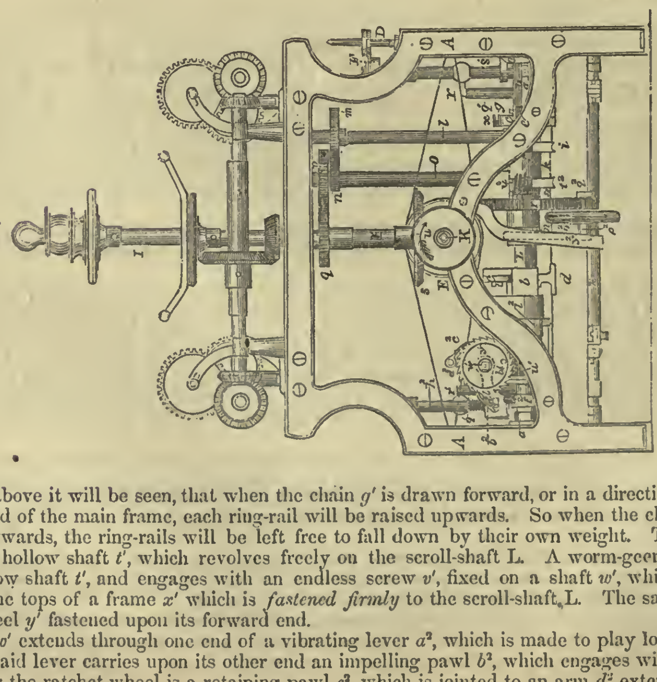
On the scroll-shaft is a cam or scroll *f′*, Fig. 920, made to move freely on the shaft. This cam has a chain *g′* attached to it, Figs. 920 and 915. The chain is carried horizontally over a guide-pulley *h′*, and thence downwards, and is connected to an arm *i′*, which projects from a horizontal transverse rocker

shaft k'. A similar transverse rocker-shaft l' is arranged parallel to the shaft k'. From each of the shafts k' l' an arm m' extends upwards, and is jointed to a horizontal connecting-rod n'. Each of these shafts has also two other arms o' o', or p' p', extending from it, Fig. 915. To each of these last-mentioned arms one of four vertical rods q' q' q' q' is jointed. Each ring-rail F is indirectly supported on two of the rods q' q'; that is to say, small studs r' r', from its vertical guide-rods s' s', rest upon the tops of said rods.

913.



914.



SCALE.—1 foot=1 inch.

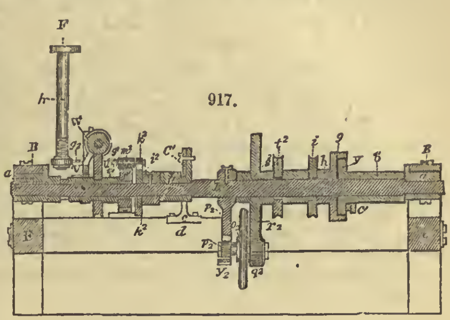
From the above it will be seen, that when the chain g' is drawn forward, or in a direction towards the right-hand end of the main frame, each ring-rail will be raised upwards. So when the chain is suffered to move backwards, the ring-rails will be left free to fall down by their own weight. The scroll f' is fixed upon a hollow shaft t', which revolves freely on the scroll-shaft L. A worm-gear u' is fixed on the said hollow shaft t', and engages with an endless screw v', fixed on a shaft w', which revolves in bearings in the tops of a frame x' which is *fastened firmly* to the scroll-shaft L. The said shaft w' has a ratchet-wheel y' fastened upon its forward end.

The shaft w' extends through one end of a vibrating lever a^2, which is made to play loosely upon the shaft. The said lever carries upon its other end an impelling pawl b^2, which engages with the ratchet-wheel. Over the ratchet-wheel is a retaining pawl c^2, which is jointed to an arm d^2 extending upwards

from the frame x'. The ratchet-wheel y' has a small crank-handle b^4 projecting from its side to turn the whole back and lower the ring-rail when the pawls are thrown up, and when desirable.

Directly under the rear end of the lever a^2 is a bent lever e^2, which turns upon the scroll-shaft as a fulcrum. Its outer end rests, when in its lowest position, on the top of a stationary standard f^2, affixed to the lower girt of the cast-iron end of the main frame. The inner arm of the said lever e^2 extends directly under a horizontal projection g^2 applied to a vertical rod h^2, extending downwards from the adjacent ring-rail F. The said projection g^2 should be so adapted to the rod h^2 that it may be elevated or depressed by adjusting-screws and nuts, in order that its position may be regulated as circumstances may require.

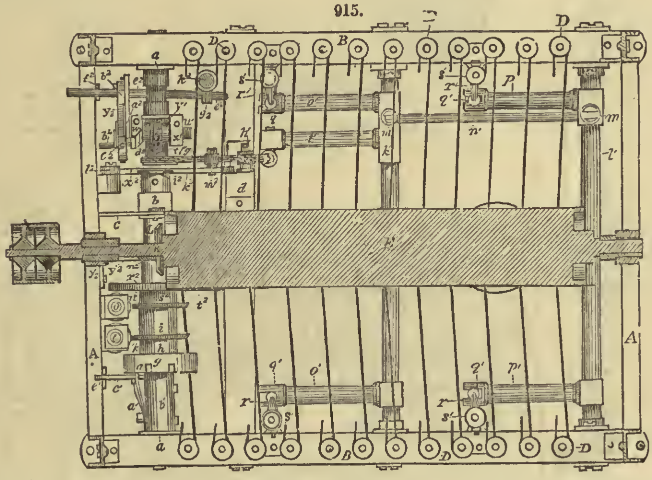
917.



The scroll-shaft has a cam i^2 fixed firmly to it. The said cam is seen in Fig. 921, which represents a section of it, and the lever beneath it. It also exhibits the chain g', and various parts adjacent thereto. The cam i^2 is made to act upon and depress a lever k^2, whose fulcrum is at l^2. The said lever carries a roll m^2, applied to the side of its inner end, and resting on the chain g^2.

Now in order that the ring-rail may not fall so suddenly as to break the yarns, or not put on the cop a sufficient quantity of binding-thread, some kind of mechanism becomes necessary to cause it to fall with the required velocity.

915.



SCALE.—1 foot=1 inch.

An arm n^2, fixed to the scroll-shaft L projects downwards from it, and carries a small fly-wheel o^2 on an axle p^2, extending horizontally from it. Said fly-wheel has a small pinion q^2 affixed to it, which engages with a spur-geer r^2 fixed to a tubular shaft s^2, which runs loosely upon the scroll-shaft. On the said shaft s^2 is a worm-geer t^2 which engages with an endless screw u^2, placed on the vertical shaft o, before mentioned. The said endless screw u^2 should so revolve the geer-wheel t^2 as to turn the shaft s^2 and the geer-wheel r^2 in the direction of the arrow on said wheel r^2.

The wheel r^2 will then act on the pinion, and put the fly-wheel o^2 in rapid revolution in the direction of the arrow; this taking place while the ring-rail is being raised, will cause a considerable momentum to be generated in the fly-wheel, which rises upwards with the arm n^2, which will be carried up by the forward movement of the scroll-shaft. Now when the ring-rail falls, the momentum so generated in the fly-wheel will be brought into action in such manner as to cause the pinion q^2 to so operate against its geer r^2, as to counterbalance in a certain degree the tendency of the ring-rail to fall too suddenly. The ring-rail will thus be eased down, so as not to break the threads, and with the degree of velocity necessary to insure the laying of a due quantity of binding-thread on the cops.

The ring-rail may be further counterbalanced by an adjustable weight v^2, applied to an arm w^2 extending from the rocker-shaft k'.

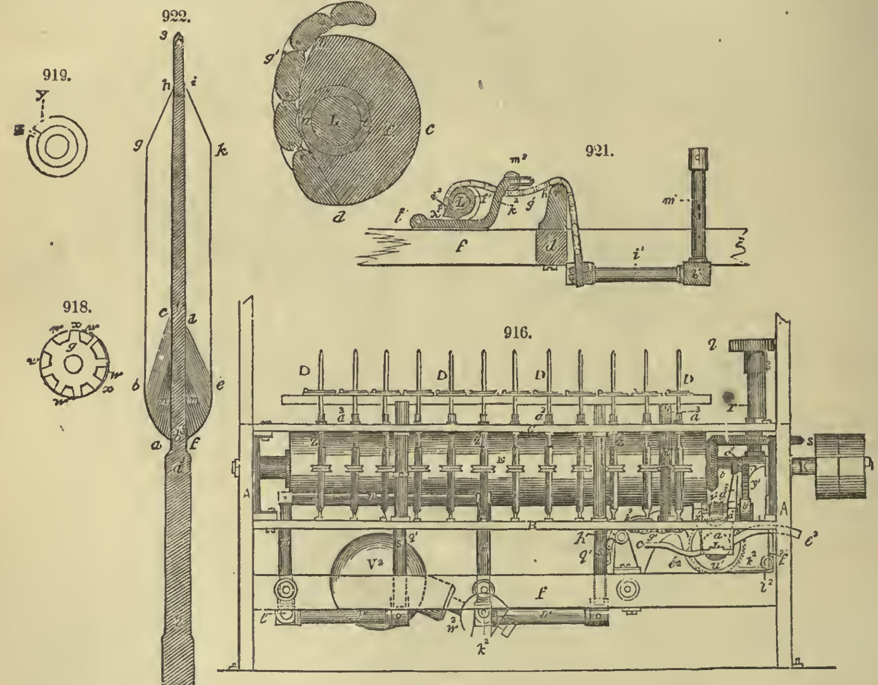
By means of the scroll f', the length of each successive layer of yarn composing the cop is regulated. The elevation of the ring-rail is gradually increased by the peculiar shape given to the scroll f', and the gradually turning said cam on the shaft.

Fig. 922 represents a longitudinal and central section of a cop, placed on a spindle l. The part $a\,b\,c\,d\,e\,f$ of the cop, is termed the *bottom part*, and all above, the top part. The first layer of yarn is wound on the spindle a distance $a\,n$, equal to about one half of the length $b\,c$ of the last layer composing the bottom part of the cop. From the above, it will readily be understood why the scroll or cam f' must be gradually turned on the scroll-shaft, so as to increase the length of each successive layer of yarn composing the bottom part of the cop.

It is the purpose of the worm u', endless screw t', shaft w', frame x', ratchet-wheel y', vibrating lever

a^2, impelling pawl b^2, lever e^2, standard f^2, projection g^2, and rod h^2, as before described, to produce the gradual rotation of the cam, both to form the bottom and top part of the cop. When the scroll-shaft is moved forward, the lever a^2 will be moved against the lever e^2, and thereby cause the impelling pawl b^2, to turn the ratchet-wheel y' a short distance, so as to create a movement of the scroll or cam f' on the scroll-shaft. The movement of the ratchet-wheel is increased by elevating the outer end of the lever e^2, which may be effected by depressing the adjustable projection g^2 of the rod h^2. Owing to the manner in which the scroll f' is made, it becomes necessary to turn it somewhat faster on the scroll-shaft at first, while forming the lower portion of the bottom part of the cop, than it does as the winding of the said bottom part continues to progress. In winding the top part of the cop, the scroll has a regular progressive motion upon its scroll-shaft, and the portion $b\,c\,d$, Fig. 920, of its periphery is then receiving and acting on the chain g'; while the bottom part of the cop is being made, the portion $a\,b$, Fig. 920, is in action upon the chain.

In order to cause the ring-rail to rise upwards with the increased velocity necessary to prevent the yarn from piling too much in one place, and thereby destroying the *conical* form of each layer of yarn, the cam i^2, lever k^2, and roll m^2, are used, the cam being so formed as to properly depress the lever k^2, to the extent required, to cause the roll m^2 to bear down upon the chain g', so as to produce the gradual increased rise of the ring-rail.



Scale.—1 foot=1 inch.

As it is very important that but very little yarn should be wound at the nose or upper part of each layer of the cop, the cam i^2 has an angular projection x^2, (see Fig. 921,) which as soon as the cam has completed its action in the lever k^2, shall in its turn depress the lever so as to cause a very sudden rise of the ring-rail sufficient to produce the effect required. A friction-spring y^2, at the end A of the main frame, acts as a stop to gradually check the motion of the arm n^2, when it falls down.

It often happens that the ring of the ring-rail may render it difficult to get hold of the end of the thread wound on the cop. In order to overcome this difficulty, the spindle, for about one inch and a half below its upper bearing, is made of the same size or diameter as the part which runs in the bearing, as seen at z^2, in Figs. 913 and 922.

By taking hold of the spindle when so made, it may be readily raised upwards, so as to carry the broken end of the thread above the ring of the ring-rail, and into such a position as will readily enable the operative to join the ends of the yarn when broken.

In order to obtain the advantages of a small spindle, and with a diameter at bottom large enough to start the traveller without danger of rupture of the yarn, the part a^3 of the spindle directly below that on which the cop is formed, is made of a diameter large enough to produce the lateral drag upon the traveller, required to overcome its inertia when first started, and give to it a velocity that will prevent the thread from breaking; and, before commencing the cop, a few turns of yarn are wound on the said part of the spindle. That part of the spindle on which the cop is formed, (viz. the part $b^3\,c^3$,) is made of as small a size as will be allowable and admit of its possessing the necessary strength.

The spindle so constructed is seen in the drawings. By this mode of making it, cops can be doffed without first being obliged to raise them upwards on the spindles by the hand far enough to allow of a

few turns of yarn to be laid on that part of each spindle on which the cop is first commenced, as is generally done in mule spinning.

A convenient velocity for the spur-geer r^2, is one revolution to sixteen of the front drawing-roller; and for the clutch g, at the rate of sixty-four one-hundredths of a revolution to eighty revolutions of the front drawing-roller. The patentee mentions these proportions, but does not confine his invention to such.

Mr. Dodge claims the combination of mechanism by which the scroll-shaft has a partial rotary forward motion imparted to it, and is allowed to fall or move backwards, the same consisting of the standard e^1, or any equivalent, the bent lever c', the spring-dog a^1, the clutch or dog wheel g, or their mechanical substitutes; the whole being arranged, applied to the scroll-shaft, and operated and made to operate together substantially. And in combination with the shaft, and machinery for imparting to it its rotative motion or motions, he claims the cam, and chain, and machinery connecting the shaft with the ring-rails. He further claims the combination of mechanism by which he is enabled to regulate the length of each successive layer of yarn composing the cop; the same consisting of the cam f^1, and made to rotate on the scroll-shaft; the worm-geer u', endless screw t', shaft w', frame x', ratchet-wheel y', vibrating lever a^2, impelling pawl b^2, lever e^2, standard f^2, projection g^2, and rod h^2, extending downwards from the ring-rail, or their mechanical equivalents; the whole being combined and made to operate.

Further, in its application to the scroll-shaft, the combination of mechanism by which the fall of the ring-rail is regulated in such a manner as to prevent it from descending too suddenly so as to break any of the yarns; the mechanism consisting of the fly-wheel o^2, and machinery for turning it, as applied to the scroll-shaft, and made to operate in connection with it. And for the purpose of causing the ring-rail to rise upwards with the increased velocity necessary to prevent the yarn from piling too much in any one place, and thereby destroying the conical form of such layer of yarn composing the cop, Mr. Dodge claims the cam i^2, lever k^2, and roll m^2, as combined with the scroll-shaft, and the chain g'. And in combination with the machinery, he claims the projection x^2, applied to the cam i^2, for the purpose of producing a very quick rise of the ring-rail, in order to finish the nose or upper extremity of each layer of yarn composing the cop. And he also claims the above-described manner of making each of the spindles, in order that it may be elevated so as to carry a broken end of yarn above the ring-rail, so that an attendant may readily seize it to piece up or join it to the thread proceeding from the draw-rollers, without being obliged to wait for the ring-rail to fall downwards.

He further claims the construction of the spindle directly beneath that part of it on which the cop is formed of a diameter proper to produce the lateral drag on the traveller, sufficient to overcome its inertia, and impart to it a velocity necessary to prevent the yarn from being broken in combination with making that part of the spindle on which the cop is formed smaller in diameter.

CORNISH BOILERS. See Boilers.

CORNISH ENGINE. A single acting beam engine, used for raising water: the steam is worked very expansively, and used for the down-stroke only, to raise an immense weight, fastened to the pump-rod, at the end of the beam: the steam having acted for the down-stroke, and the entrance-valve being closed, a communication is formed between the top and bottom of the cylinder, by lifting a valve in the steam passage, called an equilibrium valve: the pressures on the piston are thus equalized, and the weight acts to force the water up, and raise the piston.

Fig. 923 is a sectional elevation of the cylinder and valve geer, and fig. 924 a front elevation of the valve geer of a Cornish Engine.

A is the cylinder shown in section fig. 923. It is 70 inches internal diameter, and of such length as to allow of a 10-feet stroke of the piston. It stands on a large block of stone, and is bolted firmly down by four strong bolts to the masonry below.

The cylinder is enclosed in a jacket or casing of cast-iron, which is of such a diameter as to leave a clear space of one inch all around between it and the outside of the cylinder. This space is made to communicate with the boilers by a pipe a, about 4 inches diameter, by means of which it is kept constantly filled with steam, preserving thereby the cylinder at a high temperature. This is of peculiar value in the Cornish engine, as it tends to prevent the steam within the cylinder from having its temperature and pressure lowered in an undue degree, while expanding, by contact with metal cooled by exposure to the air. The heat of the jacket also checks any waste by condensation, and experience has proved that if the jacket is removed a considerable reduction in duty is the consequence.

The boilers being so placed that the water line is at a lower level than the bottom of the cylinder, the water produced by condensation in the jacket finds its way back again to the boilers at a high temperature, by the pipe a.

In order to prevent radiation and consequent loss of heat from the outside of the steam case, the whole is surrounded with an outer covering of wood (shown by dotted lines b, fig. 923,) leaving an interstice between the wood and the iron. This space is filled with some bad conductor of heat, such as sawdust or ashes.

In the best Cornish engines, the temperature of the outside casing does not exceed 70° or 80°, and the atmosphere of the engine house is frequently only a few degrees warmer than the external air.

The cylinder cover and bottom are also protected from the cooling influence of the air of the engine-house. The cover is fitted with a false lid or cap c, enclosing a thick layer of sawdust or other bad conductor, over the whole of the metal of the cover. The space d, under the bottom of the cylinder is kept constantly filled with steam by a branch from the pipe a_3.

The stuffing box on the cylinder cover, through which the piston rod passes, is of peculiar construction. In the middle of the packing, and dividing it into two horizontal layers, a small chamber is formed by two brass rings c c, fig. 923, kept apart by small pillars or distance pieces, and allowing the piston rod to slide freely through them.

Into this chamber steam is admitted by a small pipe from the jacket of the cylinder, the oject of the arrangement being to prevent any leakage of *air into* the cylinder. When the pressure of the steam within is below that of the atmosphere, which it always is during a large portion of the stroke during

expansion, such leakage, if it occurred, would be of consequence in spoiling the vacuum. The rings e e forming the chamber, have liberty to slide a little in the stuffing box when the packing is screwed down This ingenious contrivance was invented by Jonathan Hornblower.

The piston, piston rod, and parallel motion present no remarkable feature of sufficient consequence to render a description of them necessary.

The main beam is, as usual in large engines, cast in two plates, which are bolted together with distance blocks between, to keep them parallel with each other. The inner end of the beam or that to which the piston rod is attached, is generally longer in Cornish engines than the outer end, which carries the pump rods, giving a leverage of about 10 8 or 9, in favor of the piston. The object of the difference being to give the pumps a lower velocity then the piston, such being found in practice to be advantageous to their working.

There is a strong bar of iron called a *catch piece*, fixed transversely by brackets upon the upper part of the beam, and intended to prevent damage being done by the engine making too long a stroke in-doors. When the piston arrives at the bottom of its stroke, or as near to the cylinder bottom as it is thought prudent to allow it to travel, the bar touches the blocks fixed on the spring beams, and prevents its further descent. Otherwise the cylinder bottom might be broken by an increased length of stroke consequent upon an increase of steam admitted, or on an accidental detachment of some of the counter-weight by breakage of the pump-rod.

C is the plug rod for working the valves and cataract.

The plug rod is sometimes single and sometimes double, the latter is the case with the engine shown in this fig. The two rods are there marked C 2, and C 3, 4, both are seen, fig. 924. The two rods are connected at their upper extremity by joints with the back links of the parallel motion, and work through guides i i, by which means they are constrained to move in a vertical line. The rod C 3, 4, is lengthened at its lower extremity for the purpose of working the lever of the cataract, as will be explained.

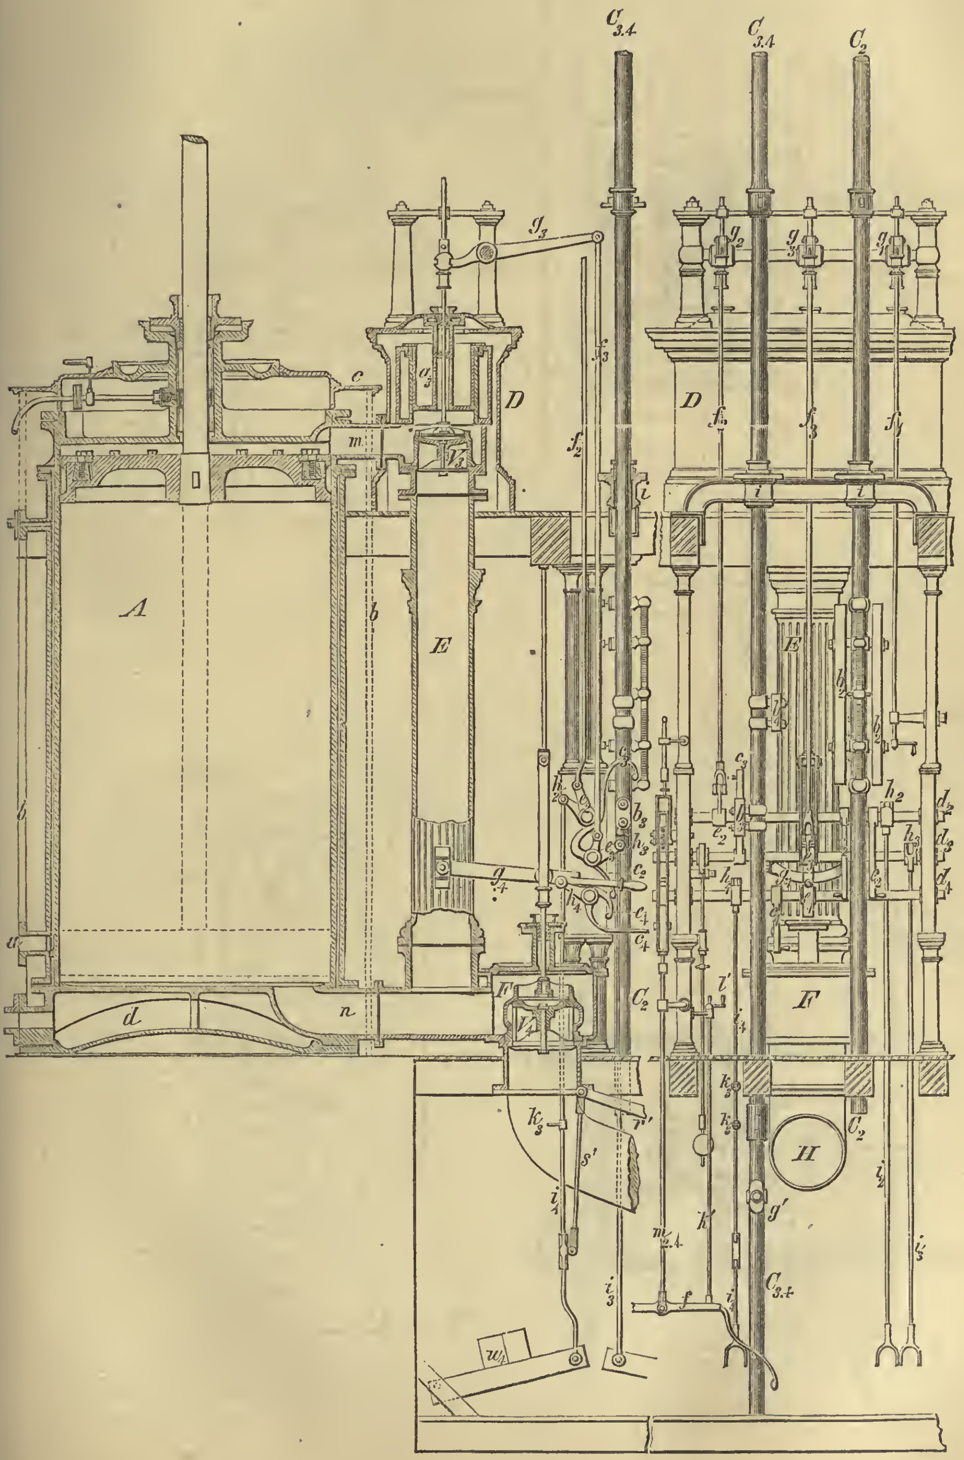
D is the top nozzle, shown on a larger scale and more fully in plan and section fig. 925-6. It contains three valves, viz. First; V_1, the *governor* or *regulating* valve, for regulating the admission of steam into the chamber k k of the nozzle, whence it afterwards passes through the steam valve V_2, into the cylinder. The opening of the governor valve is constant during the working of the engine, *i. e.*, it is not moved by the engine, but only occasionally by hand, for the purpose of regulation. It corresponds in some measure with that of the throttle or governor valve, in the rotative engine. By this means, although the pressure in the boilers may occasionally vary, the mean effective pressure in the cylinder may be maintained constant with great ease and precision. The motion of the governor valve is commanded by a handle placed within reach of the engine-man, and connected by a rod f_1 and lever g_1, with the stalk of the valve. The rod has a micrometer screw on its upper end, which works into a united socket attached to the end of the lever g_1, and thereby raises or lowers the valve. Second; V_2, fig. 925, Pl. V., the *steam valve*, for admitting steam into the cylinder. When this valve is raised (the governor valve being supposed open also), the steam finds a passage through it, from the nozzle chamber k k, into the space l, and thence by the upper steam port m into the upper part of the cylinder; the piston therefore descends, and the engine commences its in-door stroke. After the piston has travelled through a certain portion of its course, the steam valve is closed, by means hereafter described, and the communication with the boiler thereby cut off; the remainder of the stroke being accomplished by the expansion of the steam admitted. The steam passes through the chamber k k round the equilibrium valve, in the direction of the arrows (fig. 925), from the governor valve to the steam valve.

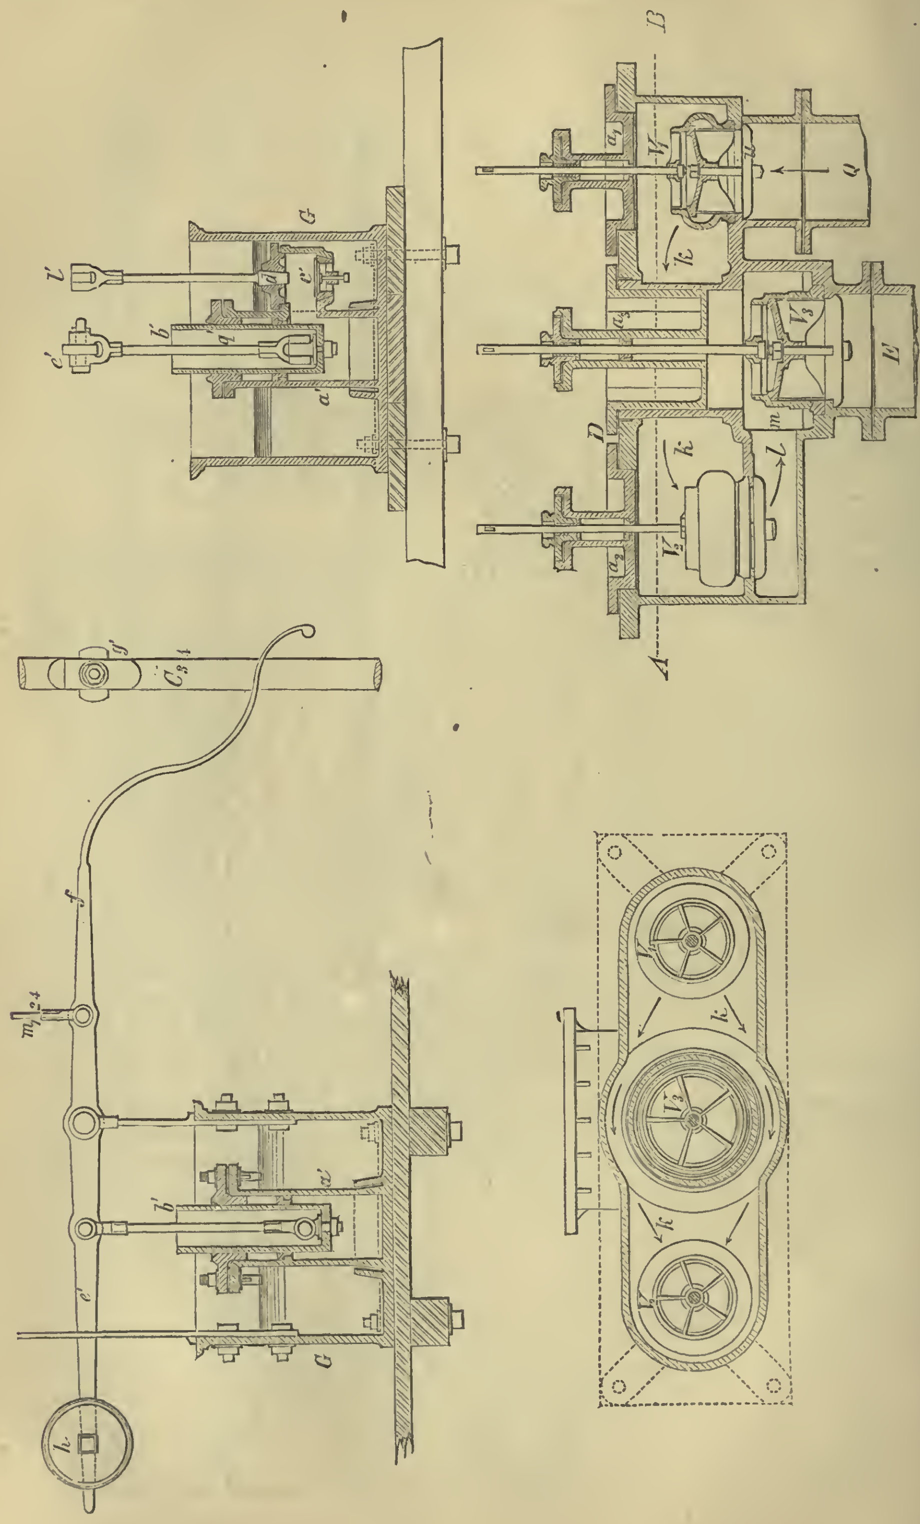
Third; V_3', situated in the middle of the nozzle, is the *equilibrium valve*, for opening the communication between the spaces in the cylinder above and below the piston. When therefore the valve is opened the steam above the piston will, by its excess of elasticity, find its way along the *equilibrium* pipe E, and by the lower port n, into the lower part of the cylinder, until an *equilibrium* is restored between the pressures above and beneath the piston, which then is at liberty to be drawn upwards by the preponderating weight of the rods hung at the outer end of the beam.

The top nozzle is, like the cylinder jacket, enveloped in an external casing, leaving an interstice all round, which is filled with sawdust or ashes to prevent loss of heat.

F is the bottom nozzle, seen in section fig. 923. It contains, V_4, the exhaustion valve, for opening or closing the communication between the lower part of the cylinder and the condenser. The nozzle chamber above the valve communicates with the cylinder by the lower port n, while to the *bottom* of the nozzle, under the valve, is attached the eduction pipe H, so that when this valve is lifted, the steam in the lower part of the cylinder has liberty to rush into the condenser, and a vacuum is thus formed beneath the piston. It will be remarked that the four valves last described are of a peculiar construction, being double-beat valves, (See VALVES), so called from their having two conical ground surfaces or beating faces, instead of, like the ordinary stalk valve, only one.

G is the cataract, fully shown in two sections, figs. 927-8, the use of which is to regulate the period of opening the steam and exhaustion valves, and thus to determine the interval between the successive strokes of the engine, that its rapidity of action may correspond with the quantity of water to be drawn from the mine. It consists of a barrel in which works a plunger, being in fact simply a small plunger forcing pump. The *inlet* is by a valve c' opening freely upwards, but the *outlet* is contracted at pleasure by a moveable plug d'. The pump is placed in a cistern of water G, and the plunger is attached by a joint to the arm e' of the lever e' f'. When the plug rod $C_{3\cdot 4}$, has descended nearly to the bottom of its stroke, a tappet g', upon the lower part of it strikes the end of the lever and thus raises the plunger, the water entering freely through the valve c'. When the stroke is finished, and the plug rod begins to ascend, the tappet g' quits the lever and the weight h', which is fixed upon the arm e', and has been raised by the preceding motion, becomes in its turn the motive power, tending to expel the water from the pump, by forcing the plunger





down. But the inlet valve before c', is closed, and the only exit for the water is by the aperture left round the regulating plug d'. It is evident therefore that the interval between the time the tappet g' leaves the cataract lever, and the commencement of the next stroke, depends upon the time occupied by the descent of the cataract plunger and ultimately upon the degree of opening given to the regulating plug d. This can be adjusted with great nicety by means of a micrometer screw and handle i (fig. 924,) connected with the regulating plug by the rod t and lever l.

H is the eduction pipe leading from the bottom of the exhaustion valve nozzle F to the condenser. This is double the area of the steam pipe. K is the condenser, L the air pump, the bucket of which has a stroke of half that of the piston. N is the feed pump, of the plunger description.

From Hughes we extract the following formula for the proportions of the cylinder. $a = \dfrac{W}{p\,v}$ a being the arc of the cylinder in square inches, W the work to be done, or the lbs. to be raised 1 foot high; p the pressure per square inch on the piston, and v the velocity in feet per minute. From numerous examples among the best machines, from 850 to 1,200 may be assumed as the value of $v\,p$.

Table showing the value of $v\,p$, from the actual working of fifteen Cornish Engines in 1855.

No. Name of Engine or Mine.	Average number of strokes per minute.	Length of stroke in feet.		Velocity of piston in feet per minute or value of v.*	Load per square inch on piston $= p$.	Value of $v\,p$ or continued product of number of strokes per minute, by length of stroke, by load in lbs. per square inch.	Average duty for the year expressed in millions of lbs. raised 1 foot high by consuming 1 cwt. of coal.

* The velocities in this column are the average monthly velocities, and are not always the product of the two first columns because the average number of strokes is only carried to one place of decimals. The velocities, however, are strictly correct.

CORN-MILL. By William Fairbairn, Manchester. Among the mechanicians who have contributed to the improvement of that description of machinery now under consideration, Mr. Fairbairn, of Manchester, occupies a most distinguished position, and accordingly, we find that he is most extensively employed in the erection of corn-mills throughout all parts of the continent of Europe. The example which we have chosen for detailed illustration is a small mill of three pairs of stones, erected by him for His Excellency the Seraskier Halil Pacha, of Constantinople. It is interesting, as exhibiting, within a small compass, an epitome of all the processes carried on in larger establishments, and thereby enabling us to show the mechanism by which these processes are effected on a larger scale than we could otherwise do.

Enumeration of the Figures.—Fig. 923 is a sectional elevation of the mill, the line of section being taken in a longitudinal direction, and exhibiting the position of the stones, the engine, and driving geering, and of such portions of the subordinate apparatus as are visible on the side of the mill which is exposed to view.

Fig. 924 is a sectional plan corresponding to the above, and taken on a horizontal line passing through the lower story of the mill.

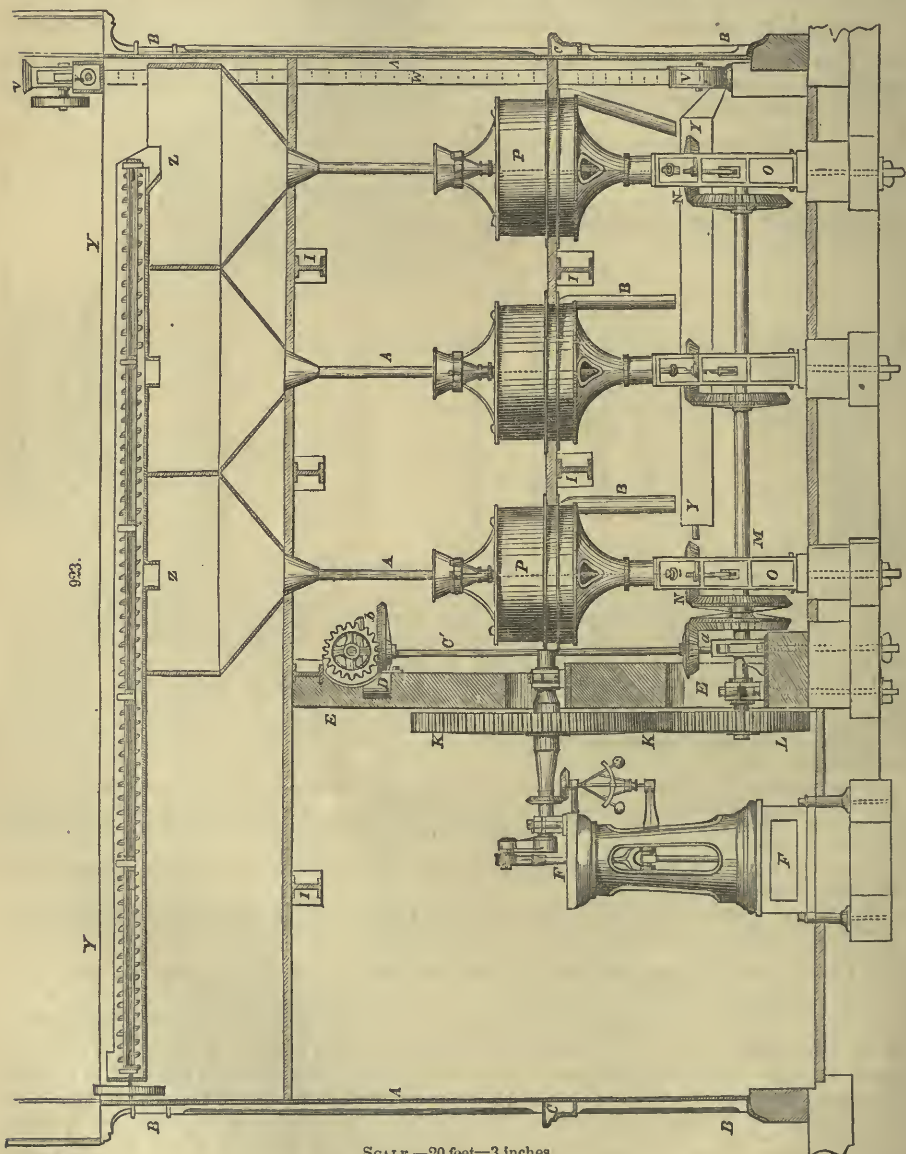
Fig. 925 is a transverse section of the entire mill, in which are shown the garners for undressed and dressed wheat, the mechanism by which it is cleaned and conveyed from the former into the latter, the sack-tackle, &c.

Fig. 926 is a sectional plan corresponding with the plan Fig. 924, the line of section being taken through the second story of the mill.

General Description.—The house in which this mill is contained consists of an assemblage of plates of sheet-iron, A A A, of a suitable thickness, consolidated and bound together by the cast-iron columns B B B, and by the strong cast-iron girders C C C, situated at such a height as to oppose and neutralize the strain of the principal working parts. It is surmounted by an arched roof D D, formed of plates of corrugated sheet-iron. A wall of masonry E E is erected in the interior, for the purpose of affording a foundation for the bearings of the heavier geering of the mill. The motive power is supplied by a high-pressure steam-engine F, of 12-horse power, its principal working parts are wholly inclosed within a large cast-iron column. By this arrangement great firmness and stability is imparted to the engine, while the space which it occupies is reduced to the smallest possible dimensions. The boilers G G are situated in an adjoining part of the house, and their flues H H are formed, in the usual manner, of brick-work, abutting on the one hand against the wall E, and on the other against the side of the house itself. Thus the engine and boilers occupy nearly the entire half of the lower story of the mill. The whole erection is strengthened and bound together by the cast-iron beams I I I, which pass transversely through the interior of the house, and are supported, in the middle of their length, by the columns J J. On these beams, also, the flooring of the lower and upper flats is disposed.

The fly-wheel K K of the steam-engine, is formed with teeth on the exterior of the rim, thus serving at once to regulate the velocity and to transmit the power of the steam-engine to which they are attached. The spur fly-wheel K K, the diameter of which is 9 feet 3¾ inches, geers with the pinion L of 4 feet 10¾ inches diameter; consequently, the velocity of the crank-shaft is nearly doubled upon the horizontal shaft M M, to which the latter is fixed, and which, by means of the bevel wheels and pinions N N N, gives motion to the stones contained within the stone-cases P P P. The shaft M M has a bearing upon the wall E, close to the back of the pinion L, and one in each of the standards O O O, to which the mechanism necessary for impelling and regulating the action of the stones is attached.

923.

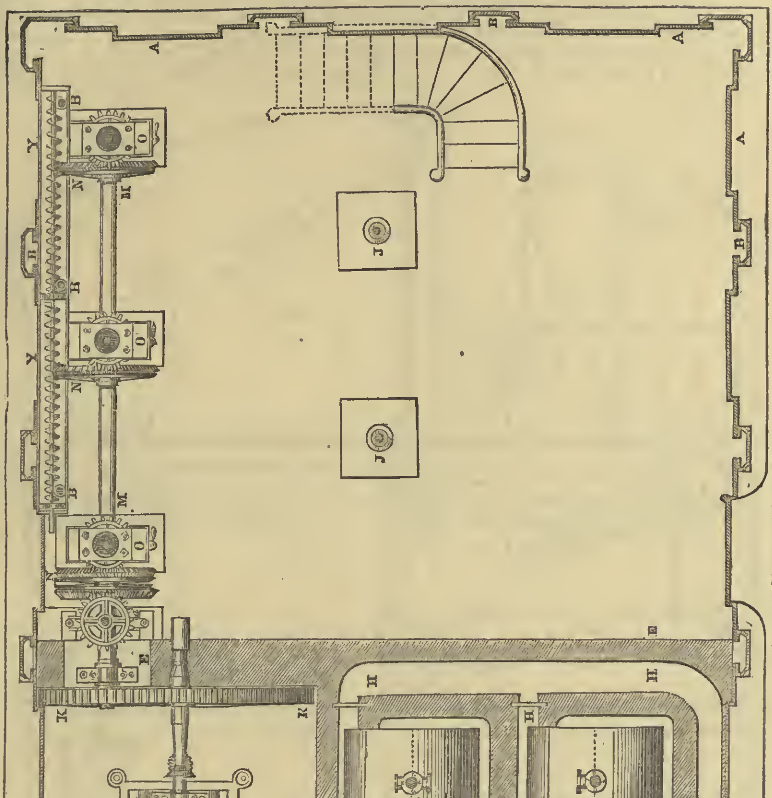


SCALE.—20 feet=3 inches.

The corn to be ground is deposited in the upper floor of the mill in the large garner Q Q, from which it is conducted through the spout R, into the *screening*-machine S S, where it is cleansed of the dust and other extraneous matter which is found more or less combined with it. This machine consists of a species of cylindrical sieve, formed of wire-cloth, and partitioned inside so as to resemble an Archimedean screw. It is mounted upon an axis, and revolves with a considerable velocity in the interior of a close box, in which it is set at an angle with the horizon. The corn enters at its upper extremity, and, after being thoroughly agitated by its passage through the partitions in the interior of the screen, and thereby divested of the greater portion of the refuse with which it was mixed, falls into a spout U, at

its lower end, which conducts it to the *elevator* V; being subjected, in its passage through this spout, to the action of a blast from the fan T, by which the remaining portion of the sand and dust that escapes with the grain is carried off by a passage leading to the exterior of the house. The grain, after being thus cleansed, is caught up by the elevator V, and raised nearly to the summit of the mill, where it is delivered, through an inclined spout X, into the *creeper-box* Y Y, by which it is distributed into the feeding-garners Z Z Z.

924.



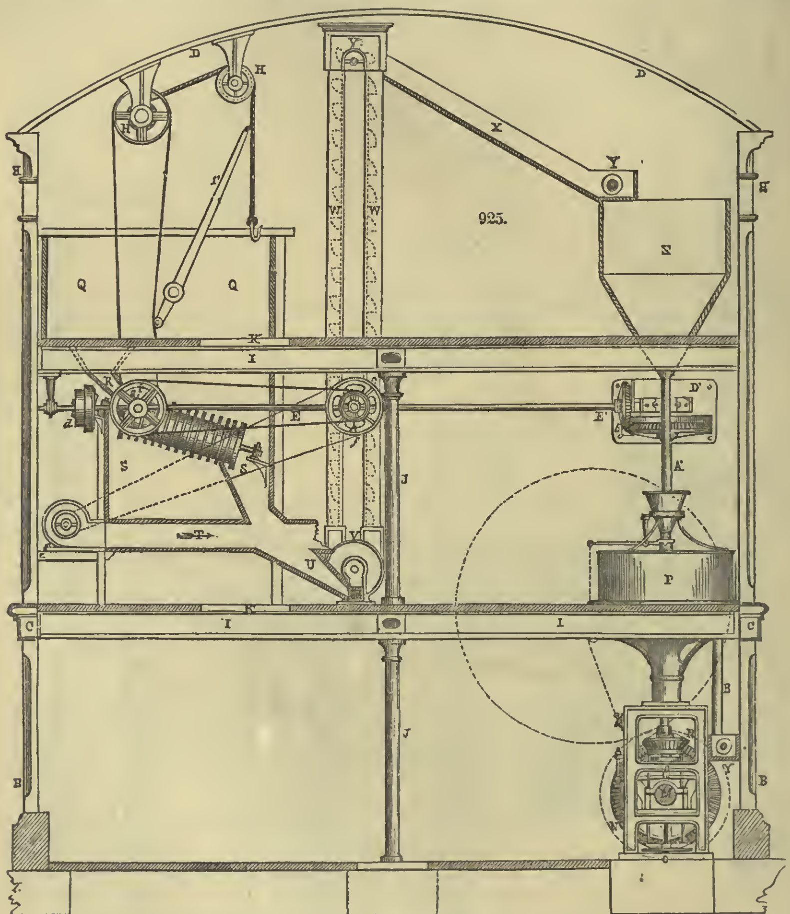
SCALE.—20 feet=3 inches.

The *elevator* consists of a long endless chain of small buckets formed of tin-plate and mounted, at regular distances, upon a leather band passing over two pulleys inclosed within the cast-iron frames V V. The uppermost of these pulleys is driven at a moderate velocity by a belt, and the buckets, passing in succession the opening by which the grain is delivered from the screen, become each charged with a small portion of it; this they convey through the wooden pipes or boxes W W, in which they are inclosed, to the upper extremity of the chain, where they deliver their contents into the spout X.

The contrivance just described is applicable only to the raising of the grain or flour from a lower level to a higher. For horizontal transport, modern millwrights make use of an apparatus called the *creeper*, a long endless screw with a wide pitch and thin threads, inclosed in a wooden box or trough, of dimensions slightly greater than its own diameter. It is made to revolve upon its axis, by means of a belt and pulleys, at a velocity corresponding with that of the elevators, and, being restricted from moving longitudinally, the threads, or rather leaves, of the screw, force the grain introduced at one end

of the trough to the other. The action of the screw in the case of the creeper is identical in its nature with that of the endless screw in giving motion to a worm-wheel.

The corn which is supplied to the garners Z Z Z, falls through the feeding pipes A′ A′ A′, into the hoppers, by which the grinding apparatus is surmounted. After being reduced into flour, it falls through the pipes B′ B′ B′, into the creeper-box Y′ Y′ Y′, by which it is transferred to the elevator V By this elevator it is again raised to the summit of the house, and carried by means of the creeper Y′ to the *dressing*-machine S′. It may be remarked that, besides the great saving in manual labor effected by the use of these contrivances for transporting the flour from one part of the mill to another, they are attended by another very important advantage: by exposing the flour liberally to contact with the air, the heat evolved during the process of grinding is abstracted, and the moisture evaporated; an operation which it is of essential importance that it should undergo previous to the process of dressing



SCALE.—20 feet=3 inches.

This machine, which is very similar in external appearance to the screening-machine already described, consists of a hollow cylinder covered with wire-cloth of different degrees of fineness, the finest being at the end which is most elevated. Within the cylinder, which is stationary, a circular brush revolves, in contact with the wire-cloth of which it is composed. The flour which is fed into the cylinder is, by the motion of the brush, sifted or rubbed through the wire, the finest through the upper end, the second through the next division, and so on, till the bran falls through the end of the cylinder, being too coarse to pass through any of the wires.* The different products thus separated are then stored in sacks, or otherwise disposed of as may be most convenient.

The sack-tackle is very simple, and will be readily understood from the drawing. It consists of a barrel H, provided with a rope of sufficient length to reach to the lower floor of the mill, and fitted to

* On the processes undergone by the corn both previously and subsequently to the grinding, much of the success of the whole operation depends. In place of the wheat-screen, an apparatus called a *sheeling-mill* is employed in some establishments. This consists of a pair of ungrooved millstones working at such a distance apart that the grain is merely rubbed between them, but not cut or broken. From the stones it is received upon an inclined sieve, where the heavier parts of the refuse fall from it, and is then exposed to the blast of a fan which deprives it of the remaining lighter portions. For dressing the *flour*, *bolting*-machines are very generally used either in combination with, or in place of, the dressing-machines described above. These contrivances, however, come more within the province of the *miller* than of the *millwright*.

i, pulley on the intermediate shaft for driving the sack-tackle.
G′, the intermediate shaft for conveying motion to
H′ H′, the sack-tackle.
I′, a lever for starting and stopping the sack-tackle.
K′ K′, hatchways by which the sacks are admitted or withdrawn.

revolve in bearings attached to the roof; it receives motion, when required, from a belt connecting the pulley on its axis with a shaft G′ worked by the engine. The length of this belt is so adjusted that the sack-tackle may remain at rest, or be set in motion, according as the long lever I′, (the action of which is to tighten or relax the belt as may be required,) is drawn to the right or left.

The geering by which the subordinate machinery of the mill is driven consists, first, of an upright shaft C′ C′, set in motion by a pair of bevel wheels *a*, from the main horizontal shaft M M. This shaft has its lower bearing in an arched standard embracing the shaft M, and at its upper extremity it is supported by a plummer-block bolted to a double bracket D′, imbedded in the wall E. Its motion is here transferred by means of another pair of bevel wheels *b*, to the horizontal shaft E′, passing transversely across the mill. On this shaft are fixed the pulleys *d* and *e*, which drive the screening and dressing machines; and a set of small bevel wheels *c c*, serve to transmit the motion to the longitudinal shafts F′ F′, by which the elevators, creepers, &c., are propelled; as also the short shaft G′, by which the sack-tackle is driven.

The dimensions of the various wheels, pinions, and pulleys, employed in this mill, and the velocities imparted by them to the machines driven by them respectively, are given in a tabular form below.

Steam-engine F, 12-Horse Power makes 40 Revolutions of Crank-shaft per Minute.

Details of Corn-Mill.—The figures exhibit the constructive details of the grinding apparatus, and of some of the subordinate machinery employed by Mr. Fairbairn in all his most recently erected mills, whatever may be their extent and the number of stones they contain. The height of the stone floor (or level at which the mill-stones are situated) from the foundation varies slightly in different mills, and the diameter of the driving-shaft must be increased or diminished in proportion to the number of pairs of stones to be driven, and to the distance of each individual pair from the prime mover. The only deviations from the form and dimensions here given, are, in the former case, to alter the length of that part of the framing called the cone B B, and in the latter to increase or diminish the diameter of the bearings in the plummer-block G G.

Enumeration of the Plates.—Fig. 927 is a front elevation of the grinding machinery, exhibiting the external appearance of the whole.

Fig. 928 is a general section taken on a vertical plane at right angles to that of the elevation, Fig. 929. In this view the millstones and the whole grinding apparatus are shown in combination.

General Description. The Framing.—A strong cast-iron standard or framing A A, securely bolted to a stone foundation by two holding-down bolts, incloses the principal part of the driving and adjusting geering for each pair of stones. It is made somewhat in the form of an oblong box, and is traversed by two horizontal diaphragms or partitions, cast of a piece with it, the upper one for sustaining the lower bearings of the mill-spindle, and the under, the plummer-block of the driving-shaft. It is surmounted by a large bell-shaped casting B B, called the *Cone*, firmly bolted, by a flange at its lower end, to the standard, while the upper extremity is expanded, and terminates in a cylinder, of a diameter somewhat greater than that of the millstones, the lower of which rests, and is secured, within it. Two straight and broad flanges are cast at the opposite sides of the cylindrical part, for the purpose of bolting the cone to the beams of the mill, or to the same parts of the framing of the contiguous pairs of stones, while another circular flange passes all round, for sustaining the flooring. Three large openings are left in the upper part of the cone to give access to the interior, and it is provided with suitable arrangements for the reception of the several adjusting screws required for the setting of the lower stone.

The Stone-Case and Feeding Hopper.—Above the cone, and of the same diameter with the cylindrical part of it, is placed the stone-case C, which surrounds the upper stone, and serves to confine the flour which is the result of the grinding. This is simply a cylinder of thin sheet-iron, resting upon the stone floor, and having affixed to the top of it a ring of wood, on which the tripod for supporting the feeding apparatus is set. This cover is made open in order to admit the air freely between and around the stones during the process of grinding. A cast-iron ring D, supported by three malleable-iron legs *a a a*, forms a sort of tripod in which is placed the hopper E, which receives the grain from the garners above.

through the feeding pipe *b*, and supplies it to the stones by means of the feeding apparatus to be hereafter described. A piece of coarse wire gauze is placed in the hopper E to intercept any foreign body that may descend with the grain.

The Driving Geer.—The driving shaft F is part of the line of horizontal shafting which is common to the whole range, and which receives its motion from the prime mover, generally through the intervention of a single wheel and pinion. The velocity of this line of shafting is usually from 70 to 80 revolutions per minute, with stones of the diameter of those in our examples. The different lengths of which it is composed are connected together by couplings of the same description as that described and represented at Figs. 950 and 951. The shaft F revolves in brass bearings, fitted into a plummer-block G, bolted to a sole formed, as before noticed, in the standard A. The strain of the shaft being entirely in a downward direction, this plummer-block requires no cover, the journal being simply protected from injury by a slight brass cap.

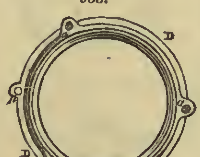
A large bevel mortise-wheel H, working into the pinion I, on the mill-spindle, serves to transmit the motion of the shaft F to the latter. The pinion is not fixed immoveably upon the spindle, but is capable of sliding vertically upon it by means of a sunk feather.

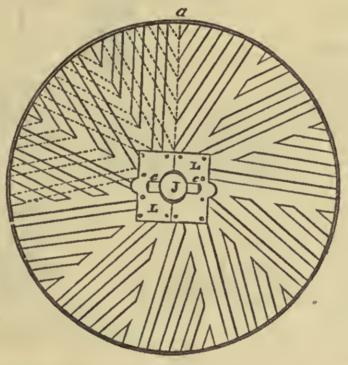
The Mill-Spindle and its Appendages.—The mill-spindle J J is made of the best forged-iron, accurately turned over its entire length, and rises perpendicularly through the standard A, the cone B, and the lower millstone. It is attached to the upper, or running stone by means of a cast-iron piece K, called the *Ryne*, which combines this function with that of regulating and delivering the supply of grain to the stones. It is in the form given to this very important part that Mr. Fairbairn's most recent improvement in grinding machinery consists. It will be observed by the drawings, Figs. 936 to 940, that it forms a species of universal joint; the small steel crosshead *c c* on the top of the mill-spindle fitting into corresponding bearings in the ryne, while the projecting tails *d d*, cast upon it at right angles to the former, work in similar bearings formed of small cast-iron pieces sunk into the stone. By this arrangement it will be observed, that the connection between the mill-spindle and the upper stone is complete, while at the same time it admits of the free and unconstrained action of the latter against the grinding surface of the lower stone.

The lower, or fixed stone is perforated by a large square hole in its centre, into which the cast-iron block L, Fig. 942, is firmly fixed by slips of wood and wedges. Into this block are fitted the three brass bushes *e e e*, which form the upper bearing of the mill-spindle. These are adjusted by means of the wedges *f f f*, the screwed tails of which pass downwards through the cast-iron ring *g*, and are regulated by thumb-screws on each side of it. The large openings in the cone, before alluded to, afford access for the working of these screws. Small semicircular chambers are formed in the socket L, between each bush, and filled with hemp and tallow, for the lubrication of the mill-spindle; and the whole is carefully protected from dust by slips of sheet-iron screwed over it, Fig. 941.

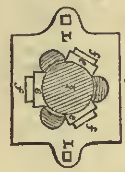
941.

933.





943.



942.

944.

The Millstones.—The diameter of the millstones most in use at the present day is 4 feet, and their thickness about 12 inches; one-half of this thickness is composed of French burr, a very hard, though porous mineral, of a silicious nature; the other half is made up of plaster of Paris. In consequence of the difficulty of obtaining sufficiently large masses of the French stone, it is usual to construct the millstones in segments, which are cemented together, and the whole firmly bound by iron hoops passing round the circumference. The lower stone is, in the first instance, carefully dressed into a perfectly flat, plane surface, but the upper one is made slightly hollow for a small distance from the central aperture, so as to allow the grain to be freely admitted between the stones. Being thus prepared, grooves are then cut on the rubbing surfaces of both, in the manner indicated in Fig. 941. The circumference of the stone is first divided into eleven equal parts;* lines are drawn from each division to the centre; these radii determine the limits of the grooves in each compartment. A chord $b' c'$ is then drawn, joining the bounding radii of any two compartments; this chord is, of course, bisected by the intermediate radius J a', in d'. Divide the line $d' c'$ into four equal parts in the points $e' f' g'$; and from these points mark off, on the line $d' c'$, distances equal to the width of the groove to be cut; then draw through all these

* The number of channels formed in the stones, and consequently the number of compartments, or *quarters* into which they are primarily divided, are varied by different millers, but the mode of drawing the lines, as here given, is applicable in all cases.

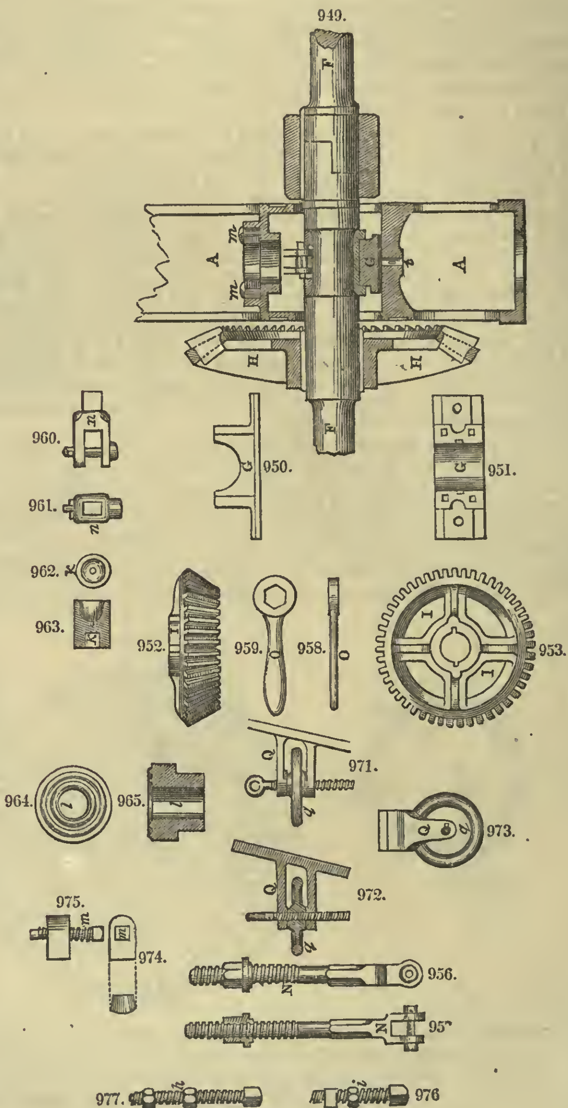
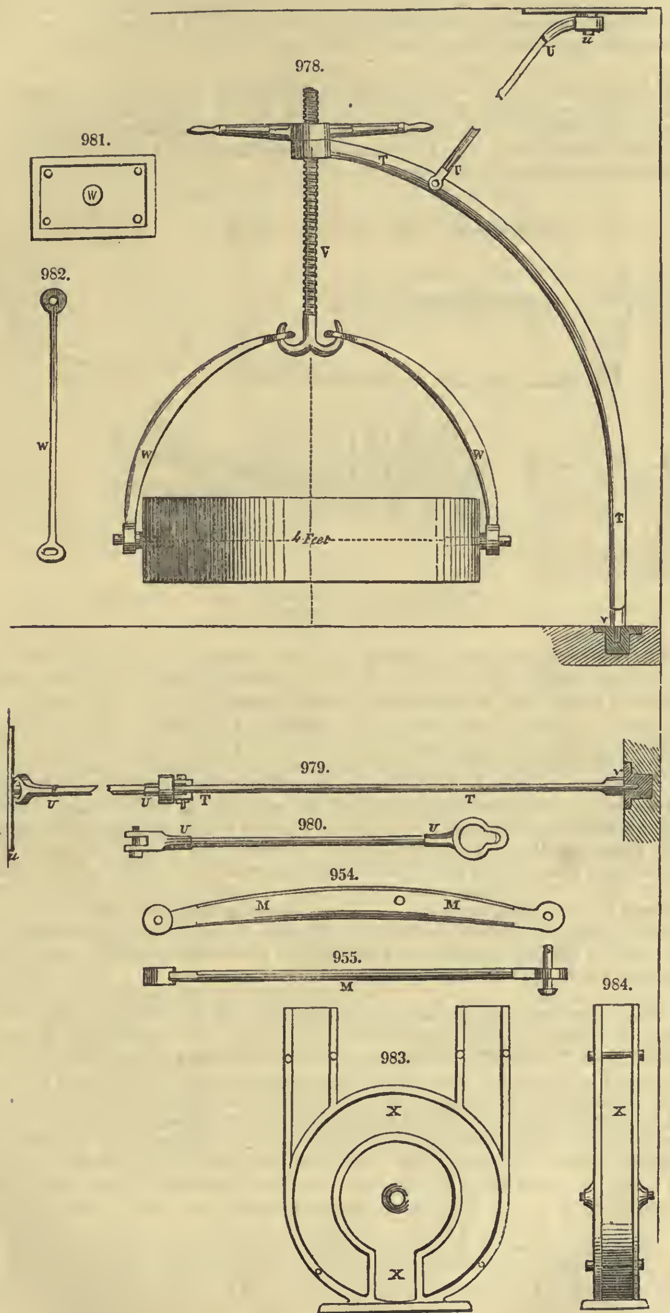
u v, the centres of motion on which it rotates.
X, the lower elevator-frame, of cast-iron.
Y Y, the creeper, of cast-iron.
w x, blocks and studs for connecting the adjacent lengths of the creeper.
y, the brackets in which it revolves.
Z Z, the creeper-box, of wood.



points of division lines parallel to the radius J a', terminating them in the radius J c'. These are the outlines of the grooves, which are then to be cut into the stone, perpendicularly on one side and obliquely on the other, so that each furrow shall have a sharp edge. The direction of the grooves being the same in both upper and lower stones as they lie on their backs in the position proper for being cut,



It is obvious that when the former is reversed and set in motion, their sharp edges will meet each other after the manner of a pair of scissors, (as partially shown by the dotted lines in Fig. 941,) and thus grind the corn more effectually when it is subjected to the action of the unbroken surfaces between the channels.

Adjustment of Lower Stone.—It is of the most essential importance to the proper working of any pair of stones, that the grinding surface of the lower stone should be perfectly level, and that its centre should be exactly perpendicular above that of the lower bearing of the mill-spindle. To secure the former of these conditions, three pinching-screws *h h h*, are fitted into the cone, (that number being greatly preferable to four in adjusting the *level* of any surface;) and, bearing against small slips of iron sunk into the stone, it can be raised or depressed by them to any required extent. The *centering* of the stone is effected by means of *four* pinching-screws *i i i i*, acting horizontally upon it. To secure it against deviating from the truth after having been properly adjusted, all these screws are provided with jam-nuts.

Adjustment of Mill-Spindle.—The lower bearing or footstep of the spindle J is also made capable of nice adjustment, both horizontally and vertically. The former is necessary in order to ensure the accurate working of the driving wheel and pinion, and the latter to regulate the pressure of the upper upon the lower stone, and to compensate for the changes produced upon both by the frequent dressings which their grinding surfaces have to undergo.

The footstep *k*, which is of gun-metal, is turned and fitted accurately into a cast-iron socket *l*, resting on the upper diaphragm of the standard A; the hole into which it is inserted and the annular recess by which it is surrounded being made of somewhat greater diameter than the corresponding parts of the socket itself. Its exact position is determined and secured by the four lateral pinching-screws *m m*, passing through the ring and working in nuts fitted into recesses cast upon its interior surface. (See Figs. 947 and 975.) The footstep *k* is not fixed immoveably into the socket *l*, but is capable of sliding vertically in it. Its proper position, in this direction, is regulated by means of a strong malleable-iron lever M, having its centre of motion in the back of the standard A, while its opposite end projects through a slot, and is raised or depressed by means of a screwed rod N, joined to it and passing through a projecting shelf cast upon the front of the standard. A small link or *saddle n*, serves to connect the lever with the footstep *k;* the saddle being provided with a *square* tail which is inserted into a similar recess in the under side of the footstep; by which means the latter is prevented from turning in its socket. Thus it will be seen that the entire weight of the upper stone and mill-spindle rests upon the lever M, and that the miller is enabled to vary at pleasure the pressure upon the grain between the stones, and consequently, the degree of fineness of the flour produced, by simply turning the nut of the screw N by means of the key *o*.

The Feeding Apparatus.—The supply of grain admitted between the stones is regulated by means of a cast-iron pipe O, open at both ends, the lower end being brought into close proximity with the ryne, while the upper part incloses the pipe in which the feeding hopper E terminates. It is suspended by means of a cast-iron lever P, which has its fulcrum in the small column *p*, depending from the tripod D. A small chain attached to the end of the lever, and passing over a friction-pulley at the bottom of the stone-case, serves to connect this feeding apparatus with an ingenious little piece of mechanism Q attached to the standard, by which the miller is enabled to regulate the supply with the greatest nicety.

This contrivance (which is represented on a large scale at Fig. 971) consists of a small hand-wheel *q*, working between the cheeks of a double bracket bolted to the standard A. A small screwed pin forms the axis of this wheel; it passes freely through the cheeks of the bracket, but is screwed into the eye of the hand-wheel, and is prevented from turning with it by means of a feather inserted into the former and fitting into a groove cut throughout the entire length of the pin, to the upper end of which the chain is attached. By this arrangement it is obvious that by turning the hand-wheel *q* to the right or left the small pin will be raised or depressed, and, through the intervening mechanism, the size of the opening between the mouth of the feeding-pipe O and the ryne will be increased or diminished.

The form given to the upper surface of the ryne may be looked upon as the highest point of perfection to which this important part of grinding machinery can be carried. We have been at great pains to give an accurate representation of it in our various views, (see Figs. 928, 936, 937, 938, 939, and 940.) The principle by which its form is determined is, that the centrifugal force of the running stone shall be employed in the most effectual manner to distribute the corn equally over every point of its surface, while at the same time, the supply admitted shall be susceptible of the nicest possible adjustment.

The Disengaging Apparatus.—The driving pinion I is fitted upon the mill-spindle so as to be capable of sliding up and down upon a sunk feather. When fully in geer with the wheel H, it rests upon a collar formed on the upper surface of a large brass nut *j*, by which the miller is enabled to keep the pinion invariably in its proper position with regard to the wheel, independently of the position of the spindle, which, as we have before had occasion to remark, requires to be slightly lowered every time the stones are dressed. When properly adjusted, the pinion is secured to the spindle by a tapered key.

It is, however, necessary to throw each pair of stones, periodically, out of geer with the general range, to admit of their being dressed, &c. For this purpose the tapered key is removed and the pinion raised out of contact with the teeth of its driving-wheel by means of a species of small jack or lifting apparatus attached to the standard, the component parts of which we shall now briefly enumerate. A cast-iron ring R, supported upon two upright rods *r r*, is brought into contact with the under surface of the pinion by turning the hand-wheel *s*, which is screwed upon its axis *t*, and carries with it in its ascent, the cross-head S, into the ends of which the lower extremities of the rods *r r* are inserted. The screw *t* is fixed into a socket cast upon the under surface of the lower diaphragm of the standard, and the connecting rods *r r* pass through holes formed for their reception in both diaphragms; being set in a diagonal direction in order to clear the lever M, and other important parts of the machinery.

On turning the hand-wheel in the contrary direction, the weight of the pinion again brings it into its working position.

The Stone-lifting Machine.—Fig. 978 is a representation of a portable lifting apparatus, for raising the upper stones from their beds and depositing them on the floor of the mill, when they require to undergo the process of dressing. It consists of a strong malleable-iron arm T T, bent into a form nearly approaching to a quadrant; the lower end works in a cast-iron step *v*, inserted into the stone floor, while its upper extremity is supported by a strong rod U, fitted to rotate upon a stud *u*, fixed into a cast-iron plate (Fig. 981) bolted to the beams which support the floor above. The fixed centres *u* and *v* are so situated that the machine shall command two contiguous pairs of stones, and the end of the rod U is made of such a form as to admit of its being easily disengaged from the stud; when the entire machine may be removed. A strong screw V, passing through the arm T, and worked by means of a nut formed into a double handle, carries at its lower end the two connecting links W W, which are attached to the stone by two studs temporarily inserted into it at points diametrically opposite. The links W W are bent so as to admit of the stone being inverted while it is suspended in the lifting machine. The running stone is retained in its place in the mill simply by its own weight; it is, therefore, only necessary to raise it out of its bearings when the grinding surfaces require examination or repair.

The Elevators and Creepers.—Figs. 983 and 984 are a representation of the form given to the lower elevator-frame; the nature and construction of this machine having been fully noticed in our previous description, it is not necessary further to advert to them. The creeper, however, Fig. 985, is an object of greater interest. The material employed is cast-iron; the creeper is made in six feet lengths; each length being in the form of a tube, 3½ inches in diameter, and about ⅜ of an inch thick, with broad leaves or threads cast round it in the form of an Archimedean screw. The thickness of the threads does not exceed $\frac{3}{16}$ of an inch at the outer extremity.

The different lengths of which the entire creeper is composed, are joined together by short malleable-iron studs *x x*, forming also the journals on which it revolves. These are made with square tails fitted into similar holes formed in the centre of the small cylindrical blocks *w w*, which are carefully turned on their exterior surfaces, and driven into the open ends of the pipes Y Y, previously bored to the same diameter. This construction at once insures a strictly rectilinear axis for the entire range, whatever may be its length. Minor details will be understood by a simple reference to the figures. The arrow indicates the direction in which a creeper, constructed in the manner shown in the general view, would propel the grain.

CORN-MILLS of MM. Cartier and Armengaud, Sen. The corn-mills after the American system, have undergone useful and important alterations since their introduction into France, though but recently introduced. This system was followed but slowly from the difference in its operation from that of the French mills. The owners of the old mills were satisfied with the work done, with little care on their part respecting improvements.

It is only since the importation of the American process that this industry has received a new impulse, and that a new era has commenced; for this system has driven before it the routine with which the old system was encumbered. The new system was already well known all over England when it made its appearance in France, where it received great amelioration.

The old method required a large number of hands, while the new supplies their place, or rather their work, by the ingenious motions imparted to the different parts of the mills by the machinery.

The construction of the different pieces, as well as their disposition, are not always similar; the mill of Cartier and Armengaud appears to us the most worthy of notice; there are ten couples of millstones set in motion by the same hydraulic wheel.

Explanation of the Figures.

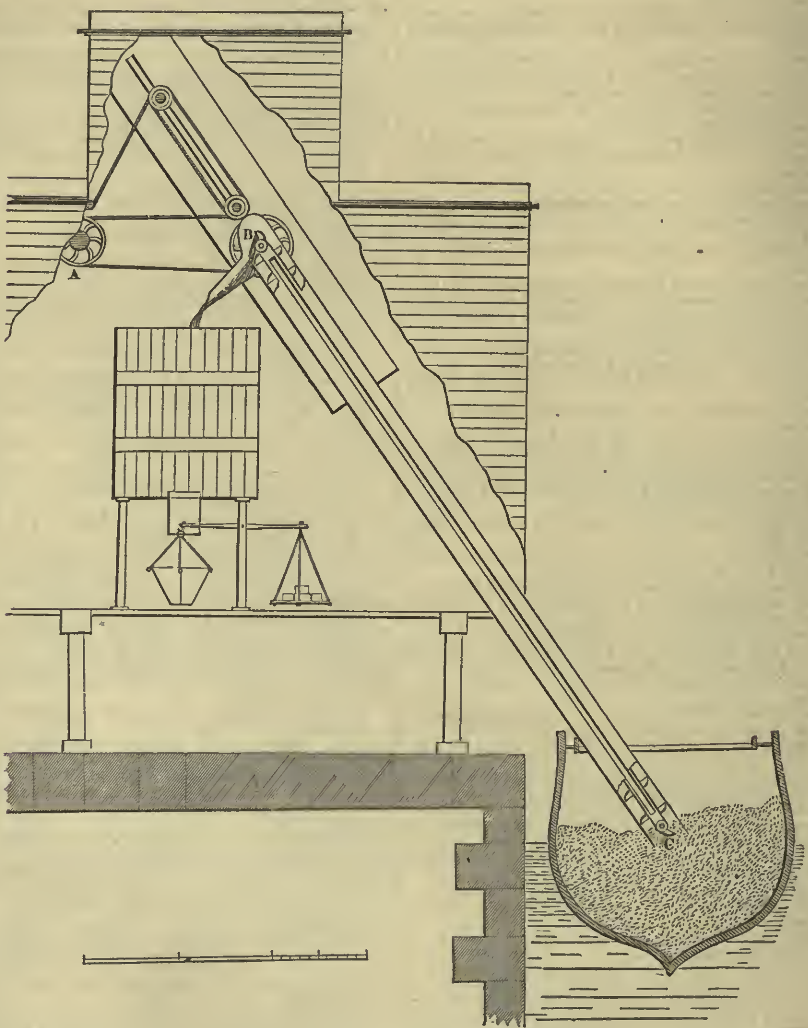
References to Figs. from 991 *to* 1002.

A, circular stone-work, on which the whole system, composed of six couple of stones rest.
B, the circular platform of cast-iron placed on the stone frame-work.
C, six iron pillars of equal height, fixed to the platform by pins which penetrate them their whole length, and also the stone circle.
D, the cast-iron rim, made of one solid piece; the pins of the pillars also penetrate it, thus fixing them firmly to this rim.
a, six long pins traversing the rim, the pillars, the platform, and all the thickness of the stone-work, thus firmly binding the different parts to each other.
E, six cast-iron cases resting on the cornice, in which the lower millstone is contained.
F, cast-iron triangles, placed at the bottom of the cases, in order to give the position required to the under millstones.
b, screws adapted to the triangles, to govern them.
c, iron plate fixed to the rim, into which the resting-rods L are screwed, receiving the pressure exercised by the nuts of the pins *a*.
d, Fig. 996, square-headed screws binding the cases to the rim.
e, round-headed screws holding the immoveable stones.
F′, immoveable stones, of the diameter of 4·26 feet, iron-bound, and borne upon the triangles F; they are furrowed, as indicated in Fig. 996.
F², running wheel, of the same diameter, revolving above the former. They are also 4·26 feet diameter.
G, vertical axles in cast-iron of the running wheels moving them.
f, cast-iron bushing of a conical shape, adapted to the axle G.
g, cast-iron chuck, having two arms contained within *f*, attached by their extremities to the moveable stone, and held in equilibrio upon steel disks, adapted to the axle of the stones, and having a spherical part, which serves as a pivot to the centre of the chuck.
H, cast-iron cylinder fixed to the nether millstones, Figs. 997 and 998.
h, flat pillow in bronze, contained within H, and bearing against the iron axles of the millstones.
h′, braces; they are of cast-iron, placed in the bottom of the drums, and fixed to them; they serve to keep the pillows firmly fixed.
*h*², cast-iron wedges, pressing the pillows against each other.
i′, steel pins, adapted to the inferior portion of the iron axles connected with the stones.
*i*², Fig. 1002, steel socket, in which the ends of the axle *i*′ rest.
I, vertical rods of iron, by which the axles and consequently the millstones are raised.
J, cast-iron pedestals, mostly round, and pinned by their base to the circular platform.
j, cast-iron sockets, placed in the superior part of the pedestals; their shape is seen in Fig. 1000.
j′, brass socket made to be adapted to the cups *j*; they rest upon the summit of the vertical rods I, to rise and descend with them, and receive the sockets *i*².
*j*², a screw to set the sockets in the centre, and consequently the axles of the millstones.
K, cast-iron balance-beam, connected with the resting-rods.
k, iron bolts, serving to rest one end of the beam K; a nut maintains each of the bolts fixed to the platform.
L, long rod, connected to the beam K, but allowed to revolve round its own axis.
l, a portion of L, of a greater diameter than the rest, and tapped at the height of the rim.
l′, cast-iron fly-wheel, at the summit of each rod L, in order to turn them by the hand.
M, large cast-iron cog-wheels, communicating with the moving wheel M′, and transmitting their movement to the two systems.
M′, vertical moving wheel in cast-iron, in two pieces, and adapted to the axle of a hydraulic wheel.
m, cast-iron bushing round each axle of the pinions; they can slide on it laterally.
m′, screw, by which the bushing is made to engage with its pinion; it is disengaged at will, when it is to put in or out of geer.
N, two cast-iron shafts, bearing the pinions M, and the bevel wheels O.
n, cast-iron fulcrum, having brass pillows, on which the turning pieces of the two shafts N rest; their plates are set in a groove made in the stones supporting them.
O, bevel with wooden cogs, and fitted to the shafts N.
P, cast-iron pinions.
Q, vertical shafts in cast-iron, turned their whole length, bearing the pinions P.
Q′, iron shaft, fitted to the summit of the preceding axles, and going towards the upper stories to work the cleaning bolting apparatus.
R, a horizontal wheel, with six arms, ending in ears pinned to the boxes of the millstones; its centre has three brass flat pillows, which keep the axle in a vertical position; force-screws press them at will.
o, keys, which maintain the pinions and the wheels S at the height determined for them, to prevent their fall, in case the screws which keep them fixed to their axle should become loose.
p, steel extremity of every vertical shaft to which it is adapted, having a conical shape; the contact suffices to keep them connected.
R′, great chair in cast-iron; the basis of which is solidly pinned to the stone R².
R², a large stone placed at the centre of the works, so disposed as to bear both systems.
q, rest-rod of the vertical axle; it is made of iron, flanged at its inferior portion, which goes through a nut in iron *r*.
r, nut, in iron, with square flanges, placed upon the centre of the base of R′.
r′, brass socket, adapted to a cast-iron muff, and containing a steel bed, similar to that of the millstone axles; it receives the point of the vertical shaft, and is governed by four screws.
S, a horizontal wheel, having fine wooden teeth, and fitted to the vertical shafts.
T, straight pinions, made of cast-iron, adapted to the axles of the stones, and to which the rotatory motion is given by the horizontal wheel S.
U, wooden box surrounding the millstones; it is placed upon the flooring of the first story.
V, brass hopper, distributing the grain to the stones.
s, zinc pipe, communicating with the hopper, which is placed in the second story. Valves open and close it.
t, brass tube, fitted into the lower part of the hoppers, and descending as far as *t*².
t′, small tube, enclosed within the last, when its opening is to be lessened before grinding the corn.
u, cross iron bar, the extremities of which are supported by screws; their office is to keep the tubes *t* at the desired height.
v, small cast-iron supports, attached to the lids of the millstone box.
X, a great circular shoot, in wood or sheet-iron, in which the ground corn is received at its exit from the stones; it rests upon the wheel R.
Y, spur-wheel, of cast-iron; it turns upon the vertical shaft, and gives attachment to the moveable branches of the shoot.
x, six iron branches, attached with pins to the ears of the wheel Y, which rotates them very slowly.
x′, wooden plates, fixed to the extremities of the branches *x*, they turn with them within the shoot, carrying forward the meal to the box of the endless screw.
y, pinion, commanding the wheel Y.
y′, strait wheel, cast with the preceding pinion, and fixed with it to an iron gudgeon, adapted to one of the arms of R.
*y*², a similar wheel on the vertical shaft, and transmitting its movement to *y*′.
Z, an endless screw, made of wood, having an iron axis and a wooden screw; it is inclosed within a rectangular box of wood, into which the meal from the shoot is received.
Z′, an oaken box, in which the ground grain falls.
z, a double pulley, mounted upon the extremity of the endless screw, and free on this axle.
z′, an endless chain, with tin buckets, fixed at intervals, in order to raise the meal from the box Z to the room where it is allowed to cool.
*z*², a small pulley, commanding the endless screw.

CORN ELEVATOR, *Steam: Pagin's Patent.* In the new warehouses attached to the Atlantic Docks, Brooklyn, there are several of these very useful engines erected. Also one on the river for discharging grain-laden ships in the stream or alongside the piers: the latter is called the floating elevator. The extremity of the shoot C is inserted in the hold of the vessel about to be discharged, its height being regulated by the guide-frame and pulleys, Fig. 1003. The machine is put in motion by means of the prime mover A and band-wheel B, when by means of a series of tin dippers attached to a belt of gutta percha or leather, tightly stretched over the wheels at B and C, the corn is brought up to a height

1003.



of 76 feet, and discharged by means of the small spout attached to the elevator into the weighing machine; from thence, by a repetition of the same contrivance, it is taken through the building to a shoot on the roof, containing an Archimedean screw, by the use of which and the elevator the grain may not only be placed on any particular floor in the warehouse, but may be transhipped (having been weighed in its passage) either wholly or partially for Europe, or any other destination.

This apparatus was erected by Barton, of Buffalo, and by means of a small high-pressure engine. 10-horse power, will raise 2600 bushels of grain 76 feet high per hour, and distribute or tranship as described.

CORN-MILL, *Old Union.* In order to render our series of Corn-Mill drawings complete, we have given in Fig. 1004 a representation of the arrangement of the stones, garners, &c., in an extensive establishment fitted by Mr. Fairbairn with machinery identical, in all important particulars, with that which we have detailed in the preceding figures and descriptions.

This mill contains seventeen pairs of stones. The whole are disposed in one straight line, close to the wall of the mill—which arrangement, on account of its undoubted superiority to any other, has

induced us to select this example. The flour produced is, for the most part, consumed by an extensive baking establishment adjoining the premises, and belonging to the same proprietors.

For our present purposes, we have deemed it necessary to give only a sectional elevation, on a small scale, and of a somewhat sketchy nature. The line of section must not be supposed to be taken in one vertical plane, but to vary in order to exhibit most distinctly the different parts.

Description.—Two powerful steam-engines are employed to drive the machinery of this mill; one of these communicates its motion to the line of horizontal shafting, near the end of the range, by means of a great bevel-wheel A, keyed to the crank-shaft, and working into the bevel mortise-pinion B upon the mill-shaft; the other, by means of a spur fly-wheel working into the mortise-pinion C, situated towards the centre of the range. By thus applying the power at two points, the weight of shafting and consequent loss from friction, &c., is materially diminished.

From the driving-shaft D D D, the power is communicated by the bevel pairs *a a a*, to the mill-spindles, which are provided with suitable bearings and adjusting geer, in all respects identical with that we have already described. Between the first and second pairs of stones, one of the standards E is employed for the purpose at once of giving great stability and firmness to the shaft D at the point where it receives the strain of the first engine, and of affording the means of transmitting its motion to the upright shaft driving the lighter machinery of the mill. A strong cast-iron bracket *b*, bolted through the wall of the mill, abuts against the framing, and the intermediate stays *c c* bind all three together laterally.

Each of the feeding hoppers *d d d* is supported by a light cast-iron framing *e*, resting upon slender columns; the tripodal form is, however, preferable to this.

The feeding-pipes H H H are of tinned plate, so constructed as to be easily withdrawn from their connection with the wheat-garners when the stones are taken up; and at the top of each is a small valve or slide *h*, to shut off the supply of wheat. Above these points the passage of the grain from the cleaned wheat-garners is effected by means of wooden spouts I I I, converging to and communicating with them.

The cleaned wheat-garners J J J are three in number, and are situated on the top floor of the mill, immediately over the stones. Between, and in front of these, are the garners K K, which receive the wheat as it is first brought to the mill, and deliver it, by means of numerous spouts or openings in the floor, to the great uncleaned wheat-garners L L, situated on the machine flat. From these the undressed wheat is conveyed, by means of a creeper and elevator, into the screen M, whence it falls through the spout P into an elevator on the stone floor, by which it is again raised to the upper story and distributed, by another creeper, into the cleaned wheat-garners J J J.

The vertical shaft *i i* is continued upwards till it terminates near the roof of the machine floor. Then its motion is transferred by means of a short transverse shaft, (which we have purposely omitted in our drawing for the sake of simplicity,) and two pairs of bevel wheels, to the long horizontal range of shafting *k k*, on which are fixed numerous pulleys for driving the various subordinate machinery of the mill.

The pulley *l* drives the lower creeper.
" " *m* " the upper creeper.
" " *n* " the sack-tackle.
" " *o* " the first elevator.
The pulley *p* drives the second elevator.
" " *q* " the fan (belt working over guide pulleys.)
" " *r* " the wheat-screen.

The dressing and bolting machines are driven by pulleys on the transverse shaft. The apparatus Q for raising the stones is shown here in action; it may be remarked that it is found necessary, in this mill, to keep a couple of stone-dressers in constant employment; each pair of stones being, in succession, thrown out of geer for twenty-four hours, to undergo the process of redressing.

Calculation of Velocities.

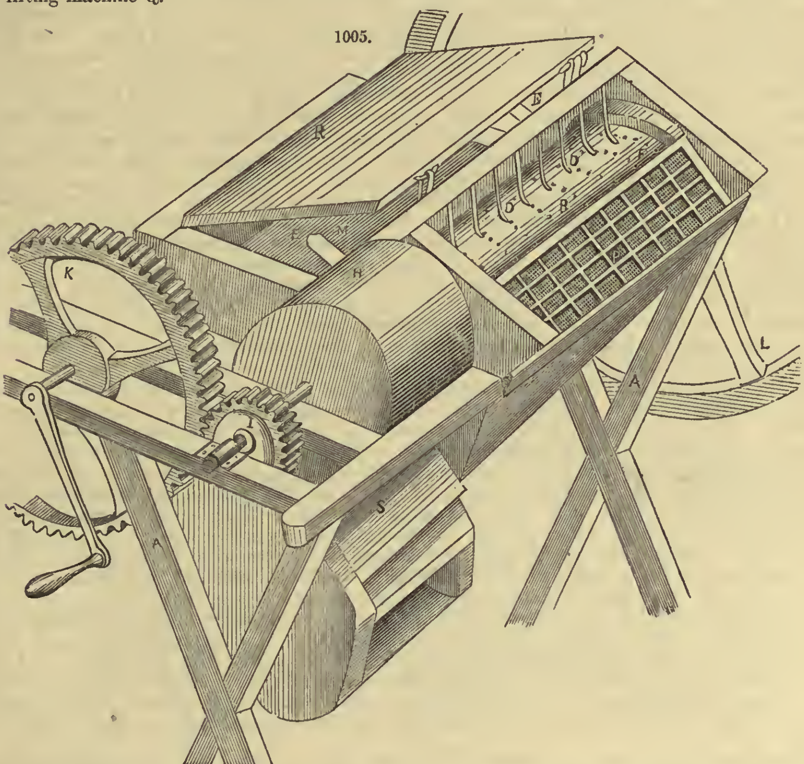
M, the brusher or wheat-screen.
N, the fan attached to the wheat-screen.
O, passage of the blast, carrying the dust, &c., outside of the mill.
P, passage of the cleaned wheat to the second elevator.
i i, the upright shaft for driving the light machinery of the mill.
j, a pair of bevels between the upright shaft and
k, the range of longitudinal shafting down the mill.
l m n o p q r s, pulleys for driving the various light machinery.
Q, the stone-lifting machine shown in operation.
t t t, studs affixed to the beams supporting the machine floor, affording fixed centres for the working of the lifting machine Q.

1005.



CORN-SHELLER. Fig. 1005 is a perspective view of L. M. Whitman's corn-sheller. A is the frame, B is a concave bed made of cast-iron plates, with projections on their inside surfaces. D is a cast-iron cylinder having projections cast on its outside surface. The ears of corn are fed in between the roller and the concave bed through M, on the other side of the lid R, and the cylinder being set in motion, are carried round between the cylinder and concave bed, and all the corn removed from the cob; the cob is carried round to the rake teeth seen above D D, and is thrown over the frame P, and falls over the side of the machine. The concave bed is hung on strong springs E E, which allow it to spring to the various sizes of the ears of corn—making it flexible for that purpose. The plates C, which form the concave bed, are placed a small distance apart from one another, so that the corn falls down between them into an inclined conduit, which carries the corn below H, a revolving set of fans, where the grain is perfectly cleaned; the dust, &c., being blown out through an opening below S. and the corn being heavier, passes into the granary or receptacle out of the opening T.

COROSOS, or *Nut Ivory*. See Woods, *varieties of*.

COTTON. The process of manufacturing into cloth.—The cotton from the bale is first sorted, and it is then subjected to the action of a large and powerful machine called a *willow*. This machine consists of an inner frame-work, capable of revolving with very great rapidity, and enclosed in an outer case. Upon the four edges of the inner frame are fixed a series of iron pins or pegs, which in their rotation pass between other similar pins fixed to the inner surface of the outer case. Now if a quantity of cotton be put in the receptacle between the inner and outer frames, and the inner one be made to rotate, the clotted locks of cotton, tossed about within the machine, are caught by the various iron pins, and torn open fibre by fibre. All the dirt and other impurities which may have been mixed with the cotton are at the same time separated from it, and made to fall through a kind of grating.

The next process is to complete the opening and cleansing thus begun. This process is called "picking." The cotton is laid upon a kind of endless apron, which by its movement conveys its burden to a fitting spot, where flat bars, carried rapidly around, strike the cotton violently as its exudes from between two rollers, and thus separates the fibres most thoroughly. There is also a particular kind of fan or vane, so arranged as to produce a powerful draught, by which all the dirt and dust are carried up and conveyed away—not only out of the machine, but out of the room, and out of the factory itself.

The cotton is now in the form of a very clean, light downy fleece called a lap, consisting of short fibres thoroughly disentangled. But these fibres are not *parallel;* they lie across each other at every imaginable angle, and any attempt to combine them together in this state would be fruitless: they must be rendered parallel, and to effect this is the object of *carding*. The cotton is brought into the form of a 'lap,' or flat layer by the "picker," and in that state transferred to the carding-engine.

The cotton leaves the carding-engine in the state of a delicate, flat, narrow strip or riband, called a *sliver;* and these slivers have now to be converted into *drawings* by being elongated, narrowed, and thinned to a still more delicate condition. In the first place the slivers are collected in tall cans, generally either four or six in number, on one side of '*drawing-frame*,' and are from thence carried upwards to two pair of rollers, the two rollers of each pair revolving in contact. Here all the slivers or cardings are collected into one group, and are drawn between the rollers by the rotation of the latter. Now if these rollers all revolved equally fast, the cotton would leave them with the same united thickness as when it entered; but the last pair revolve quicker than the first, so as to draw out the cotton into a more attenuated riband; because the more slowly-revolving rollers do not supply the material fast enough for the maintenance of the original thickness. This is perhaps the most important principle in the whole range of the cotton manufacture; for it is exhibited alike in the present process and in the next two which follow. All the four or six slivers are connected into one before being caught between the rollers; and after leaving the rollers, the united 'drawing' passes through a kind of trumpet-shaped funnel, and thence conducted into a tall can, round the interior of which it coils itself. One consequence of the drawing process, if properly conducted, is that the drawing is perfectly equal in thickness in every part, and formed of parallel fibres; and in order to ensure this, the drawing is repeated more than once, each narrow riband being 'doubled' with others before each successive drawing.

The slender ribands thus produced next pass through the 'roving-machine,' where they are brought to the state of *rovings*. In many respects the process of roving is similar to that of drawing, inasmuch as it draws out the cotton to a state of still greater attenuation; but as the cotton, in its now reduced thickness, has scarcely cohesive strength enough to make the fibres hold together, the roving has a slight twist given to it, by which it is converted into a loose kind of thread or spongy cord.

The 'bobbin-and-fly frame' consists of a system of vertical spindles, on each of which is placed a reel or bobbin, and also a kind of fork called a 'fly,' still farther removed than the bobbin from the axis of the spindle. The drawing or delicate sliver of cotton is first drawn through or between rollers, and elongated to the state of a roving; then this roving passes down a tube in one prong of the fork or fly, and becomes twisted by the revolution of the fly round the bobbin, while at the same time the twisted roving becomes wound with great regularity upon the bobbin. The machine in fact performs three different and distinct operations; it first attenuates the 'drawing' to a state of still greater thinness and delicacy than it had before; it then gives to the 'roving' thus produced a slight twist, sufficient to enable the fibres to cohere; and lastly, it winds this twisted roving upon a bobbin, on which it is conveniently transferred to the spinning-machine. Instead of the bobbin and fly frame, in this country the speeder and stretcher are more commonly used, especially on the coarse yarns.

We then come to the *spinning* process, which finally presents the cotton in a state fit for the weaver, by elongating the roving till it contain in thickness exactly as many fibres as are necessary to produce the required size of yarns, and twisting of these fibres into a compact thread.

In modern cotton-factories the spinning-machines partake of the character either of Arkwright's or of Crompton's machines, *i. e.* the *throstle* and *mule;* the first for the stronger, and the latter for the finer work. Some factories have both throstles and mules, arranged in different parts of the building.

The yarn produced by these two classes of machines is appropriated to various purposes according to its fineness, strength, hardness, smoothness, and other qualities. Some is employed as *warp* or long threads for coarse goods; some for *weft* or cross-threads; some for printing calicoes; some for fine muslins; some for cotton hosiery; some for bobbin-net; some for sewing-cotton.

But before the weaving is effected, there are many intermediate steps to be attended to, such as 'dressing,' 'beaming,' 'winding,' 'warping,' &c. The *dressing* is a process by which either melted size or flour paste is applied to the yarn used as warp, as a means of rendering it smooth and stiff. The threads of yarn spread out in a parallel layer, after dipping into a trough of paste, are rubbed by two moveable brushes, by which the paste is laid smoothly over the surface, and the threads are then dried by passing over steam-heated cylinders or boxes.

The long threads of a piece of cloth or cotton, called the *warp*, are fixed to the weaving-loom, while cross-threads called the *weft*, are fixed to the shuttle. The process of 'winding' is that by which the

weft is transferred from the bobbins to the shuttle, and is done in a very simple manner by means of a wheel. The process of 'warping' is more complicated. Supposing there to be a thousand threads in the width of a piece of cloth, then the yarn, wound on the bobbins as it leaves the hands of the spinners, must be so uncovered and laid out as to form a thousand lengths, constituting, when laid parallel, the warp of the intended cloth.

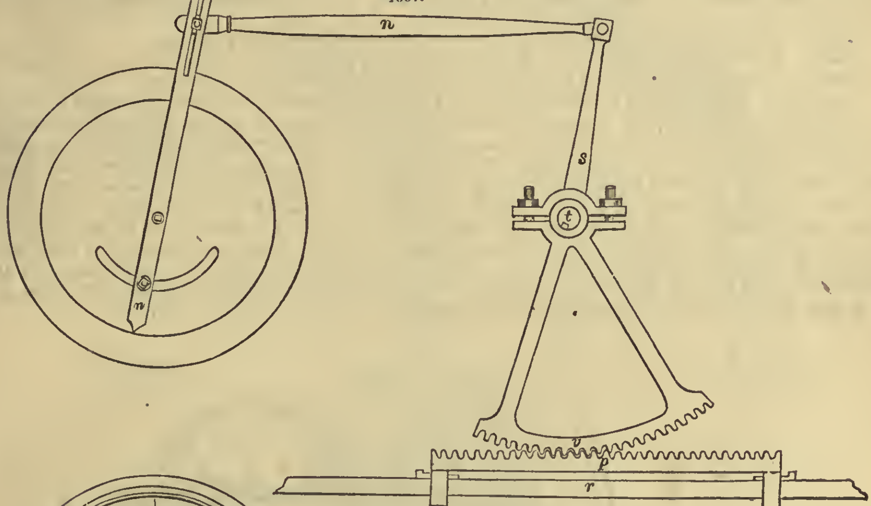
The arrangements here described are for the purpose of arranging parallel as many threads as will form the width of the piece of cloth to be woven; and all these threads collected are called the *warp*. This warp, being removed from the warping-mill or frame, is next 'beamed,' or wound on the beam of the loom. The threads in this latter process are wound as evenly as possible on the beam; a kind of comb being used to lay them parallel, and to spread them out to about the intended width of the cloth. Arrangements are then made for drawing or attaching the warp-threads individually to certain mechanism of the loom. At about the middle of every heddle or string is a loop or eye, through which the warp-yarns are drawn, one through each eye; and the passing of the yarns through these loops constitutes the 'drawing.' Half of the warp-yarns, that is, every alternate yarn, pass through the loops in one leaf of *heddles*, and the other half through the other leaf; and as the two leaves are so connected by pullies as to cause one to rise when the other sinks, the warp becomes divided in two portions, one above the other, near the anterior end of the loom.

COUNTER. See GAS.

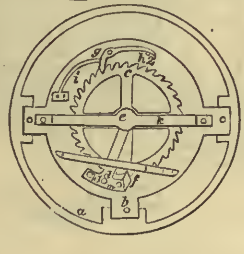
COUNTER PROPORTIONAL, by W. H. Lindsay. The construction and operation of this instrument, will, with the aid of the drawing, be readily understood.

Whatever distance or quantity a space from point to point, as from 3 to 4 on the outer circle of the dial-plate, is intended to represent, is attained by proportioning the arm *n* 2, and the segment of toothed-

1007.



1008.



wheel *v*, to the length of the stroke made by the rack *r*. To facilitate the adjustment with the greatest accuracy, the radius of the counter-arm *n* 2 can be lengthened or shortened by means of the pin *w*, which can be shifted up or down in the slot; and when the proper distance is obtained, made fast by a nut on the back side of the arm. The ratchet-wheel *c*, and centre pin *e*, which passes through an eye in the shoulder of the cross-piece *k*, on the frame *b*, give motion to the dial hands. The ratchet-wheel is moved in proportion to the length of stroke communicated to the counter-arm *n* 2, by means of four or five pawls or catches *f*, each a little longer than the other: for instance, if the space between two teeth on the ratchet-wheel be divided into four equal parts, and four or five pawls are used, they are each longer than the other by that distance; by which means, one or more of the set are always in contact

with the tooth nearest their points, thereby obtaining a continuous bearing or hold of the ratchet-wheel, without the possibility of the least slip or play. The moveable pawls *f* all work on the same centre or pin on the arm *d*, which works on the same centre as the ratchet-wheel. The pawls are made of steel; their points are kept in contact with the tooth nearest to them, by means of the curved elongation of each pressing against the pin *h* 1 on the off-side of the arm, to prevent the least slip or return of the ratchet-wheel during the back travel of the arm with the pawls, or whilst the pawls are moving back over the teeth. Catches *g*, of the same construction and number as those on the arm, are placed on the frame *b*, working on a pin in it, so that their ends are pressed into the space between the two nearest teeth on the ratchet-wheel, to render the stop-catches more effective. The ends of the spring *i*, which is a piece of brass bent or curved, and slit into as many pieces as there are catches for it to act on, presses against the curved part of the catches. The guard *l* crosses the arm *d*, keeping the arm and catches steady when moving. The pin *m*, in the centre of the arm, passes through the slot in the back of the counter, to which the counter-arm is made fast by a nut.

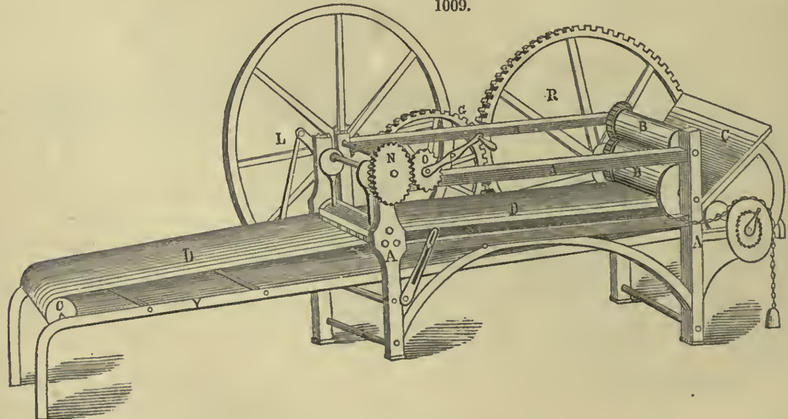
The counter's operation requires but little explanation: the length of stroke of the rack being determined, say 12 inches, and the pin in the slot adjusted by that length of travel, so that the hand on the outer circle of the dial-plate exactly makes a space, as from 3 to 4. Whatever distance within 12 inches the rack moves forward, say 3, 5, 8, or 10 inches, it will give motion to the ratchet-wheel and hand only in that proportion, the stop-catches allowing the ratchet-wheel to move round during the forward motion of the rack; but on the back travel of the rack-arm and catches, they being pressed by their own as well as the springs *i* into the space between the teeth nearest their ends, prevents not only the return of the ratchet-wheel, but also the least slip or return, by which means the face hands remain where they were carried to during the forward motion of the rack; from which it will be seen that whatever the index, or from point to point on the outer circle represents whether distance or quantity, by communicating motion to the rock a given distance, it will, on inspection of the dial-plate at any time, be found what has been performed.

COVE. Any kind of concave moulding; the concavity of an arch or of a ceiling.

CRAB. A moveable machine, made similar to a capstan, and used for similar purposes. The term is sometimes employed for a species of moveable windlass, fitted with geers and cranks.

CRACKER AND BISCUIT MACHINE. It is highly important where large quantities of biscuit are made for sea, either for the commercial or war marine, that there should be some machine for the speedy preparing of such kind of provisions, so as to preserve the flavor and quality of the flour, which we well know is not the case with all kinds of bread, as some will not keep fresh longer than two or three days. The machine represented in the engraving was patented some years ago by W. R. Nevins; and although there have been a number of machines built for the same purpose, yet good judges have pronounced it to be the best machine of the kind in existence, and in its present improved condition, without a rival. One of these machines was put up at St. Augustine during the Florida war, and it was of great benefit to the troops there. It has been examined by commissioners of the British navy, and has met their entire approbation. The Brazilian government has also requested one to be sent them, and there are others in use at Norfolk, Va., and Louisville, Ky.

1009.



Description.—A A A A is the frame. B B are two feeding-rollers, the dough being fed into them on the board C. D D is an endless band the same width as the feed-rollers. This band is for carrying the dough from the feed-rollers to the cutters and forward off the cutters on the band-frame Y, to be taken off after the dough is cut into the desired size and form. The frame Y, on which the band D runs over the roller C, can slide under the machine when the machine is not in operation, so as to occupy as little room as possible. P is a crank for working the machine, and on the crank-shaft is a cog-wheel O, meshing into a larger cog-wheel N. The cog-wheel N moves the cutters, not in a rotary motion, but up and down, cutting the biscuit clean by the reciprocating motion ingeniously combined with the rotary by two eccentrics on the shaft, which will be observed between N and the larger, or fly-wheel, on the

other side of the frame. While the cutters are moved by N, the shaft of O gives motion to the cog-wheels on the other side of the frame, and by the accumulation of power on the fly-wheel the whole apparatus is very easily worked. The cog-wheel G meshes into the cog-wheel R, for the purpose of giving the feed-rollers a uniform speed, something very necessary, as bakers know, so that there may not be too much friction by the rollers, in which case crackers and biscuits are afterwards apt to split open, and in warm latitudes soon spoil. The endless band is made to bring forward the dough by two cranks, one seen on the opposite side of the frame, inside of the fly-wheel, which works a pendulum shaft below the handle P, on which is a cord passing over a pulley at the end of the feed-board C; on the end of this cord is a weight which works by the pendulum the toothed pulley, on which is a clamp to slip and cut the exact distance the band is wanted to move for every cut of the cutters, for the band D passes over the roller of the toothed pulley, on which is the cord, and round by C. There is a slot in the pendulum shaft, so that the pin can be moved up or down, for a long or short cut, and by the shifting or changing the tooth-wheels O and N, the speed of the cutters will be increased while the rest of the machine keeps a uniform motion. It will be observed that the cutters do not fall or press down upon the canvas direct from the shaft, there is a plate between the canvas and the cutters, so that a fine clean cut is made through the dough.

One of these machines with cutters only for three biscuit in the breadth of the frame, has cut as fast as one in use in the British navy with fifty cutters, thus showing a great superiority. But the best recommendation comes from those who have them in operation, Mr. Stratton, of Brooklyn, and Mr. Wilson, of this city, who speak in the highest terms of their qualities. This machine is the invention of Mr W R. Nevins, No. 609 Greenwich-street. New York, who manufactures them.

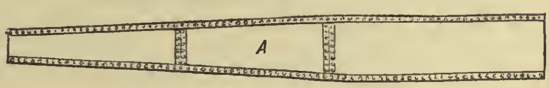
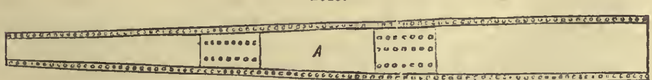
1016.



1015.

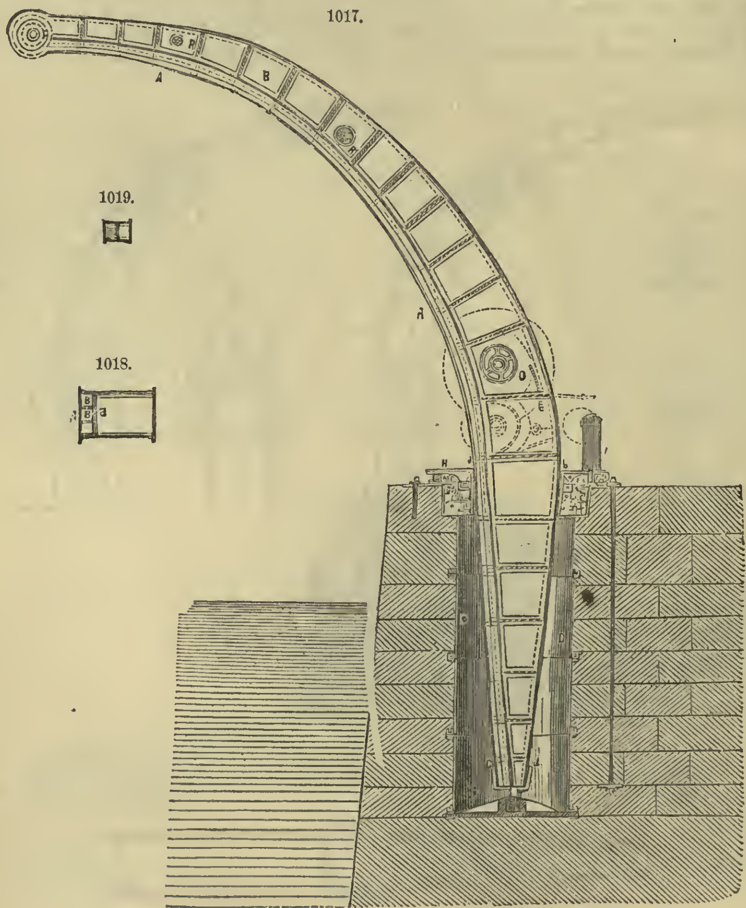


CRANES. Fairbairn's Tubular Cranes. These improvements consist in constructing the jib of such machines of metal plates, so arranged and combined as to form a connected series of tubular or cellular compartments, instead of forming the jib of one solid piece as heretofore.

Fig. 1010 is a vertical section of a crane constructed according to said invention, and calculated for lift-

ing or hoisting weights up to about eight tons. Fig. 1011 is an elevation of the same; figs. 1012 and 1013 are cross sections on the lines *a b*, *c d;* and fig. 1014 a transverse vertical section on the line *i k*. A A is the jib, which in its general outline is of a crane-neck form, but rectangular in its cross sections, as shown in fig. 1013. The four sides are formed of metal plates firmly riveted together. Along the edges, the connection of the plates is effected by means of pieces of angle iron. The connections of the plates at the cross joints, on the convex or upper side of the jib, are made by the riveting on of a plate which covers or overlaps the ends of the two plates to be joined; the rivets at this part are disposed as represented in fig. 1015 (a plan of the top plates), and known as "chain riveting." B B is the pillar which is firmly secured by a base plate *p*, to a stone foundation B,[1] and fits at top into a cup-shaped bearing C[1], which is firmly secured to the side plates of the jib, at or near to the point where the curvature commences, and on which bearing the jib is free to revolve. Fig. 1014 is a transverse vertical section of the lower part of the jib, showing the manner of fitting the bearings for the chain barrel, (which is placed in the interior,) and the spindles and shafts of the wheel gearing by which the power is applied thereto. D is the chain pulley, which is inserted in an aperture formed in the top of the jib. The chain passing over this pulley enters the interior of the crane, and is continued down to the chain barrel. E is a pulley or roller, which is interposed about half way between the chain pulley and the chain barrel, for the purpose of preventing the chain rubbing against the plates. Fig. 1016 is a plan of the lower plates.

1017.



1019.

1018.

Fig. 1017 is a vertical section of another crane, constructed on the same principle as that which has just been described, but calculated for lifting much greater weights (say 20 tons); it differs in having the lower or concave side A A of the jib strengthened by means of three additional plates B, B, B, whereby the interior is divided into one large and three smaller cells, as shown in figs. 1018 and 1019, which are cross sections on the lines *a b* and *c d* of fig. 1017. This arrangement of the cells to strengthen the lower or concave side is advisable, in order to obtain sufficient resistance to the compression exerted by the load lifted, without unnecessarily increasing the weight of the other parts.

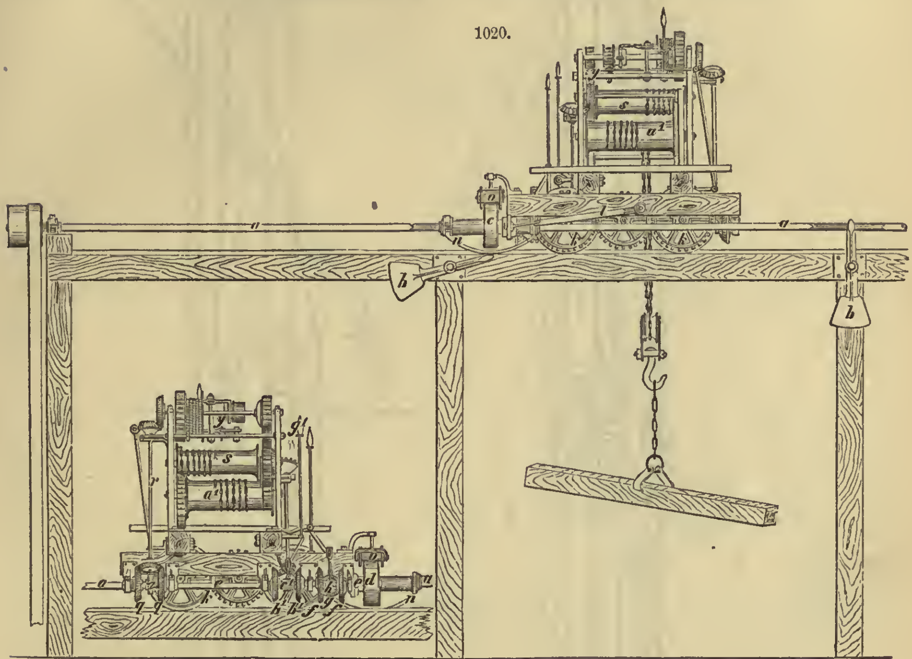
Travelling cranes are constructed somewhat similar in their upper works to the Foundry Crane, figs. 1025, 1026; but instead of a single post or support, there are two horses or spreading frames which are

supported on trunks, admitting of traverse in one direction on a line of rails, whilst the truck, as E F fig. 1026, admits of a motion at right angles to the former.

McNicoll and Venon's PATENT STEAM TRAVELLING CRANE.

This machine, like the ordinary hand travelling crane, moves upon a tram road laid upon longitudinal beams, raised from 15 to 20 feet above the level of the ground, the beams being supported at intervals by uprights. A square shaft *a*, (figs. 1020 and 1022,) $2\frac{1}{2}$ inch diameter, runs the entire length of the tram road, and is attached to the longitudinal beams by movable support, *b b b*. This shaft is connected at one extremity to the engine. Upon it, and revolving with it, is placed a drum, *c*, which works by means of a leather belt, the pulley *d*, attached to the moving platform. The pulley *d*, is fixed on th shaft *e*, upon which are placed the bevel wheels, which impart the threefold motion to the crane. Th

1020.

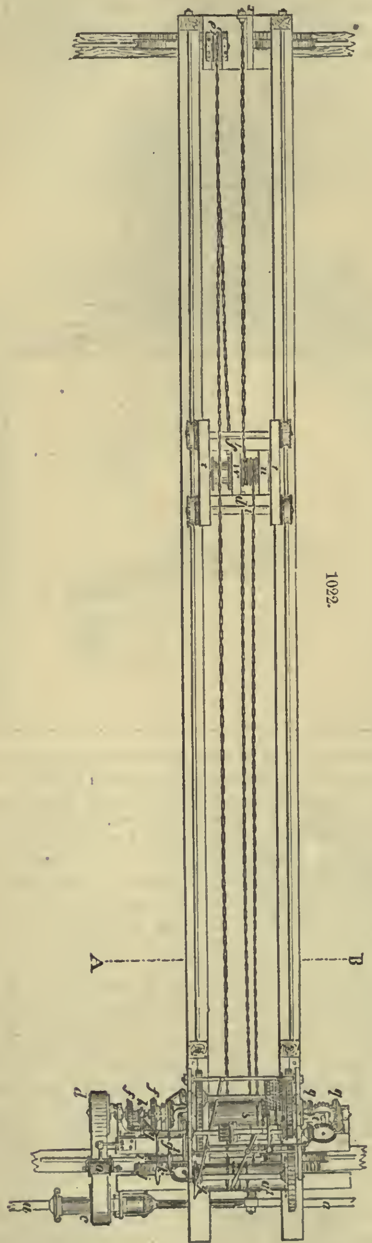


bevel wheels *f f*, which revolve freely on the shaft, are made so as to turn the bevel wheel *g*, by means of the clutch box *h*, which is attached to the shaft; so that by withdrawing the clutch box from one of the bevel wheels and putting it in gear with the other, the motion of the bevel wheel *g*, is reversed, and when the clutch box is out of gear the bevel wheel *g* is stationary. The bevel wheel *g*, is fastened upon the small shaft *i*, to the other end of which is attached the pinion *j*, which works the spur wheel fixed to the roller wheel *k*, and imparts the longitudinal motion to the whole platform. As the platform would otherwise move away from the drum *c*, which communicates the motion, it is made to slide freely upon the shaft, and being attached to the moving platform by means of the rod *l*, it always preserves its relative position with regard to the pulley *d*. The difficulty of making the drum pass over the numerous brackets, that a long shaft must necessarily have to support it, is overcome by making the brackets swing on a centre, so that when the drum *c*, protected by the guard *n*, comes in contact with one of the brackets, *b b*, it yields as shown in fig. 1020, and allows the drum to pass over it. Immediately it has so passed, the weight of the lower extremity of the bracket causes it to resume its position, and the machine passes on to the next bracket, where the operation is repeated. In order to prevent the shock that would be felt in putting in motion so heavy a body as a travelling crane of 50 feet span, carrying in addition to its own weight, a load of 3 or 4 tons, a friction roller *o*, is made to press upon the leather belt that passes round the drum *c*, and the pulley *d*, so that before putting the machine in gear, the friction roller is raised; the machine is then put in gear, and the friction roller gradually lowered. The momentary slipping of the belt round the pulley *d*, when the weight of the friction roller is only partially resting upon it, causes the machine to move forward with an easy motion, and directly it is under way, the friction roller is allowed to bear with the whole of its weight, and the crane then moves forward with its load, at its usual speed of 100 feet in 45 seconds.

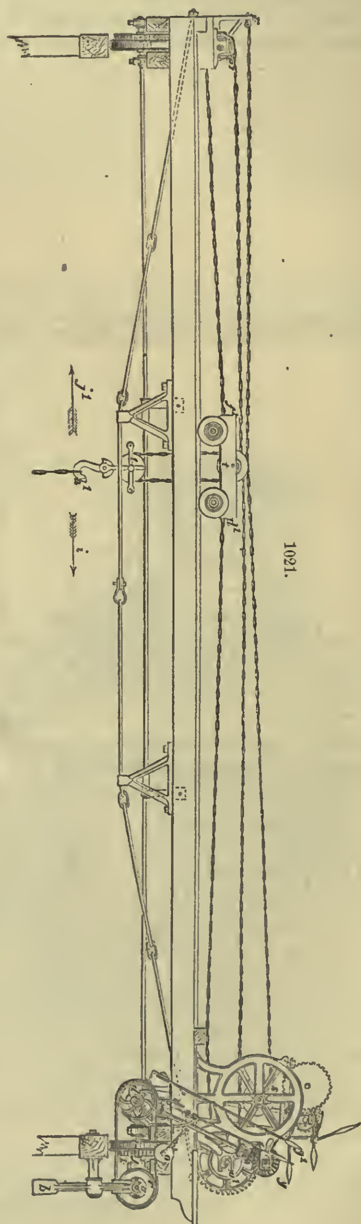
The hoisting motion is obtained by communicating the power through the bevel wheels *q q*, and the shaft *r*, to the barrel *s*, round which the chain revolves. In order to render the hoisting motion independent of the transverse motion, the hoisting chain passes from the barrel round which it is coiled to the truck *t*, and after passing over the pulley *u*, under the snatch block *v*, and over the pulley *w*, it is finally attached to the point *x*, at the extreme end of the platform. To hoist a weight therefore, it is merely necessary that the handle *y*, which communicates with the clutch box *z*, should be moved a few inches.

The transverse motion is imparted to the load by means of the barrel '*a*, which is worked from th

shaft e, by the bevel wheels $'b\ 'b$, and clutch box $'c$, in the same manner as the longitudinal and the hoisting motions. Two chains are attached to the barrel in such a way, that one winds when the other unwinds. One of these chains is attached to the small truck t, at $'d$, and the other is carried round the pulley $'e$, and fastened to the truck at $'f$, so that by alternately pulling the clutch box $'c$, in geer with one or other of the bevel wheels $'b\ 'b$, by means of the handle $'g$, the truck, and with it the load, is moved backwards or upwards along the platform at right angles with the motion of the platform itself.



1022.

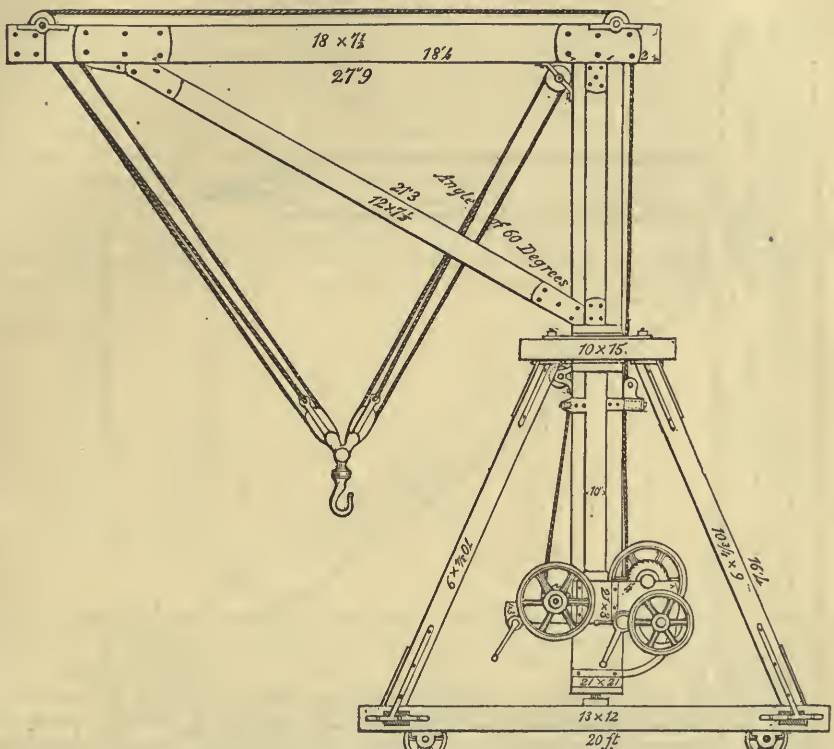


1021.

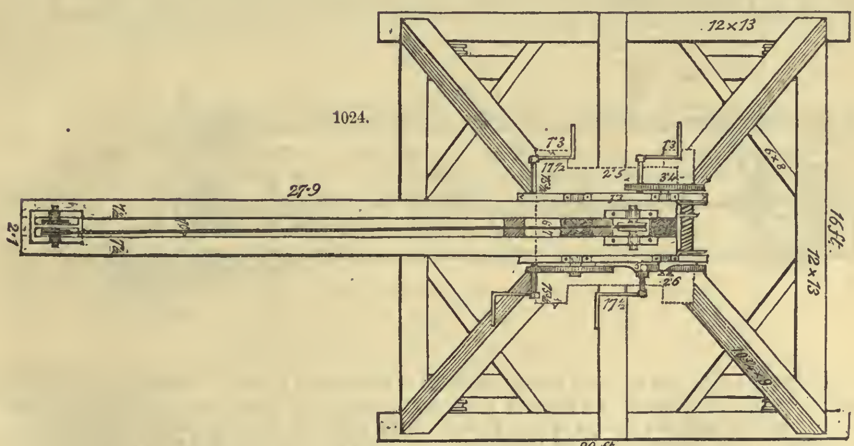
Each of the above—the longitudinal, the transverse, and the hoisting motions, can be used independently of either of the others; or any two of the motions may be used in combination; or the whole three may be used simultaneously. For instance; at the same time that a weight attached to the hook $'h$, is being raised from the ground by the barrel s, the truck t, and consequently the load suspended on the chain, may be moved in the direction $'i$ or $'j$, at the same time that the longitudinal motion is imparted to the whole platform by the roller k.

Fig. 1023 represents an elevation and fig. 1024 a plan of a moveable crane, arranged and used for laying the voussoirs in the inverted arches of the United States Dry Dock at Brooklyn, New York, by Wm J. Mc Alpine, predecessor to Mr. Stewart, the present Chief Engineer.

1023.



1024.



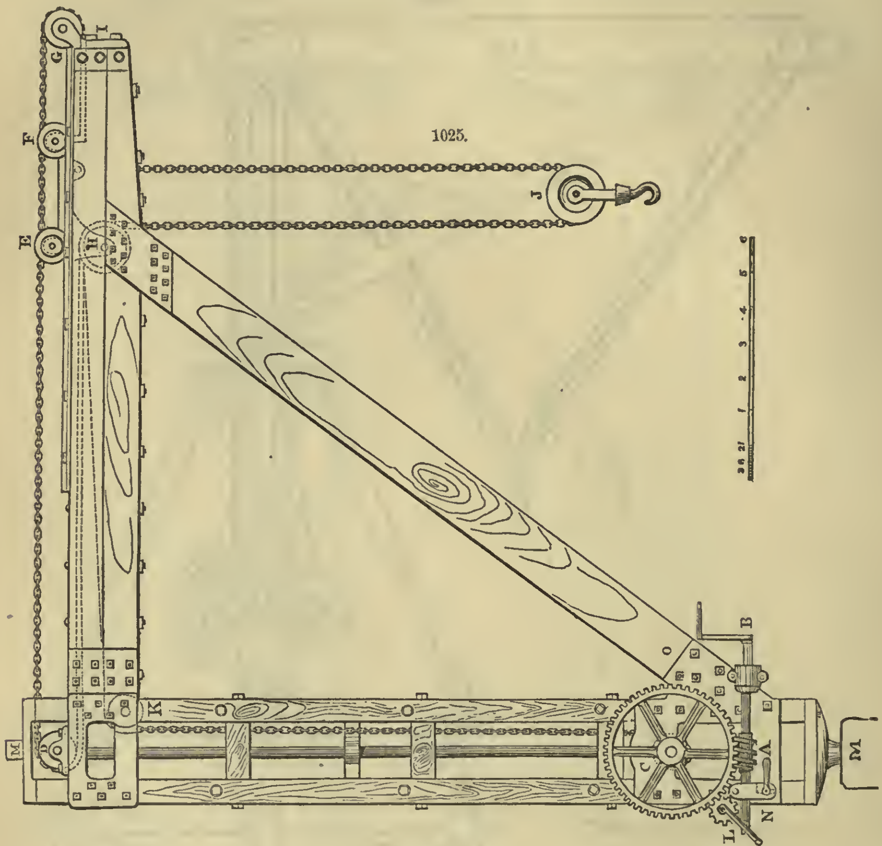
Scale.—8 feet=1 inch.

This crane has been used for hoisting stone weighing from ten to fifteen thousand pounds, at the extremity of the arm, which describes a circle of fifty feet diameter. It has also been used with an outrigger, by which stones from three to five tons weight were hoisted ten feet beyond the extremity of the arm.

A similar crane was used by the same engineer in the construction of the locks of the enlarged Erie Canal. A moveable sheave traversed along the arm of the crane, which was laid on an inclination

towards the mast of twenty degrees. By the use of the "Siamese blocks," the stone is moved towards or from the mast and hoisted or lowered with the accuracy requsite for setting fine-cut stone

1025.



1026.

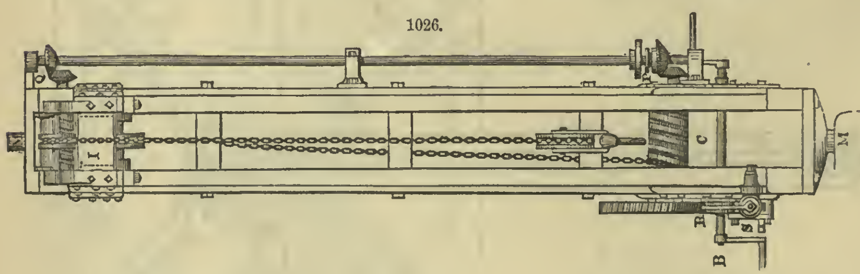


Fig. 1026 is a side, and fig. 1027 an end elevation of a FOUNDRY CRANE as constructed at the Lowell Machine Shop. It is operated as follows: the weight is suspended from the sheave J, and is raised by the chain passing over the pulleys H and K, and around upon the barrel C, either by the boom A or the pinion L, according to the weight to be raised. The pulley H is suspended from a carriage supported by the wheels E and F, traversing on rails at the top of the cope. Motion in or out is given to this carriage by means of the upright shaft and bevel wheels at B and P, which causes the drum D to revolve, and draw either at the upper part of the chain, which passing over the pulley G, is attached to the outer extremity of the carriage, or at the lower part of the chain, which is fastened to the inner extremity.

CRANE. See DERRICK.

CRANK. Elucidation of the principles of the action of the crank as used for the conversion of a reciprocating into a rotary motion. With a pair of compasses describe a circle, draw a line through the

centre; from one point of the intersection of this line with the circle divide the latter into twenty equal parts, 20 and 10 occurring at these points: now suppose that the constant pressure of the steam in the cylinder be represented by 100, this pressure is communicated to the crank by means of a connecting-rod, and we will suppose that the above circle is the circle described by the crank-pin 0 and 20 coinciding, and with the division 10 forming a right line with the centre of crank-shaft and the centre of the cylinder; of course the point 0 or 20 and the point 10 are the two points where the pressure in the cylinder has no effect in turning the crank, called the "dead points." The points 5 and 15 are the points at which the effects of the pressure on the piston is a maximum, decreasing each way to zero. Supposing, for simplicity, the direction of the connecting-rod to remain parallel with its first position, then the effect of any pressure communicated by it to the crank-pin is resolvable into two; one acting on the centre of the crank, and of course inoperative towards producing motion in it, and the other acting tangentially to turn the crank. The first of these is greatest at the commencement or 0 and 10 of the circle of the crank, and least at the points 5 and 15, while the second is least at the first-named points and greatest at the last; and this variation is (from the well-known principles of the composition and resolution of forces) in the ratio of the sines of the angle made between the direction of the crank and the direction of the connecting-rod.

The subdivision of the crank circle into 20 parts gives as the angle of each division 18°, and calling the radius of this circle 100, the sines of the respective angles formed by the crank and connecting-rods will represent the per centage of power communicated by the latter to turn the former. Thus:

Crank-pin at	0	0°		0·0
" "	1	18°	Sin.	30·90
" "	2	36°	"	58·78
" "	3	54°	"	80·90
" "	4	72°	"	95·11
" "	5	90°	"	100·
" "	6	108°	"	95·11
" "	7	126°	"	80·90
" "	8	144°	"	58·78
" "	9	162°	"	30·90
" "	10	180°	"	0·0
			Mean power	63·11

The pressure of the steam on the piston forces the connecting-rod twice the length of the diameter of the circle, in the same time that the crank-pin travels through a space equal to the whole circumference of this circle, and as the circumference of this circle bears to twice its diameter the ratio of 100 to 63·6, it follows that the pressure on the crank and piston are inversely as the spaces through which they move. The effects of moving powers may be represented for comparison by the product of the pressures, into the spaces described in the same time. The power of the steam in the cylinder being 100, and moving through a space represented by 2, we may represent it by 200, and the mean pressure on the crank, as shown above, being 63·11, moving through a space represented by 3·1416 we may represent its effect by their product 198·26, differing but 1·74 from the power given out by the steam in the cylinder. This difference will appear smaller and smaller according as we multiply the number of points in the circle from which we calculate the mean pressure on the crank, until finally the differences become so small as to satisfy us that the discrepancy arises solely from our inaccurate approximation, and the things are, in truth, equal.

The above calculation, when made by means of the differential calculus, shows that the crank is no consumer of power (beyond the friction incidental to all motion of machinery), but gives out all the power it receives from the steam.

In the year 1849, the Society of Arts offered a prize "for the best collection of diagrams (with explanations) to illustrate the action of the forces on a crank or cranks turned from a horizontal direct-action steam cylinder or cylinders; the effect of various proportions of connecting-rods, and degrees of expansion of steam, being shown."

The present paper was communicated to the society in accordance with their invitation, by W. Pole, C. E., and obtained the silver Isis medal.

The varieties of expansion, taken in these diagrams, are three, viz.:

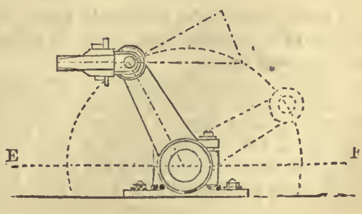
Steam admitted during the whole stroke (Nos. 4, 5, 6).

" " half the stroke (Nos. 7, 8, 9).

" " one-fourth the stroke (Nos. 10, 11, 12).

The varieties of length of connecting-rod have also been taken at three, viz.:

No. 1.



Connecting-rod indefinitely long (supposed to act always in parallel directions.) (Nos. 1, 4, 7, 10).

Connecting-rod five times the length of crank, which may represent about the ordinary length. (Nos. 5, 8, 11).

Connecting-rod three times the length of crank, or about the shortest made. (Nos. 6, 9, 12).

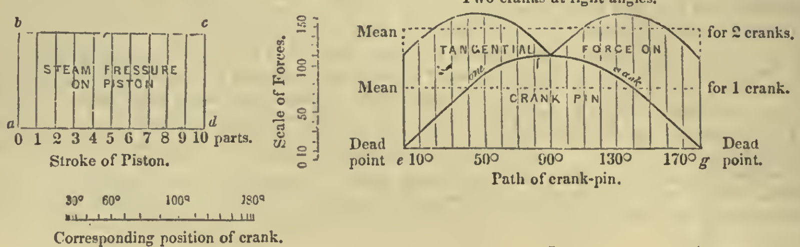
Diagram No. 1, is explanatory of the action of the forces in the transmission of the power from the piston to the crank, for an indefinite length of connecting-rod. The piston rod is shown by the long dotted line

The object of diagrams Nos. 4 to 12, is to exhibit the values and variations of the forces at the beginning and end of the engine; *i. e.*, the pressure of steam on the piston, and the force turning the crank round.

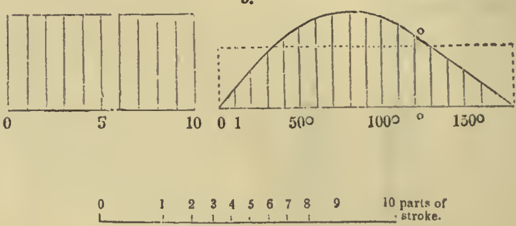
Each set of these diagrams contains a figure showing the pressure on the piston at all points of the stroke, on the plan of rectangular co-ordinates; the abscissa representing the space passed over by the piston, and the ordinate the corresponding pressure. Thus, when the piston has moved from 0 to x, No

4.

Two cranks at right angles.

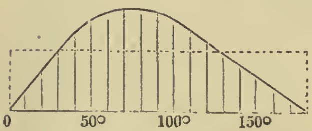


5.



Corresponding position of piston.

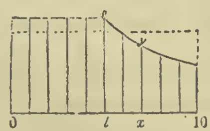
6.



7, or $\frac{7}{01}$ of the whole stroke, the steam pressure upon it is represented by the line $x\,y$. The scale given under the left-hand figure, in Nos. 4, 5, 6, and which also applies to Nos. 7 to 12, shows the position of the crank corresponding to any given position of the piston: thus, in No. 6, it is seen, by inspection, that when the piston has passed through $\frac{5}{10}$ of its course, the crank has passed through about 81° from the dead point, and so on.

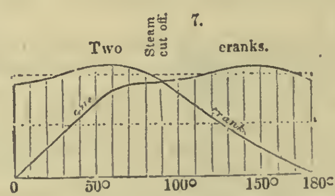
The right-hand figure in each diagram represents the tangential or working force, acting on the crank-pin, at every point of its semi-revolution from E to F, Nos. 1, 2, and 3. The curve of this figure is also laid down by rectangular co-ordinates: the path of the crank-pin (reduced to a straight line) forms the line of the abscissa, while the ordinates express the corresponding forces. Thus in fig. 5, when the crank-pin has moved from 0 to o, or 120° from the dead point, the tangential force, tending to turn it round, is represented by the line o o.

7.

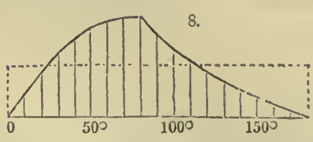


7.

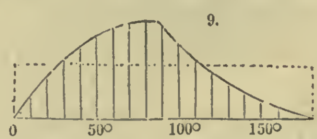
Two cranks.



8.



9.



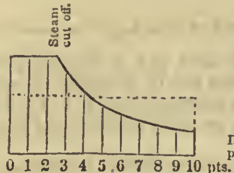
The additional scale, under this figure, shows the position of the piston corresponding to any given position of the crank: thus, in fig. 5, when the crank is at 140°, the piston has moved through $\frac{9}{10}$ of its stroke, and so on.

The lines representing the forces are measured by a scale, which is appended to fig. 4. The pressure of the steam upon the piston, while the steam-valve is open, is made = 100 on the scale; and the ratio of any other force to this pressure is therefore easily ascertained by simple measurement.

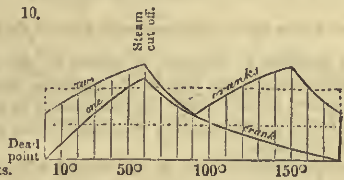
In No. 4, the connecting-rod is supposed indefinitely long; the pressure on the piston is uniform at 100. The tangential force on the crank-pin begins at 0 when the crank is at the dead point; increases to 100 when it arrives at 90°; and diminishes again to 0, in the same ratio as the increase. The mean value of the force, throughout the semi-revolution, is = 63·6, which × the space passed through by

the crank-pin, is exactly = the pressure on the piston + the length of its stroke; or, in other words, the area of the figure $e f g$ = the parallelogram $a\ b\ c\ d$. The result is in accordance with the principle of "conservation of *vis viva*," by which we know that (neglecting friction) the amount of power or work given out at the crank-pin is equal to that performed by the steam on the piston.

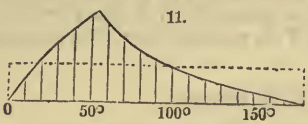
In No. 5 is seen the effect of the connecting-rod being made five times the length of the crank. Here the tangential force commencing at 0, arrives at a maximum value of about 102 when the crank has passed through about 80°



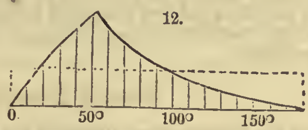
10.



11.



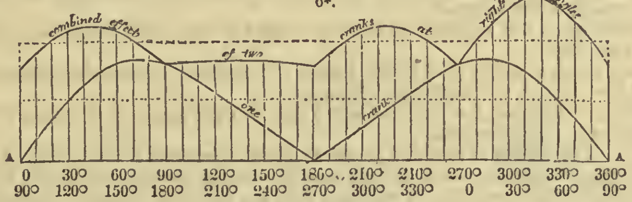
12.



In No. 6, where the connecting-rod is three times the length of the crank, the tangential force arrives at a maximum value of about 106 when the crank has passed through about 75°.

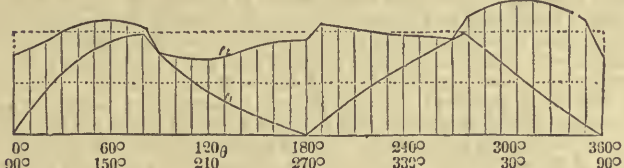
It will be perceived, however, that these variations make no difference in the mean force throughout the whole figure; the effect of the connecting-rod being merely to vary, in a slight degree, the distribution of the force over the path of the crank-pin, without affecting the total amount of power conveyed to it by the machinery. The comparative merits of long and short connecting-rods in other points of view, involve considerations which it would be out of place to introduce here.

6*.

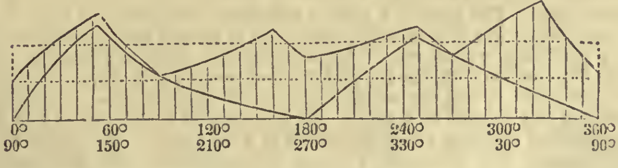


A A′, path of the two cranks.

9*.



12*.



The return stroke, or the other semi-revolution of the crank, does not exactly correspond with the figures shown in diagrams 5 and 6, owing to the reversed condition of the connecting-rod. The nature of the variation will be seen in fig. 6*, where the tangential force is shown for an entire revolution of the crank. It will be observed here, that the force at 10° (commencing at A′) corresponds with that at 350°, at 60° with 300°, and so on.

Nos. 7, 8, 9, show the effect of cutting off the steam at half the stroke. Here the mean pressure on the piston is = 84·6, and the mean tangential force on the crank-pin is = 54; the equality between

the areas of the right and left hand figures being still preserved. The power of the engine is diminished in the proportion of 1000 : 846, although the economy is much increased, as is well known.

Nos. 10, 11, 12, show the effect of cutting off the steam at one-fourth of the stroke. Here the mean pressure on the piston is = 59·6, the mean tangential force is = 38; and the power of the engine is reduced from 100 to 59·6.

Nos. 9* and 12* show the values of the tangential force through an entire revolution of the crank, in the cases above alluded to under corresponding numbers.

Combined action of two Engines, with Cranks fixed at right angles with each other.

The effect of two engines, so coupled, is shown in six cases out of the nine previously described, namely, with three variations in the degree of expansion, and two in the length of connecting-rod. The curve of tangential forces is laid down for two cranks in diagrams Nos. 4, 7, 10, 6*, 9*, and 12*; in the three former, for half a revolution (the other half being precisely similar), and in the three latter, for a whole revolution of the crank.

It is presumed that these figures will be understood without any further description. As an example: at θ (No. 9*), one crank is supposed to have travelled 130° from the dead point E (No. 3); the tangential force on it being expressed by the line $\theta\,\rho^1$: the second crank will then have travelled 220° from the same point; and the combined tangential force will be represented by the line $\theta\,\rho^2$. The undulations of the upper line will therefore represent the inequalities of the working power in the crank-shaft throughout its whole revolution.

Method of Construction of the Diagrams.

In laying down the forces in these diagrams, the following points have been assumed

(*a*). That as long as the steam-valve remains open, the pressure of the steam in the cylinder is uniform. This is not always the case in practice, but must generally be assumed in calculation.

(*b*). That after the steam-valve is closed, the steam expands according to Marriotte's law; the pressure varying inversely as the volume. This is the usual assumption. The causes of variation from this law are treated of in works on the steam-engine, but cannot be comprehended in an investigation of the present nature.

(*c*). That no power is lost by friction, in the transmission of the force through the machine.

(*d*). The influence of the clearance space on the volume of the steam, in expanding, has been neglected. This is but of small moment; and its introduction would have interfered materially with the simplicity and clearness of the diagrams.

(*e*). The moving parts are supposed to have no weight or mass; the forces being considered in a statical point of view only.

The curves have been formed by finding the length of ordinates at convenient distances apart, and tracing a curved line through the points thus obtained.

CROWN WHEEL. A wheel, the teeth of which are at right angles to the plane of the wheel, or parallel to the axis of it. See GEERING.

* CRUCIBLES. The process of reducing an ore to metal is performed in crucibles or pots, of which we employ two distinct kinds; the one is the clay crucible which is free from all carbon, and the other is the plumbago pot. Cast iron crucibles, or retorts of iron, are also used, but not so frequently as to form a particular object for description. Clay crucibles are not, as yet, manufactured in this country. The well-known Hessian crucible is chiefly used. These are perfectly well adapted for most assays, and are cheap and durable. Plumbago crucibles are manufactured in this country to great perfection, and equal to the imported ones. Their use is very limited in the assay. There is no particular necessity of using this crucible at all, because we can line a clay crucible with fine coal dust, which is equal in effect to the plumbago of the black pot. In some instances crucibles of pure coal are necessary; these may be made of a piece of strong charcoal and are then inserted into a Hessian crucible. Generally, a Hessian crucible is filled with finely powdered charcoal, slightly moistened and firmly rammed into it until quite full; a hole is then carved or scraped into the middle, which forms the pot. In other cases, moisten the fine coal dust slightly with gummy water, a solution of starch, oil, salt water, or a weak solution of carbonate of potash or soda. The paste thus formed is in either case rubbed over the inner surface of the clay pot; a lining of about ⅛ of an inch thick is thus formed, which is firmly dried, and forms the coal crucible. The best lining for a crucible is formed of dust from soft coal, such as willow, poplar, or buttonwood coal. The powdered coal is moistened with water and firmly driven in an iron pot which has a form similar to a clay crucible; the cavity is scraped out by means of a knife, and the inner surface finely polished by a glass rod. This lining may be dried in a red heat, provided the caution is taken to fill the crucible with fine dry coal dust and cover it with clay. After burning, it forms a strong pot of a close grain, so that the smallest particle of metal may be detected in it. This coal crucible is inserted in a clay pot and used with it. It is made ¼ and from that to ½ of an inch thick in the sides. Good coal-lined crucibles are indispensable in some assays. Wrought-iron crucibles or retorts are frequently in use. The latter may be made of wrought-iron pipe, bent, and one end stopped up by an iron plug.

Crucibles must be provided with a cover in order to protect the test against the influence of coal and atmospheric air. This cover should have a handle on its upper side, and fit closely to the crucible. In case no regular cover can be obtained, a slab of fire clay, or even a piece of fire brick, may be used as a cover. A good coal, that is, a knotty or spongy piece of coal, may also serve as a cover, but in most cases these throw off splinters which fall into the melting mass and frequently spoil the whole assay. If

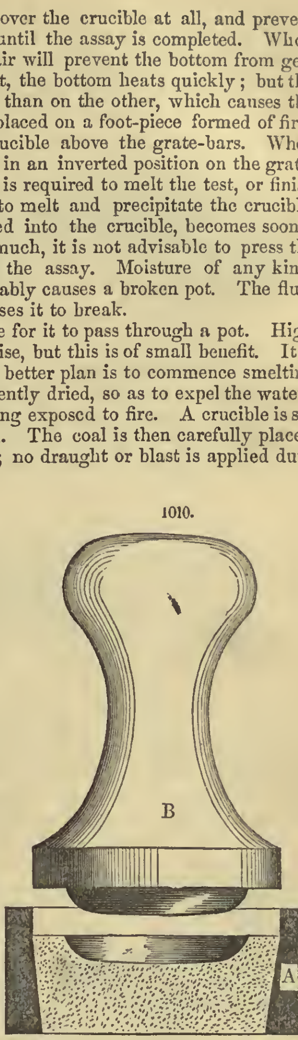
* Overmann's Metallurgy.

the mineral is of such a nature as to boil when heated, we do not cover the crucible at all, and prevent the dropping in of coal by setting around it such coal as will last until the assay is completed. When crucibles are put on the grate-bars of a furnace, the draft of cold air will prevent the bottom from getting hot; if we raise it above the grate-bars and the coal is below it, the bottom heats quickly; but the coal above, in consuming will often sink on one side a little more than on the other, which causes the crucible to incline and spill its contents. A crucible is generally placed on a foot-piece formed of fire-brick. This is from three to four inches high, and elevates the crucible above the grate-bars. When the heat required for the assay is not very high, an old crucible, set in an inverted position on the grate, may serve as a foot-piece. If a very high and a protracted heat is required to melt the test, or finish the assay, the foot-piece must be made of good fire-clay, so as not to melt and precipitate the crucible. The material of the test—that is, ore and fluxes—by being pressed into the crucible, becomes sooner heated. If the test is of such a nature as to melt easily and boil much, it is not advisable to press the mass too strongly, as it may cause the crucible to crack, and spoil the assay. Moisture of any kind, such as water or oil, &c., is objectionable in the crucible; it invariably causes a broken pot. The fluid hardens the mass, which, in expanding more than the crucible, causes it to break.

Crucibles are bad conductors of heat, and it requires a long time for it to pass through a pot. High temperature causes the heat to penetrate a little faster than otherwise, but this is of small benefit. It is therefore of no use to expose a crucible to a high heat at once; the better plan is to commence smelting at a low heat and gradually increase it. All crucibles should be gently dried, so as to expel the water; and any pot which has not been thus dried is liable to crack on being exposed to fire. A crucible is set firmly in the furnace, upon its sole-piece, while the furnace is cold. The coal is then carefully placed around it and the fire kindled, so that the heat may increase slowly; no draught or blast is applied during the first half or three-quarters of an hour.

* CUPEL. Those small flat crucibles in which a part of a metallic alloy is oxidized, and the oxide absorbed by the vessel, are commonly made of white bone-ashes. A variety of materials can be used for the same purpose, but none are superior to bone-ashes, and few cheaper and more readily obtained. A good cupel is a most important instrument in the dry assay. The quantity of precious metal contained in a ton of alloy is often determined by operating upon a few grains of the alloy; and if the cupel is imperfect, the result must be so likewise. For making cupels the bones of sheep, or oxen, or, in very particular cases, the cores of ox-horns, are used; these are broken fine and burned in an open fire of charcoal, and the white ashes resulting from the operation are ground fine and saved for occasional use. It is essential to good success in cupelling, that all carbonaceous matter should be expelled from the bones. The calcining is therefore repeated when any doubt exists as to its having been performed perfectly in the first operation. The bone-ashes must be perfectly white, without a shade of gray when moistened. The burned bones may be crushed in a mortar, or ground in a mill. In all cases they must be converted into a fine powder, which is worked through a fine silk sieve, and is subsequently washed in lukewarm water. The latter operation removes the soluble salts which are in the ashes. It may be repeated to free the powder entirely from such salts, because these always absorb moisture, retain it, and cause the cupel to crack on being exposed to heat. The remaining powder consists chiefly of phosphate of lime, mixed with a little carbonate of lime, and some silicious matter derived from the ashes of the charcoal.

1010.



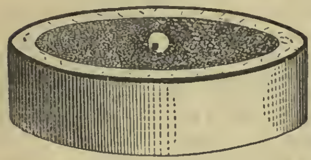
The cupels are formed in a circular mould made of bronze or wrought-iron, or of steel. This apparatus is represented in fig. 1010 in section. The mould A forms a ring, more or less inclined within, nicely turned and smooth; this mould is firmly set on an iron plate, and filled with previously moistened bone-ashes. These are pressed into the mould by an iron ramrod until it is filled. The pestle B is then set upon the surface of the ashes, and driven firmly into it, forming a smooth concavity in the cupel. In driving the pestle with a wooden mallet into the mould, it must be turned around its axis, which will cause the cavity to become smooth. In order to facilitate the latter operation, a little dry bone-ashes is sifted upon the cavity, which causes its surface to be more compact and assume a perfect smoothness. Small cupels, such as those of from ½ inch to two inches diameter, are strong enough when manufactured in this manner. Larger cupels, even those of two inches in diameter, are not strong enough to resist the influence of a great heat without breaking. When this happens, the assay is lost, or at least uncertain. Large cupels are made by filling an iron ring with bone-ashes, as is shown in fig. 1011. Such a ring has the diameter of the cupel, and is from ¾ to one inch high. It is filled with damp ashes, firmly rammed in; and the cavity is scraped out by a knife, and polished by rubbing it smooth with a convex steel button. The iron ring, which may be roughly made, is used so long as it is not burned, and often serves for twenty and more successive cupels and smeltings. Each refining, or assay, requires in all cases a fresh cupel.

The moistening of the ashes for making the cupel is a delicate operation, particularly when they have been dry for some time. The degree of dampness at the time of making the cupel has a marked influence on the result of the operation. If the ashes are too damp the cupel will

* Overmann's Metallurgy.

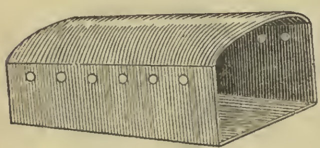
be porous, and liable to absorb metal with the oxides. If the ashes are too dry, the cupel will be close, not sufficiently porous, and work slow; it requires a high heat to imbibe the formed oxides. The best time for making the cupel is when the ashes have been washed with warm water and are thoroughly wet. In this damp state they are exposed to the influence of a warm room, or to the rays of the sun, and constantly stirred to prevent particles becoming too dry. The mass is dried in this manner until it will hardly adhere together when squeezed between the fingers. It is now wrapped in paper and surrounded by a damp cloth, to prevent the evaporation of more moisture. In this state it is employed for making cupels at once. Some manufacturers use farinaceous substances, such as beer or dissolved starch, for glueing the ashes together. When this way of damping the ashes is adopted, the cupels must be exposed to a red heat before they are fit for cupellation. Such admixtures cause the cupels to be porous, and for alloys of gold, silver, and particularly copper, too porous. Good cupels consist of ashes neither too fine nor coarse; fine ashes are required for alloys of gold and silver. In assays on minerals it is necessary to make use of the finest kind of bone-ashes, and use more time in cupelling. All the disadvantages resulting from the use of fine ashes are slow work, more fuel and time; but the assay is always more correct than in cupels made of coarse ashes.

1011.

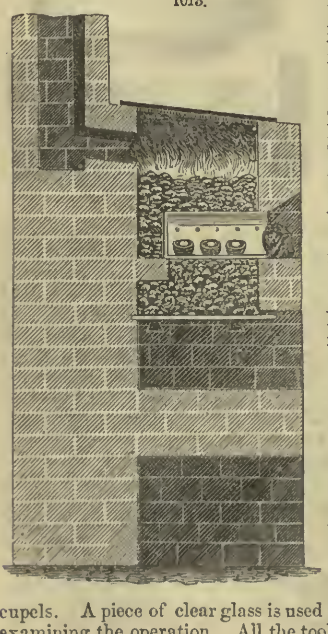


Cupel Furnace. To heat the cupel a furnace of peculiar form is required In some instances it is portable and the fire urged by bellows; for other purposes it is found preferable to employ a stationary furnace. The essential part of a cupel furnace is the muffle. This is a box in the form of a travelling trunk, one end of which is open. In fig. 1012, a muffle is represented. It is a clay trunk of from 10 to 15 inches in length, 5 to 7 inches in width and height. The size is determined according to circumstances. A small muffle of 10 by 5 inches is for small assays all sufficient. In the two sides of the muffle, a series of round apertures is formed to cause a draught of fresh air to pass through the interior. The muffle is made of fire-clay, about half an inch thick and well backed before it is walled in. In large cities muffles may be bought ready made in potters' warehouses. The vapors and oxide of lead which are the result of the cupelling operation, are very severe on the clay of the muffle, and the bottom of it suffers more than any other part; for this reason, the bottom is covered sometimes with bone ashes or common ashes. This is however of little use, for the lead will still reach the clay. It also causes the cupel to heat slowly. When a bottom is eaten through, the muffle is of no farther use and must be replaced by a new one. In fig. 1013 a furnace is represented in which the muffle is walled in. In this instance the whole of the muffle is surrounded by hot coal; it is in the centre of the heat; its bottom is about five inches above the grate-bars, so that coals which come down on both sides may fill the space below. The bottom of the muffle need not be so hot as the top. The oxidation and evaporation of lead is caused by reflection from the top of the muffle. One end of the muffle rests in the front brick wall, and the other is supported by a bracket of brick in the opposite wall. The bottom must be perfectly horizontal in order to afford the cupels a horizontal position. The fire is kindled below the muffle, and in the first stages of the operation, some few pieces of charcoal are laid at the mouth of the muffle, in order to heat it quickly and uniformly. This furnace, with its muffle, is also used for roasting and calcining ore.

1012.



1013.



When a muffle cannot be obtained, a large crucible may be set in a furnace and serve the same purpose; or if no cupel furnace can be had, a cupellation may be performed in a crucible, in the bottom of which a hole has been pierced. The cupel is set on a level with its metal in the crucible, and the latter in the smelting furnace, so that air may be drawn in from below through its bottom, and pass around the cupel, the top being uncovered. It requires some attention to prevent the crucible from falling on one side, in consequence of the unequal consumption of fuel in the furnace. The pierced crucible may also be posted on a pierced sole-piece. This mode of working keeps the cupel rather cool. In a charcoal fire, a sole-piece is of great utility; in a coke fire, a little attention will be equivalent to the sole-piece, and in an anthracite fire there is no difficulty whatever in cupelling in this manner.

The instruments used in cupelling are a pair of small tongs, some hooks of iron wire, and at times bent glass rods, also a pair of light tongs and an iron spoon for bringing the lead upon the cupels. A piece of clear glass is used to protect the eye against the radiating heat from the muffle while examining the operation. All the tools should be provided with wooden handles.

CUTTING AND CARVING MACHINERY. *Machinery and Apparatus for Cutting and Carving Substances to be applied for Inlaying and other purposes.*—This invention consists in certain improved constructions or arrangements of machinery, having a revolving cutter, by means of which, in conjunction with a moveable table, tablets of wood and other materials can be cut away, carved, countersunk, and perforated, in various ornamental forms, with great facility, for the production of inlaid devices, gothic tracery work, and other kinds of ornaments hitherto usually wrought by hand.

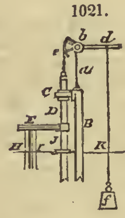
1021.



1016.

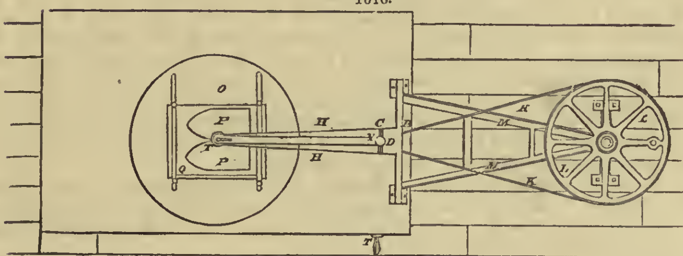


Fig. 1014 represents a side elevation; Fig. 1015, an end elevation; and Fig. 1016, a horizontal view of the machinery. A A is a bench or table, for supporting the several parts of the machine; B B is a standard or bracket-frame, firmly fixed to the said bench; which frame is provided with plummer-blocks and bearings C C, to receive a spindle D. E is a forked frame or swinging arm, firmly fixed upon the spindle D; and the other end of the arm E is furnished with suitable bearings, which carry, in a vertical position, a spindle F. The lower end of this spindle F is formed to receive a chuck V, or other suitable contrivance, for attaching and holding securely the tool, drill, or cutter X, or such other cutter as may be required; and upon the spindle F, near its upper end, is fixed a conical pulley G, having grooves of different diameters, for the purpose of determining the velocity with which the spindle shall be made to revolve. This pulley is designed to receive an endless band or cord H, which passes round the lower part of a similar pulley I, running loosely upon the spindle D; the upper groove of the pulley I is made to receive another endless band or cord K, that passes around a wheel or drum L, supported by a standard or frame N, which is connected by a similar frame M, to the standard B; but the band K may be driven by any other means. O is a horizontal moveable table, mounted upon a vertical shaft R, which passes through the bench A; its lower end being supported by, and turning freely upon a step or bearing S, in the arch Z, fixed to the framing of the bench. The tablet or slab of wood, or other material intended to be wrought by the cutter X, is to be placed upon the turning-table as at P, and made fast thereon by screwed clamps. At the left-hand end of the bench A, there

is a vertical bar J made fast to the wood framing, in which there is a fulcrum-pin for the lever W to turn upon; one end of this lever W is formed into a concave socket to receive, as a step, the lower end of the spindle D before mentioned, and the other end of the lever is connected by a joint with a treadle-rod T. This treadle-rod and lever are for the purpose of raising, when required, the spindle D, with the forked frame E, carrying the drill. U is an adjustable screw set in the leg of the bench as a stop to the lever, intended to regulate the descent of the spindle D with the frame E, in order that the cutter X shall not penetrate deeper into the material or substance P than may be desired.

Fig. 1021, and the part dotted in Fig. 1015, represent another arrangement for raising and lowering the spindle D with the forked frame and drill, instead of the lever and treadle-rod before described: this arrangement is used when the carving of variable relief, such as foliage, figures, &c., is required to be executed.

Upon any convenient part of the standard B is fixed a frame *a*, with bearings *b b* to receive and support the axle of a quadrant *c*, which has a lever *d* attached to its centre. From the periphery of the quadrant *c* is suspended by a chain *e*, or other suitable contrivance, the spindle D, carrying the forked frame E with the drill. To the lever *d* a weight *f* is suspended by a rod, or other convenient means, hung in any of the notches provided in the lever for that purpose; which weighted rod acts as a counter-balance to the spindle D and the several parts attached thereto, thus enabling the cutter X to be raised or lowered with the greatest facility and precision; all the other parts of the machine, and their action, being the same as hereinbefore described.

Fig. 1017 is an elevation, and Fig. 1018 an under-side or end view, of a tool or cutter for cutting or carving a semi-circular or quarter-round hollow, for mouldings, gothic tracery, &c.; Fig. 1019 is an elevation, and Fig. 1020 an under-side or end view, of a tool or cutter for cutting or carving a bed and fillet, or astragal. These are only two examples of cutters, but of course a great variety may be employed, and these must depend upon the form of the edge of the recess intended to be cut or formed; as any and every variety of rounds and hollows, ovolos, ogees, &c., separately or combined, may be executed, not only in straight lengths, but to the form of any regular or irregular curve that may be desired.

The mode of cutting or carving with this machine is as follows:—Upon the revolving table O, the tablet, slab, or piece of wood, or other material P to be cut or carved, is fixed; and on its upper surface, when desired, is placed a template or pattern Q, (formed of iron, brass, or other approved material,) of the design required to be cut or carved; and the two are firmly held upon the table O, by cramps or cramping-bars, as shown. Motion being given by any convenient power to the wheel or drum L, or communicated by any other means to the band or cord K, the pulley I will be made to turn rapidly upon the spindle D; by which means the band or cord H passed round the pulley G will cause the spindle F carrying the cutter X to revolve with great speed, the velocity of the cutter being determined by the proportions which the diameters of the pulleys G and I bear to each other, and the speed of the driving power. The cutter X being set to the depth of cut required by adjusting the stop U, the workman passes down the treadle-rod T with his foot, which causes the lever W to raise the spindle D with the cutter X, and the several parts attached thereto: thus the forked arm E is raised, and being moved around the cutter X, may be passed over the tablet P in an arc; at the same time the moveable table O must be turned, so that the cutter may be perpendicularly pendent over the part of the tablet where the work is to commence. The revolving cutter X is then let down, by removing the pressure from the treadle-rod T, and it immediately penetrates into the tablet. The form in which the cutter moves over the tablet is now to be determined by guiding the shaft of the cutter against the edges of the template or pattern; the table O, with the tablet P upon it, being moved at the same time, in order to keep the edge of the template always close to the shaft of the cutter. By thus moving the swinging-frame E and the table O, various arcs of circles that are constantly tangental to each other may be traced upon the tablet under operation; thereby enabling every possible variety of regular and irregular, curved, and straight forms to be cut or carved in the material acted upon; and this combined or simultaneous action forms the principal novelty of the invention.

The patentee claims the combination and application of the several parts as herein shown and described, and any variation of that combination or application for effecting the principle of his invention; provided the swinging-frame which carries the cutter, and also the table on which the article to be wrought is placed, have both the means of circular motion.

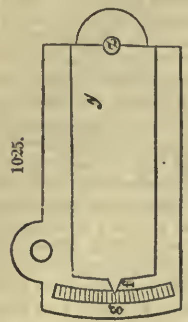
CUTTING-ENGINE. Mr. Joseph Gaume, of Cincinnati, Hamilton County, Ohio, has invented a new and useful improvement in the Cutting-Engine, or machine for dividing and cutting the teeth of cog-wheels. In the accompanying engravings, Fig. 1022 is a plan, Fig. 1023 a side elevation, and Fig. 1024 a front view. The same letters indicate like parts in all the figures.

The leading object of this invention is to adapt the common lathe, by the addition of certain parts, to the cutting of cog-wheels, chiefly for the use of small shops and manufactories where a lathe and cutting-engine are only required occasionally. And the nature of the first part of his invention consists in adding to a lathe, and in combination with the mandrel thereof, a puppet made in two parts for carrying the cutter, the lower half to be attached in the usual manner to the bench, and connected with the upper one by an inclined plane, that the upper part may slide on the lower one at an angle of forty-five or any other number of degrees, for the purpose of carrying the cutter or curr over the wheel in the operation of cutting the cogs of bevel-wheels. The second part of his invention consists in combining with this puppet the cutter-frame, which carries the spindle of the cutter or curr by means of an adjustable horizontal slide, on which the cutter-frame moves to and fro to carry the cutter over the wheel in which the cogs are to be cut; the said slide being a plate with dove-tail or other formed edges, embraced by or embracing the cutter-frame, and attached at one end by a fixed bolt to the top plate of the puppet, and at the other by a screw bolt that passes through a curved slot, whereby the cutter-frame may be made to carry the cutter in its horizontal motion diagonally with the axis of the mandrel for the cutting of diagonal cogs: the spindle of the cutter or curr having its bearings in an adjustable slide

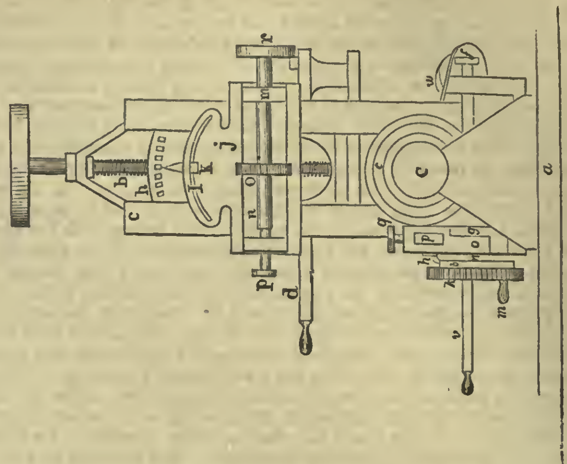
that moves at right angles to the mandrel, to bring the cutter over the axis of the mandrel, (the bed of the slide being connected with a vertical side in the cutter-frame to adapt the cutter to wheels of different diameters,) by means of a fixed bolt on one side and a screw-bolt passing through a curved slot on the other, that the axis of the cutter may be placed at any angle with a vertical line. The third part of the invention relates to the method of dividing the cogs, and consists in placing the index-wheel on a slide, that it may be adjusted to a wheel of any desired number of cogs on an arbor that communicates by a screw or its equivalent to the mandrel which carries the wheel to be cut, so that, by merely changing the wheel on this arbor, a single division index may be used for the cutting of any desired number of cogs. The fourth part of the invention consists in combining the dividing apparatus with the mandrel of a lathe, by means of cogs on the pulley of the mandrel or on the mandrel, the dividing apparatus being so arranged that it can be thrown in and out of geer. In the accompanying drawings *a* represents the bench of the lathe, and C the mandrel with its set of cone pulleys *c*, the face of the larger one of which is a crown cog-wheel *d*, the cogs of which engage with the threads of an endless screw on arbor *e*: the threads of the screw are shown by dotted lines in the plan, Fig. 1022. One end of the arbor runs on the point of a pivot-screw *f*, and the other has a long journal that runs in a box in a standard *g* attached to the bench or the puppet head of the mandrel, so that when the rear end is liberated from the pivot-screw, the arbor can be moved far enough in the standard *g* to carry the ends of the screw out of the cogs of the crown-wheel, that the mandrel may be used for turning the cog-wheel: in this way the wheel can be made with great accuracy, for it is turned and cut on the same mandrel, and therefore there is no danger of not having the wheel properly centered. When the wheel is to be cut, the arbor *e* is properly mounted, and its outer end is adapted by a collar and nut to receive a spur-wheel *j* of any desired number of cogs, which take into the cogs of the wheel K, one face of which is provided with the division plate or index *b*, and the other end with a handle *m* for turning it. This wheel is fitted to and turns on a stud-pin *n*, projecting from plate *o*, that slides on an arm *p* of the standard *g*, that it may be set to the proper pitch line of a wheel of any desired size on the arbor *e*, and there held by a screw *q*. A spring point or catch *r* is used to catch in the notches of the index or division plate *b*.

From the foregoing it will be seen that with any given size of wheel on the arbor *e*, the number of cogs to be cut may be varied by the motions of the dividing or index wheel, as in the ordinary dividing-engine, and that, by changing the wheel on the arbor *e*, any variation can be given to these divisions. The wheel having been turned and the dividing apparatus put in connection, the centering puppet head *s* of the lathe is thrown back, and the extra puppet *t* is secured in place on the bench. This puppet is made in two parts, (t *t*,) connected together by a dove-tail or other slide *u* at an angle of 45°, or any other number of degrees with the plane of the bench. The lower half *t* is secured to the bench, and the other (t) can be made to slide on it by means of a handle or lever *v* that turns on a fulcrum-pin *w* attached to the lower half, and connected with the upper half by a pin X that passes through a slotted hole in a well-known manner. The top plate of the upper half is in a plane parallel with the mandrel, and has a dove-tail slide *y* connected with it at the forward end by a fixed bolt *z*, (see Fig. 1025, which is a plain view of this part,) and at the other end by a screw bolt (a) that passes through a curved slot (see the dotted line) in the top plate, so that any horizontal inclination desired may be given to this slide which is embraced by the bottom plate H of the cutter-frame, (c,) and which can be made to slide thereon by a handle or lever (d) that turns on a fulcrum-pin attached to the puppet and connected with the cutter-frame by a joint-link, (e,) so that by the motion of this lever the attendant carries the cutter to and fro horizontally over the edge of the wheel to be cut, for cutting spur cogs in a direction parallel with the axis of the mandrel, or inclined therewith as the slide may be set, to be indicated by a pointer (f) on the cutter-frame, and an index (g) on the top plate of the puppet. But when the machine is used for cutting the cogs on bevel-wheels, then the cutter-frame is carried by sliding the upper part (t) of the puppet head on the lower part Fig. 1025; the inclination of this slide determining the bevel of the cogs cut. The forward part of the cutter-frame has a plate, (h,) that slides in it vertically by means of a screw, (b,) to adapt the cutter to any desired diameter of wheel to be cut; to this is connected another plate (j) that turns on a bolt, and further secured by a screw-bolt (k) that passes through a curved slot, (l,) by means of which the plate (j) may be turned on the fixed bolt as a centre to give any desired inclination to the axis of the cutter; and this last-named plate is provided with dove-tail ways in which slides the cutter-carrier (m,) which is a frame in which are the bearings of the spindle (n) of the cutter, (o,) so that this may be regulated endwise by a set screw (p.) The cutter is rotated by a belt (q) that passes from any first mover over a pulley (r) on the spindle. From the foregoing it will be seen that the cutter can be adjusted in any direction relatively to the axis of the mandrel that carries the wheel to be cut, and that, by means of one of the handles or levers, the cutter-frame can be moved to and fro to cut the cogs by sliding the cutter-carriage on the puppet in a horizontal plane parallel with the axis of the mandrel, which, by the adjustment of the ways or slide on the puppet, may be adjusted to move in a vertical plane projected from the axis of the mandrel or at any inclination therewith to cut oblique cogs; or, by means of the other handle, that the cutter-frame may be made to move with the upper part of the puppet on an inclined plane to cut the cogs of bevel cog-wheels. It will be obvious, from the above, that the plan of the junction of the two halves of the puppet may be made at any inclination desired to suit the bevel of the wheel intended to be cut.

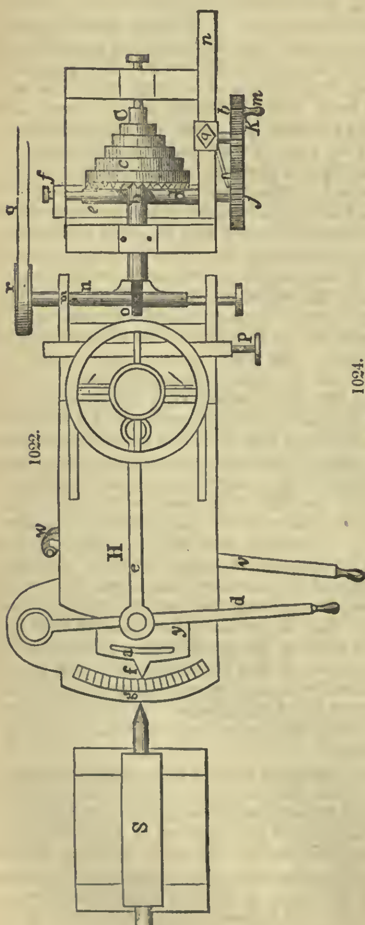
What he claims as his invention and has secured by letters patent, is making the puppet which carries the cutter-frame in two parts, separated by an inclined plane, that one may slide on the other for cutting the cogs of bevel-wheels, in combination with the cutter-frame that slides thereon; and also the cutter-frame and double puppet combined together in combination with the mandrel of the lathe. He also claims the method of adapting the index or division plate that has but one set of divisions, to any division of cogs desired to be cut, by means of shifting the wheel on the arbor that communicates motion to the mandrel, in combination with the sliding connection of the index or division wheel, whereby numerous divisions on the index plate are avoided. And further, he claims the dividing apparatus in combination with the mandrel of a lathe by means of the cog-wheel and pulleys put on one end of the



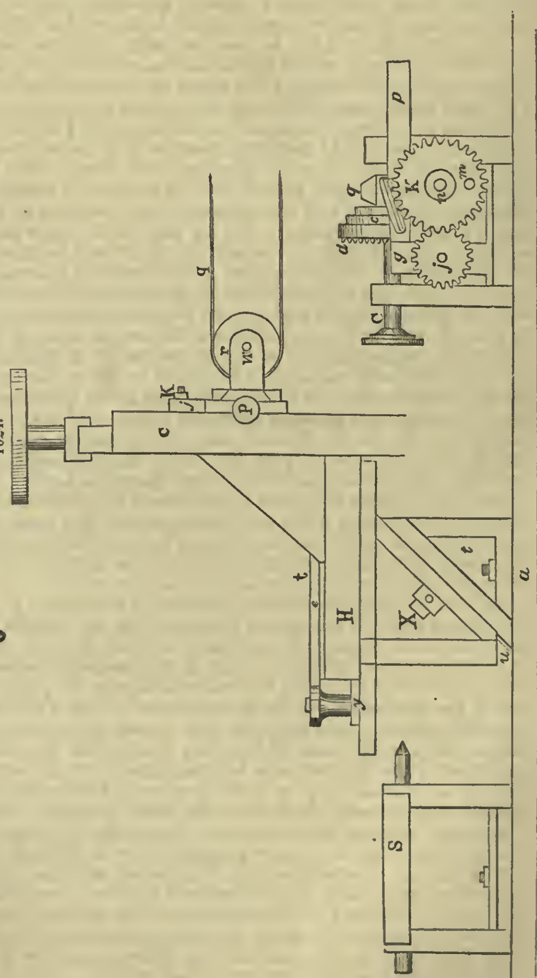
1025.



1023.



1022.



1024.

same mandrel, whereby the wheels to be cut can be turned and cut on the same mandrel without being removed therefrom to insure good work, and whereby also the turning-lathe may be used for a cutting engine.

This machine may be composed either of a single lathe, or of a complicated one, of any desired dimensions, and nothing need be added to it but a side-coupling, to form the division.

First. Its advantages are: turning the wheel on its points; it is thus cut on these same points, with the axis, the length which may be placed on the lathe; likewise, by turning the wheel on the flat side, the hole in the centre and the circumference are cut without its being removed.

Second. This machine can cut a wheel on the circumference obliquely, to the right or left, with any desired inclination; and also the same with regard to the wheel on the side.

Third. The wheel can be cut at an angle of forty-five degrees. This machine can take the place of, and even offers more advantages than the "Great Platform." It can be constructed of any dimension, always being able to cut the wheel which can be turned on the lathe, even should it be fifteen feet in diameter. This machine can be adapted to a lathe placed upon a wooden bench, with only one hundred and fifty pounds additional weight of castings. This cutting machine may be obtained, with all the above-mentioned advantages, from one inch in diameter to two feet. The cast-iron lathe offers more solidity, and with a little additional expense. The division extends to all numbers with the greatest precision.

CUTTING AND PUNCHING MACHINE. See Punching and Cutting Machine.

CUTTING TOOLS, *general remarks upon.* Cutting tools may be included in three groups, namely, Paring Tools, Scraping Tools, and Shearing Tools.

First. Paring or splitting tools, with thin edges, the angles of which do not exceed sixty degrees; one plane of the edge being nearly coincident with the plane of the work produced, (or with the tangent, in circular work.) These tools remove the fibres principally in the direction of their length, or longitudinally; and they produce large coarse chips or shavings, by acting like the common wedge applied as a mechanical power.

Secondly. Scraping tools with thick edges, that measure from sixty to one hundred and twenty degrees. The planes of the edges form nearly equal angles with the surface produced; or else the one plane is nearly or quite perpendicular to the face of the work, (or becomes as a radius to the circle.) These tools remove the fibres in all directions with nearly equal facility, and they produce fine dust-like shavings by acting superficially.

Thirdly. Shearing or separating tools, with edges of from sixty to ninety degrees, generally duplex, and then applied on opposite sides of the substances; one plane of each tool, or of the single tool, coincident with the plane produced.

In explanation of these views, the diagram, Fig. 1026, is supposed to represent seven different tools, the bevels or edges of which are all at the angle of sixty degrees; this may be considered as the medium angle of the paring, scraping, and shearing tools.

The cutting and scraping tools are supposed to be moving from A to B, which line represents the face of the work; or the tools may be considered to be at rest, and the work to be moving from B to A.

Or, in turning, the tool may be supposed to remain fixed, and the circle to represent the moving surface of the work; one plane of the tool then becomes a tangent or radius.

The shearing tools, if in pairs, are proceeding towards each other on the line C D, whilst A B still represents the face of the work. The single tools act on the same principle, but the body of the material, or the surface of the bench or support, supplies the resistance otherwise offered by the second tool.

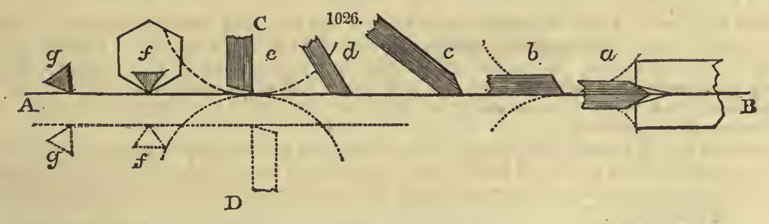
The tools *a c f* are bevelled or chamfered on both sides, the others from one side only; in these latter, the general face of the tool forms the second side of the angle, and allowing for exaggeration, both as to excess and deficiency, the diagram may be considered to represent the edges of the following tools.

[*a b c d*, Splitting and Paring Tools, proceeding from A to B.]

a, The axe, or the cleaver for splitting.

b, The side hatchet, adze, paring and drawing knives, paring chisels and gouges, the razor, penknife, spokeshave, the engraver's graver, and most of the engineer's cutting, turning, and planing tools for metal.

1026.



c, The turning chisel for soft wood, the chipping chisels for iron, stone, &c.

d, The joiner's chisels and carving tools, used with the bevels downwards, the joiner's planes, the cross-cut chisel for metal, and some other metal tools.

[*e f*, Scraping Tools, proceeding from A to B.]

e, When single, the scraping tools for turning the hardwoods, ivory, and brass, the hand-plane for metal; and when multiplied, the various saws and files.

f, When single, a triangular scraper for metal; and when multiplied, the cross-cut saw for wood, and also polygonal broaches or rimers with any number of sides, for metal.

[*e f*, Shearing Tools, proceeding from C to D.]

e, When duplex, shears with edges from eighty to ninety degrees, commencing with delicate lace

scissors for single threads, and ending with the engineer's shears for cutting iron bars and plates upwards of one inch thick; also duplex punches with rectangular edges, for punching engines and fly-presses.

e, When single, the carpenter's firmer and mortise-chisels, the paring-knife moving on a hinge, and cutting punches for gun-wadding and thin materials.

f, When duplex, common nippers for wire; more generally, however, the blades are inclined so that one bevel of each blade lies in one and the same plane, and which is vertical to A B, as at *g g*.

f, When single, the smith's cutting-off chisel.

In practice, the tools differ from the constant angle of sixty degrees, assumed in the diagram for the convenience of explanation, as the angles of all tools are determined by the hardness and the peculiarity of fibre or structure of the several substances upon which they are employed. The woods and soft fibrous materials require more acute angles than the metals and hard bodies; and the greater or less degree of violence to which the tools are subjected, greatly influences likewise the angles adopted for them.

Thus, under the guidance of a little mechanism, the thin edge of a razor, which is sharpened at an angle of about 15 degrees, is used to cut minute slices or sections of woods, in all directions of the grain, for the purpose of the microscope. But the carpenter and others require more expeditious practice, and the first change is to thicken the edges of the tools to range from about 20 to 45 degrees, to meet the rough usage to which they are then exposed, whether arising from the knots and hard places in the woods or the violence applied.

In tools for iron and steel from 60 to 70 will be found a very common angle, in those for brass 80 to 90, in hexagonal broaches for metal it increases to 120, and in the octagonal broach sometimes employed the angle is still greater; in the circular broach required by clock and watch makers, the angle disappears and the tool ceases either to cut or scrape, it resolves itself into an instrument acting by pressure, or becomes a burnisher.

To a certain extent, every different material may be considered to demand tools of a particular angle, and again the angle is somewhat modified by the specific mode of employment: these conditions jointly determine the practical angles suited to every case, or the angles of greatest economy or most productive effect.

The diagram shows that, independently of the measure of the angle of the tool, we have to consider its position as regards the surface of the work, the broad distinction being that, in the paring tools, the one face of the wedge or tool is applied nearly parallel with the face of the work; and in the scraping tools, it is applied nearly at right angles, as explained in the foregoing definitions. Indeed the paring tools, if left to themselves, will in some cases assume the position named; thus, for example, if we place a penknife at an elevated angle upon a cedar pencil, and attempt to carry it along as a carpenter's plane, the penknife, if held stiffly, will follow the line of its lower side and dig into the wood; but if it be held slenderly, it will swing round in the hand until its blade lies flat on the pencil, and it will even require a little twisting or raising to cause it to penetrate the wood at all. This disposition appears to be equally true in the thin edges of the penknife or razor, and in the thick edges of the strong paring tools for metal.

The action of a cutting tool in motion is two-fold. The moving force is first exerted on the point of the wedge, to sever or divide the substance particle from particle; the *cohesion of the mass* now directly opposes the entry of the tool, and keeps it back. But the primary motion impressed on the tool having severed a shaving, proceeds to bend or curl it out of the way; the shaving ascends the slope of the wedge, and the *elasticity of the shaving* confines the tool in the cleft, presses it against the lower side, disposes it to pursue that line, and therefore to dig into the substance.

The Forms and Motions of Tools, as regards the production of Lines, Superficies, and Solids.—The principles of action of all cutting tools, and of some others, whether guided by hand or by machinery, resolve themselves into the simple condition, that the work is the combined copy of the form of the tool, and of the motion employed. Or in other words, that we exactly put into practice the geometrical definitions employed to convey to us the primary ideas of lines, superficies, and solids; namely, that the line results from the motion of a point, the superficies from the motion of a line, and the solid from the motion of a superficies.

It therefore follows, as will be shown, that when the tool is a point having no measurable magnitude, that two motions must be impressed upon it, one equivalent to the breadth, and another equivalent to the length of the superficies. When the tool is wide, so as to represent the one dimension of the superficies, say its breadth, then only one motion is to be impressed, say a motion equivalent to the length of the superficies; and these two are either rectilinear or curvilinear, accordingly as straight or curved superficies are to be produced.

To illustrate this in a more familiar way than by the ideal mathematical conceptions—that a point is without magnitude, a line is without breadth, and a superficies without thickness—we will suppose these to be materialized, and to become pieces of wood, and that the several results are formed through their agency on soft clay.

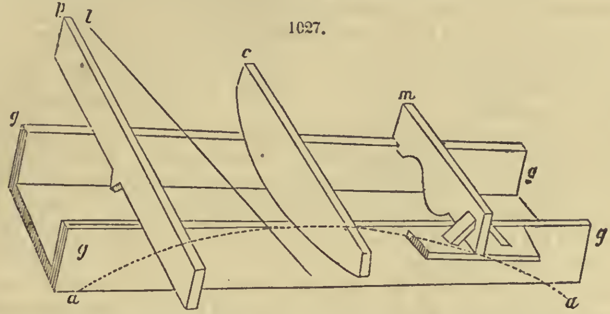
Thus supposing *g g* to be two boards, the edges of which are parallel and exactly in one plane, and that the interval between them is filled with clay; by sliding the board *p* along the edges of *g g*, the point in *p* would produce a line, and if so many lines were ploughed that every part of the clay were acted upon by the point, a level surface would at length result. The line *l*, such as a string or wire, carried along *g g*, would at one process reduce the clay to the level of the edges of the box.

Either the point or the line might be applied in any direction whatever, and still they would equally produce the plane, provided that every part of the material were acted upon; and this, because the section of a plane is everywhere a right line, and which conditions are fulfilled in the elementary apparatus, as the edges of *g g* are straight and give in every case the longitudinal guide, and with *l* the second line is formed at once, either with a string, a wire, or a straight board; but in *p* the point

requires a second or transverse guide, and which is furnished by the straight parts of the board p rubbing on the edges of $g\,g$, and therefore the point obtains both a longitudinal and a transverse guide, which were stated to be essential.

The board c, with a circular edge, and m, with a moulding, would respectively produce circular and moulded pieces, which would be straight in point of length in virtue of $g\,g$ the line of motion, and curved in width in virtue of c or m the lines of the tools. But now c and m must always advance parallel with their starting positions, or the width of the moulding would vary; and this is true, whenever curved guides or curved tools are employed, as the angular relation of the tool must be then constantly maintained, which it is supposed to be by the external piece or guide attached to m.

1027.



Supposing $g\,g$ each to have circular edges, as represented by the dotted arc $a\,a$, or to be curved into any arbitrary moulding, the same boards p, l, c, m would produce results of the former transverse sections, but the clay would in each case present, longitudinally, the curved figure of the curved longitudinal boards $a\,a$; here also the line of the tool and the line of the motion would obtain in the result.

If, to carry out the supposition, we conceive the board $a\,a$ to be continued until it produced the entire circle, we should obtain a cylinder at one single sweep, if the wire l were carried round at right angles to $a\,a$. But to produce the same result with the point p, it must be done either by sweeping it round to make circular furrows very near together, or by traversing the point from side to side, to make a multitude of contiguous lines parallel with the axis of the cylinder. In either case we should apply the point to every part of the surface of the cylinder, which is the object to be obtained, as we copy the circle of $a\,a$ (which is supposed to be complete) and the line l, or the transverse motion of p, which is equivalent to a line.

But it is obvious that, in every case referred to, there is the choice of moving either the clay or the tool, without variation in the effect. If in respect to the circular guide $a\,a$, we set the clay to rotate upon its centre, we should produce all the results without the necessity for the guide-boards $a\,a$, as the axis being fixed, and the tool also fixed, the distance from the circumference to the centre would be everywhere alike, and we should obtain the condition of the circle by *motion alone*, instead of by the *guide;* and such, in effect, is turning.

An every-day example of this identical supposition is seen in the potter's wheel; and the potter also, instead of always describing the lines of his works with his hands, as in sketching, occasionally resorts to curved boards or templets, as for making the mouldings for the base of a column, or any other circular ornament. But here, as also in ordinary turning, we have choice either to employ a figured tool, or to impress on a pointed tool a path identical with the one section; for example, the sphere is turned either by a semicircular tool applied parallel with the axis, or else by sweeping a narrow or pointed tool around the sphere in the same semicircular path.

Having shown that in every case the superficies is a copy of the tool and of the one motion, or of the point and the two motions, it will be easily conceived that the numerous superficies and solids, emanating from the diagonal, spiral, oval, cycloid, epicycloid, and other acknowledged lines, which are mostly themselves the compositions of right lines and of circles, may be often mechanically produced in three different ways.

First, by the employment of tools figured to the various shapes, and used with only one motion or traverse; secondly, by the use of figured guides, *cams*, or *shaper-plates*, by which the motion is constrained, just the same as p makes a right or a curved line, in virtue of its straight or curved guide; and thirdly, by the employment of a point actuated by two motions, by the composition of which most geometric lines are expressed.

Thus when *uniform* motions are employed, two rectilinear motions produce a diagonal to themselves; one circular and one continued right-line motion, give the spiral, the screw, and the cycloid: also if, during *one* circular revolution, either the circle or the point make *one* oscillation in a right line, we obtain the oval; by two circular movements we obtain the epicycloid, by three motions the compound or double epicycloid, and so on. And when one or both of the rectilinear or circular generating motions are *variable* as to velocity, we obtain many different kinds of curves, as the parabola, hyperbola, and others; and thence the solids, arising from the revolutions of some of these curves upon an axis.

We produce the practical *composition* of any two lines or movements, whether regular or irregular, by impressing these movements on the opposite extremities of an inflexible line or rod; from which rod we obtain a compounded *line* if we trace the motion of a point inserted in any part of the rod, and we obtain a compounded *superficies* if we copy the motion of the entire line. This may need explanation.

Supposing that in Fig. 1027, the back guide $g\,g$ to remain a straight line, the front to become the

circular arc *a a*, the board *p* being now traversed in contact both with the straight and curved edges, the point *p* would describe a line if it were close against the line *g g*, or an arc if close against the arc *a a;* midway it would describe an arc of about half the original curvature. On the other hand, the line *b* would cut off the clay in a superficies, possessing at the three parts these same conditions, and merging gradually from the right line to the arc *a a*.

But a similar composition of the two lines or motions would occur, were the lines *g g*, *a a* to be exchanged for any others, similar or dissimilar, parallel or oblique, or irregular in two directions; and in mechanical practice we combine, in like manner, two motions to produce a compound line or a compound superficies. Indeed in many cases there is no alternative but to impart to two edges *g a* of a block the marginal outlines of the superficies, and then, generally by *hand-labor*, to reduce all the intermediate portions under the guidance of a straight edge applied at short intervals upon the two edges, which thus become compounded or melted together in the superficies. Numbers of irregular surfaces can be produced by this mode alone.

In fine, in mechanical processes, we translate the mathematical *conceptions* of the rectilinear, circular, and mixed motions of points and lines, into the mechanical *realities* of rectilinear, circular, and mixed motions of pointed or linear tools.

It is not imperative, however, that the tools should have but one fixed point or edge, as without change of principle a succession of similar points may be arranged in a circle, to constitute a revolving cutter, which by its motions will continually present a new point, and multiply the rapidity of the effect. In most cases, the introduction of a tool with a figured outline, cancels the necessity for the means otherwise required to generate such figured line by the motion of a point; and a tool with a figured superficies, cancels also the remaining motion required to produce the superficies, and the tool is simply impressed as a stamp or die.

In tracing the method of applying these theoretical views to the explanation of the general employment of cutting tools, or the practice of the workshop, we may safely abandon all apprehension of complexity, notwithstanding the almost boundless variety of the elements of machinery, and other works of cutting tools. For although all the regular figures and solids referred to are in reality met with, besides a still greater number of others of an irregular or arbitrary character, still by far the greater majority of pieces resolve themselves into very few and simple parts, namely, solids with plane superficies, such as *prisms*, *pyramids*, and *wedges*, and solids with circular superficies, such as *cylinders*, *cones*, and *spheres*. These are frequently, as it were, strung together in groups, either in their entire or dissected states; but as they are only wrought one surface at a time, the whole inquiry may be considered to resolve itself into the production of superficies.

The *guide principle* is to be traced in most of our tools. In the joiner's plane it exists in the form of the stock or sole of the plane, which commonly possesses the same superficies as it is desired to produce. For instance, the carpenter's plane used for flat surfaces is itself flat, both in length and width, and therefore furnishes a double guide. The flat file is somewhat under the same circumstances, but as it cuts at every part of its surface, from thousands of points being grouped together, it is more treacherous than the plane as regards the surface from which it derives its guidance, and from this and other reasons it is far more difficult to manage than the carpenter's plane.

In many other cases the cutting instrument and the guide are entirely detached; this is strictly the case in ordinary turning, in which the circular guide is given by the revolution of the lathe mandrel which carries the work, the surface of which becomes the copy of the tool, or of the motion impressed upon the tool, either by the hand of the workman under the guidance of his eye alone, or by appropriate mechanism.

When the lathe is employed under the most advantageous circumstances to produce the various geometrical solids or figures, the tool is placed under the guidance of a ruler, or rather of a slide, by which its path is strictly limited to a rectilinear motion. Thus, for a cylinder the slide is placed exactly parallel with the rotary axis of the mandrel, and for a plain flat surface the tool is moved on a slide at right angles to the axis. Generally two slides fixed in these positions are attached to the lathe to carry and guide the tool, the machine being known as the sliding-rest; but mostly the one slide only is used as a traversing or directional slide for guiding the tool, the other as an adjusting or position slide for regulating the penetration of the tool into the work.

Sometimes the two slides are moved simultaneously for the production of cones, but more generally the one slide is placed oblique and used alone. The lathe is employed with great effect in producing plane surfaces, but the more modern engine, the planing-machine, the offspring of the slide or traversing lathe recently adverted to, is now also very much employed for all kinds of rectilinear works.

The planing-machine being intended principally for rectilinear solids of all kinds, its movements are all rectilinear, and these are in general restricted to three, which are in the same relation to each other as the sides of a cube; namely, two are horizontal and at right angles to each other, and the third is vertical, and therefore perpendicular to the other two. The general outline of the machine will be conceived by imagining a horizontal railway to take the place of the revolving axis of the lathe, and the slide-rest of the lathe to be fixed vertically against the face of a bridge stretching over the railway.

In the general structure of this most invaluable machine, the railway is the cutting slide, upon which the work is slid to and fro. For producing a horizontal surface, the horizontal slide is employed for traversing the tool across the face of the work, which is thus reduced by ploughing a series of parallel grooves, not exceeding in distance the width of the pointed tool, so that first the line, and then the surface arise, exactly as in the geometrical suppositions. For vertical planes, the vertical is the traversing slide, the horizontal, the adjusting; and for oblique planes, the vertical slide is swivelled round to the assigned angle, the imaginary railway being employed in all cases to give the cutting motion.

When we examine into almost any machine employed in cutting, it will be found that the end to be obtained is always a superficies, either plane or curved, and which superficies reduced to its elementary condition, presents length and breadth.

When therefore we have put on one side the mechanism required for connecting and disconnecting the engine with the prime mover, whether animal, steam, or other power, it will be found that when the superficies is produced by a pointed tool, the primary motions resolve themselves into two, which may be considered representative of length and breadth. The velocity of the one primary motion is suited to the speed proper for cutting the material with the most productive effect, which for the metals is sometimes as low as ten or twenty feet per minute, measured at the tool, and for the woods the speed is above ten or twenty times as great.

The principal limit of velocity in cutting machines, appears to be the greatest speed the *tool* will safely endure, without becoming so heated by the friction of separating the fibres as to lose its *temper* or proper degree of hardness.

The cohesion of iron being very considerable, a velocity materially exceeding ten to twenty feet per minute would soften and discolor the tool, whereas in general the tools for iron are left nearly or quite hard. Brass, having much less cohesion than iron, allows a greater velocity to be used; lead and tin admit of still more speed; and the fibrous cohesion of the soft woods is so small, that when the angles of the tools are favorable, there is hardly a limit to the velocity which may be used. Water, soap and water, oil, milk, and other fluids, are in many cases employed, and especially with the more fibrous metals, for the purpose of lubricating the cutting edges of the tools to keep down the temperature, the fluids reduce the friction of separating the fibres and cool both the tool and work, thereby allowing an increase of velocity; and at the same time they lessen the deterioration of the instrument, which when blunted excites far more friction, and is likewise more exposed to being softened, than when keen and in perfect working order. There are, however, various objections to the constant use of lubricating fluids with cutting tools.

The velocity of the other primary motion is generally very small, and often intermittent; and it becomes a mere creep or traverse motion, by which the pointed tool is gradually moved in the second direction of the superficies under formation.

In producing circular bodies, one of these primary motions becomes circulating or rotary, and in complex or irregular forms an additional movement, making in all three, or *sometimes* four, are compounded; and lastly, when linear or figured tools are employed, one of the motions is generally expunged.

DAMS. An erection of earth, wood or masonry, above the channel of a stream, for the confinement of the water for the purposes of navigation, or for water supply.

Fig. 62 represents a section of the Dam across the Croton river, which supplies the city of New York with water. The base of this work is composed mostly of cob, or crib-work of logs or timber, their intervals being filled in with stone, and the intervals between the piers of crib-work, with concrete. The upper portion, and the apron, or down stream face of the dam, is made of cut stone. A secondary dam is constructed below, in order that the discharges or overflow of the water may fall into back-water, and in that way check the force of the current. Dams constructed in this way, with a curved or inclined apron either of stone or wood, are called *rolling* dams. When the foundation is upon rock, it is cheaper and better to make the dam without an apron, the water falling directly upon the ledge. The slope of the upstream face of the dam in this case, is made at an inclination of 2½ or 3 horizontal to 1 vertical, in order that the tendency of water passing over it may be to press it down upon the foundation than to displace it. In timber dams, the most usual form is to place main timbers perpendicular to the face of the dam and at the inclination of the face, in frames or sections from 3 to 8 feet apart, these frames consisting of inclined timbers blocked upon each other. The foot of the timbers being bolted securely to the ledge, the face being formed by thick planks treenailed upon the outer timber, the slope is then loaded with gravel. In some cases the upper timber is inclined, and the lower timbers placed horizontal.

Dams constructed of masonry are laid full in cement, or dry, with a sheet piling of brick or stone laid in cement, on the upstream face. Their forms are various, but they should be of sufficient section to resist the pressure of the water, for calculation of which, see WALLS.

In all dams for permanent purposes, it is of the utmost importance that they should be well secured at the bottom, to prevent the water passing beneath the structure. This is usually effected by sheet piling of plank or masonry on the upper face, and to prevent any wash at the wings, the spiling is extended into the banks at the sides, or in case of rock, connected with it.

Temporary dams are often made of crib-work floated into the stream and loaded, gravel being thrown on the upper side to make them tight. By felling of trees across the stream and filling in with branches, straw, turf and earth, a temporary purpose may be served.

Of the obstructions caused by dams, the height to which the water is raised by such structures, see HYDRAULICS.

DADO. A term for the die or plane face of a pedestal. The dado employed in the interior of buildings is a continuous pedestal, with a plinth and base moulding, and a cornice or dado moulding surmounting the die.

DAMASQUINE. A term applied to ornamental work of gold or silver, incrusted on iron or steel.

DAMPER. A valve placed in a chimney, to diminish the draught when the heat is too intense.

DERRICK. A species of crane for the raising of heavy weights, &c. It differs from the crane properly so designated, in that the boom or arm is movable. It is chiefly applied in constructions, whilst the crane may be considered a fixture for workshops, foundries and warehouses. Fig. 1032 represents the common form of derrick, used for the setting of small stone, in this particular example, as the building of the Dry Dock in Brooklyn. Its construction will be easily understood from the figure. The mast is supported in its upright position by radial guys, made fast severally to posts set firmly in the ground. The weight to be raised is attached to the lowest block, which is suspended by means of another

* Holtzapfeld's Turning and Mechanical Manipulation

block to the end of the boom. The rope passes over a pulley or shear in or on the boom, and thence over another near the top of the mast, thence passing down parallel to the mast, it is attached to a barrel or drum, and can be taken up or let out by means of a geer and pinion and crank, thereby raising or lowering the weight. The boom can be raised or lowered by means of the rope at the bottom of the mast, which is passed two or three times round a small fixed cylinder, and is united to the end of the boom by a system of blocks. By the slacking of this rope, the boom may be lowered whilst the weight is suspended, which enables the workmen to take up the stone at one distance from the mast, and lay it at another more remote. The machine is swung into position by a small rope attached to the end of the boom or to the weight itself.

1031.

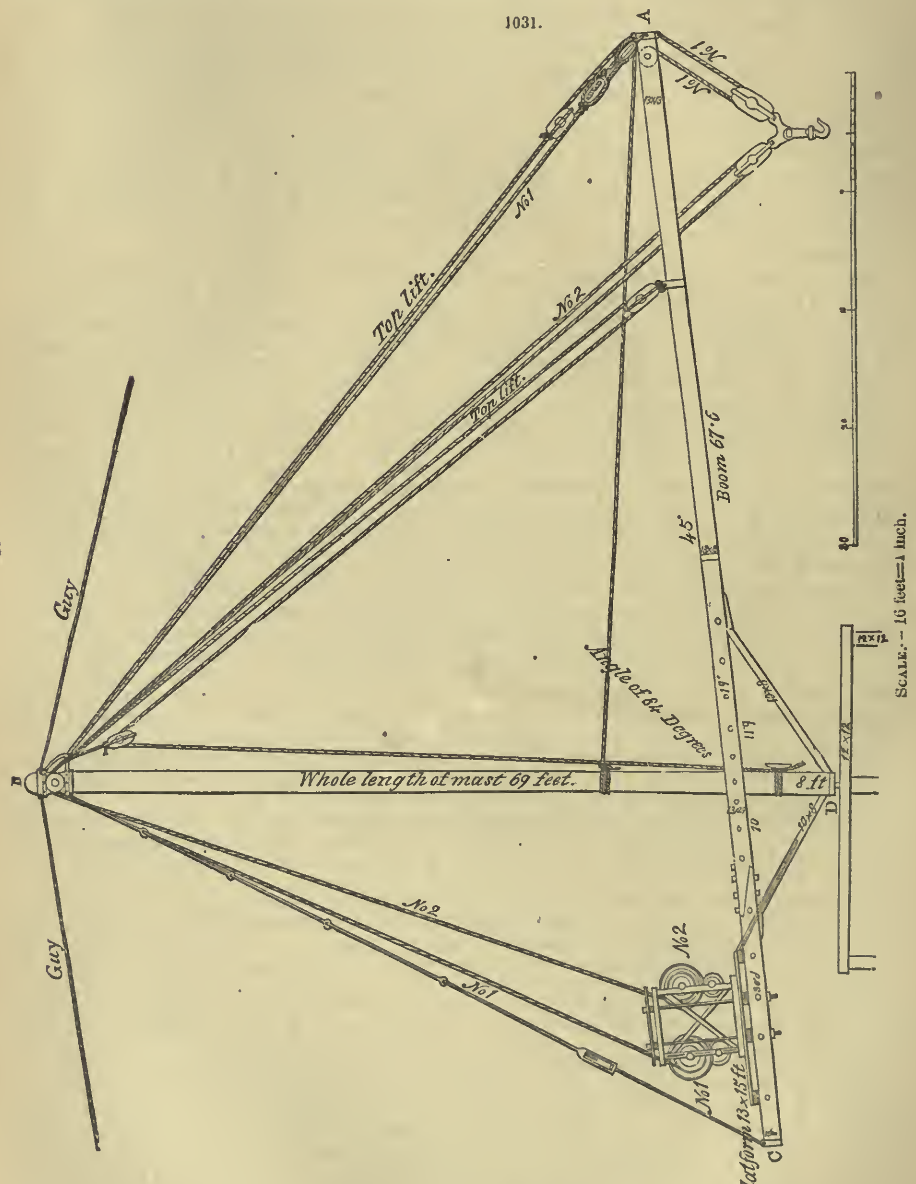


Fig. 1031, represents Savage's Derrick as improved by Mr. McAlpine, and used at the Brooklyn Dry Dock for the laying of the heaviest stone. It differs somewhat in its arrangement from the simple machine already described. It will be seen that the hook for the suspension of the weight, is supported by two blocks. By tracing the position of the rope No. 1, it will be seen that by it the right hand one of

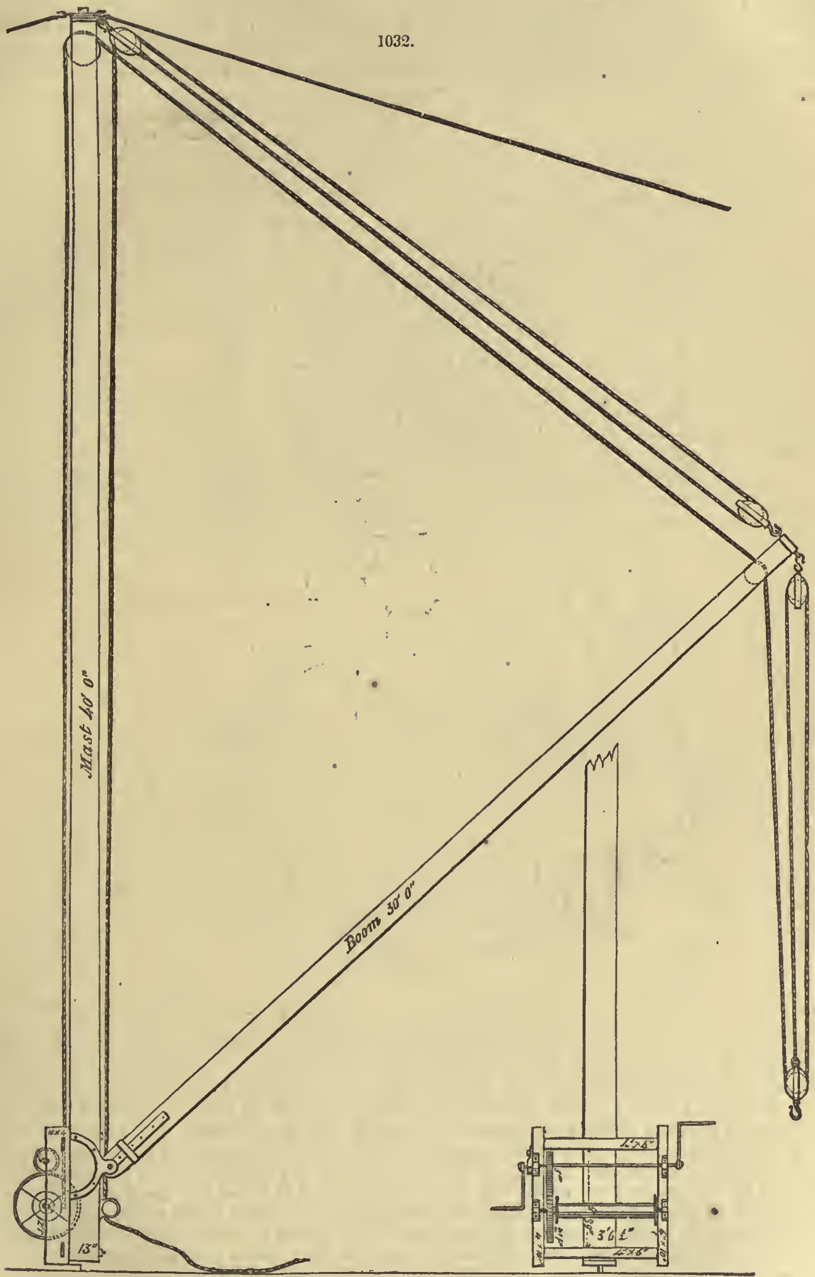
these blocks can be raised or lowered by means of the crank, pinion, geer and barrel. No. 1 of the crab, at the opposite end of the boom; in a similar way, the left hand block is raised by rope No. 2. Thus it will be seen that by the winding up of rope No. 1 on the barrel, a motion upwards and outwards is given to the suspended weight, whereas by the winding up of No. 2, the weight is raised upwards and

1032.



Scale.—6 feet=1 inch.

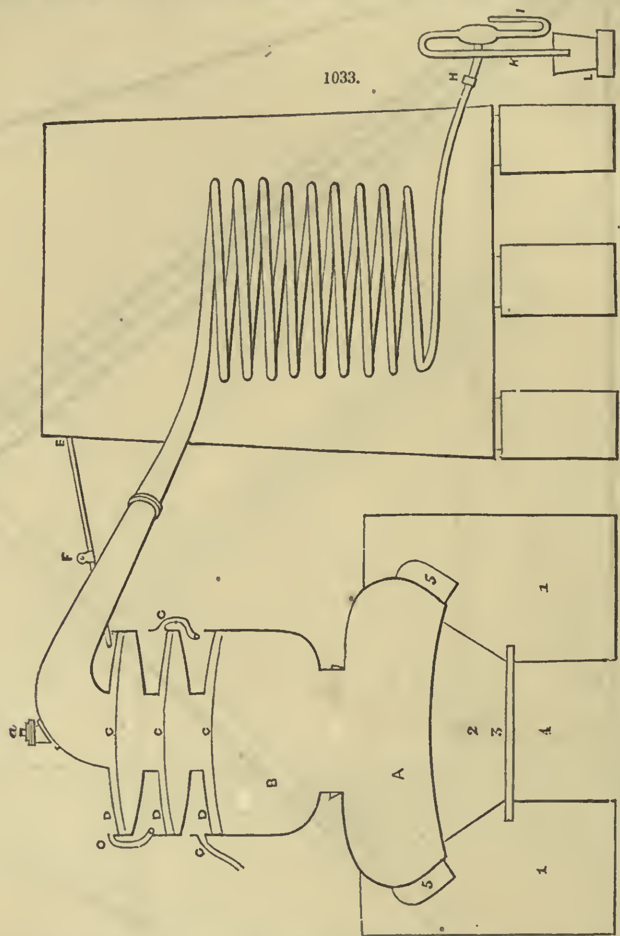
inwards. Again, if rope No. 1 alone be slackened, the weight is lowered and tends inwards, and again if No. 2 be slackened, the weight is lowered outwardly; by these means the stone may be deposited at any spot within reach of the boom.

DISC ENGINE. See Engine.

DISTILLATION. The evaporation and subsequent condensation of liquids and even solids. The vessel used for generating the vapor if of large size is called a *still.* Distillation as carried on by the chemist is usually by means of *retorts*, and the vessel that receives the distilled matter is called a *receiver*; this is perhaps the most simple method of distilling. The distillation of coal in the manufacture of illuminating gas is conducted in cast-iron retorts, and is an example of this form of distillation.

There are two distinct operations in the production of ardent spirits. The one is the conversion of certain vegetable principles into alcohol, the other the separation of the alcohol from other substances with which it is necessarily blended in its production. The vegetable principle which is essential to the formation of alcohol is sugar, and this is sometimes used directly, as when molasses and like products are

1033.



subjected to immediate fermentation, or it is indirectly obtained by subjecting amylaceous grains to certain processes by which the starch they contain is first converted into sugar, and the sugar afterwards alcoholized. For this latter purpose, the various grains are subjected to the operation of bruising or *mashing*, and infused under constant agitation in a proper quantity of water in the mash tun. In this way the *wash* is obtained which is run into the fermenting vats, where mixed with a small quantity of yeast, it is subjected to the process of fermentation which requires from 6 to 12 days, the term varying with the mass of liquid and the temperature of the atmosphere. As the fermentation progresses, the wash attenuates; as this attenuation reaches the maximum, the wash is drawn into the still and subjected to heat, the spirit or more volatile matter passing over first, is condensed in the worm, and yields spirit. In general, the wash is first subjected to distillation, from which a weak spirit is obtained, then this spirit is re-distilled from which proof spirits are obtained, the stronger spirits being the most volatile, being the first to pass over.

Of stills there are almost an endless variety, differing not in essential principles but in detail. We instance one of the earliest improved stills, that invented by Corty, and afterwards much simplified by Messrs. Shears & Sons.

Fig. 1033 is a representation of this still: A being the body of the still into which the wash is put; B is the still head; C C C are three plates of copper fitted into the upper part of the boxes D D D, which are kept at a regulated temperature by water being conducted over their outer surface, by means

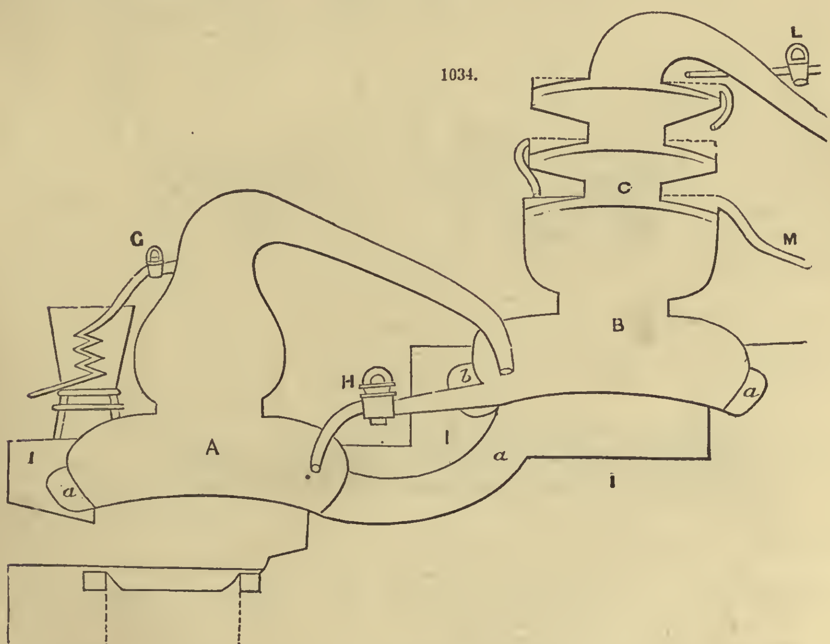
of the pipe E and the distributing pipes G G G. The spirit vapor then rising from the body of the still meets a check at the lowest plate C, by reason of the coolness occasioned by the water; this condenses the grosser part of the vapor and throws it back, whilst the lighter proceeds on to the second plate C, where a further coolness condenses another portion of the vapor, leaving a much purer spirit to encounter the increased coolness at the third plate C. Here the last separation takes place; the aqueous and oleaginous particles being unable to sustain the temperature maintained, fall back condensed, and only a very strong spirit passes over in the gooseneck. By means of the cock F, in the pipe E, the supply of water to the boxes D can be very exactly regulated; and, as a natural consequence, the temperature can be very accurately adjusted. If the temperature of the upper box be kept at 174°, for example, the alcoholic vapor which passes over will be comprised of 90 per cent. of pure alcohol, or 65 over proof; but with a temperature of 194° Fahr. the vapor will contain only 66 per cent. pure alcohol, or 30 per cent. over proof. *a* is a screw-cap, through which a jet of steam or water may be sent to clear away the deposite, which otherwise will more or less accumulate on the upper surfaces of the plates C. At the lower end of the worm-pipe is affixed, by means of the brass swivel-joint screw H, a gas apparatus. The peculiar form of the pipe I into which the spirit runs from the worm, causes it to be filled shortly after the still commences working; whilst the other branch pipe K rises to some height, then returns, and is immersed in the small box L to the extent of about two inches in water. The gas from the still escapes by this pipe through the water, as the pressure can be but trifling.

It is held, that by means of this gas apparatus the distillation proceeds in a partial vacuum, and that thereby there is a great economy in fuel. As the spirit enters the worm at so much lower a temperature than in the old stills, that quantity of water is not required to cool the spirit vapor as would be otherwise.

A still of 400 gallons is said to work off four to five charges in the day of twelve hours; yielding a spirit on an average of 35 per cent. over proof: which, for rum, is considered the most advantageous strength to run it at.

Fig. 1034 is another arrangement of the same kind of still; being the addition of the common still A to the patent still B. In this case the contents of B are drawn down from time to time into A, and that of A run off as dunder; the spirit from A being conducted into B. One fire heats both stills; and it is stated that by the general adaptation and arrangement, a very large quantity of fine spirit is produced by the consumption of a very inconsiderable amount of fuel.

1034.



DIVING-BELL. A box, shaped somewhat like a bell, and usually constructed of plate iron, intended for the purpose of enabling a person to descend beneath the surface of the water. It is open below, and is lowered into the water, the air beneath being condensed in proportion to the depth to which it is sunk beneath the surface. To give sufficient air-space in the bell, and to supply fresh air for the purpose of breathing to the parties within it, air is forced in from above through a flexible tube by means of a condensing pump. This machine is extremely valuable in setting foundations beneath the water, and in making examinations of sunken wrecks.

DOCKING SHIPS, *Apparatus for*. The Marine railway. The *slip*, Figs. 1039 to 1042, consists of three timber ways laid down on piles or on the firm beach, and running into deep water. These ways carry a rail, on which work the trucks or rollers of the carriage or frame D D. This carriage or frame

consists of three strong longitudinal trucks, secured together by six, seven, or more movable cross-pieces, the carriage being hauled upon the ways by means of a wheel and pinion, capstan, or other purchase. On the keel-beam D of the carriage, blocks are laid to such a height that the keel of the vessel may clear the ends of the cross-pieces, and each block carries four rollers. On the cross-pieces, on each side, are laid sliding or chock-blocks F F, which are made to suit the rising of the ship's bottom, and are worked backwards and forwards on the cross-pieces by tackle. They are also secured on the cross-pieces by a rack and pawl. On the aftermost cross-pieces are also two shores I I, which turn upon a joint, and are prevented from falling outwards, when the vessel is floating on, by means of a small chain.

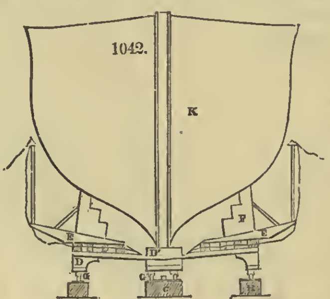
A vessel having floated on to the slip, the sliding-blocks are adjusted by the tackle under her keel, the tackle being taken on board the ship, and hauled tight. By this means the sliding-blocks are brought into the proper place, and the pawls fall into the racks on the cross-pieces, and wedge the vessel firmly in. The iron guides at her forefoot and at her stern are also hauled up, so that she is well secured to the carriage. Of course, the carriage being inclined, the vessel takes first the foremost blocks, but the others are gradually adjusted, and as the carriage is hauled up the slip, the vessel takes the remaining slide-blocks in succession. When duly prepared, the vessel and carriage are hauled up the slip at the rate of from $2\frac{1}{2}$ to 5 feet per minute. The power employed is in about the proportion of six men to every hundred tons.

When hauled up, the vessel is shored from the ground, and the keel-beam being relieved from the weight can be run back so as to be used again. It should be observed, that during the hauling up, the carriage is prevented from falling back by means of three or more pawls at different parts of the framing, working on the rack on the midway.

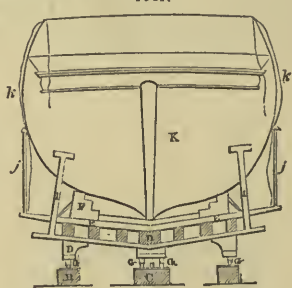
The launching of a vessel from the slip takes place very easily, by putting the cross-pieces and chock-blocks under her and the keel-beam.

This slip admits of more than one vessel being on the slip at the same time, as the carriage or cradle is movable, and the vessel, when ashore, can be shored up in the usual way.

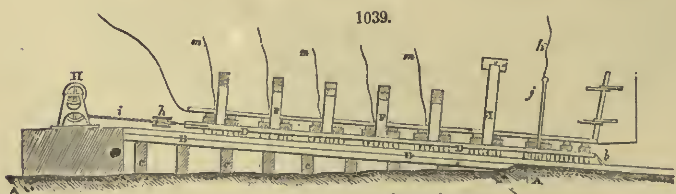
1042.



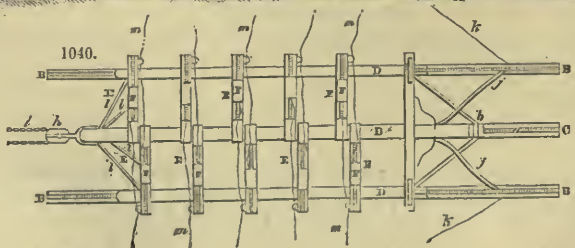
1041.



1039.



1040.



The American Marine Railway, or the Railway Dock, as it is styled in the patent. The plan of construction is thus described by Mr. J. L. Sullivan, C. E. :—

"The bottom is to be levelled to the proper slope. The foundation piles are to be driven in four lines; the two inner rows near to each other, in order to support the keel; the two outer rows to come under the shores. The piles to be cut off under water must be cut off in the exact inclination of the plane, and level

with each other transversely. The necessity of previously marking each pile separately, on every side, in accordance with the intended inclination of the ways, led to the invention of instruments requisite to the occasion.

"*An aerial inclined plane* parallel to that intended to be established under water is obtained by first fixing a true level across the head of the railway, and denoting each station by a target, the staff of which is so much above the line of plane as will bring the lower end of the aerial plane above water; targets, having each a staff of the same length, being next applied, and nailed to the outer, and some few to the intermediate piles, will exactly indicate the aerial inclined plane, while the point of the staff attached to the pile will indicate a point on one side thereof in the intended plane of the foundation.

"The *level and bevel* is an instrument by which to ascertain every other point on the sides of the pile which will be in the intended inclined plane. Fig. 1043.

"The *diving-bell* may now be supposed to be brought over the pile, and as much of this as it will take in cut off, together with the target staff, still leaving the lower end. This cutting is repeated till the workmen arrive in the bell to the bottom of the staff, which remains a little below the last rough cutting. The level and bevel is then set on: this consists of a base-board, with a post arising from its centre to support a plumb-line playing in a cant piece having a centre notch, to determine whether the base is level transversely; and as this base is at the same angle with its post that the intended plane is to a perpendicular line, and the base being equally thick, its under side also indicates a parallel plane, so that, being secured in its place, the distance is measured by compasses from the ascertained point to the base-board, and thence to every point in the circumference of the pile that is also in the intended plane, thus marking it with accuracy for cutting. This operation being the same for each pile, it results that every one must be truly in the intended inclined plane, ready to receive the frames of the railway, which are floated over, and sunk down to their places; or a plank is first secured upon the head of the piles, upon which the frames are successively slid down.

"The *iron rails* will, in point of size, depend upon the weight they are to bear. They must of course spread a sufficient base to prevent being indented into the wood by a heavy load. The two middle rails, and the rack piece for the pawls, are generally cast in one; but if the rails are to be of rolled iron, the rack will be separate. The pawls prevent the ship from accidentally running back.

"The pressure of the load will, in merchant ships, be greater forward and aft than at midships, because they generally become a little hogged; provision must therefore be made for this contingency, and it will be safe to suppose cases in which the largest class of ships to be received will bear all their weight on the first 10 feet forward and the last 10 feet aft.

"The weight of a ship is often erroneously stated to be as many tons as she measures tons. The fact is, that when laden she displaces a quantity of water that would precisely weigh her whole weight, cargo included; and, as she generally carries as many tons as her measurement, she cannot, when light, weigh as many tons as she measures; she weighs only as much as the water she then displaces, and that will be in accordance with the weight of her materials, oak, pine, or cedar. Wherefore, for explanation, I shall suppose the positive weight of ships to be one half of their nominal tonnage.

"A ship of war will be received upon a railway carriage with the precautions to be subsequently explained, and its weight distributed equally over it and the foundation. The tendency of all ships being to acquire some curvature of keel, it will generally be injudicious to straighten them on the dock, as they will resume their lines on being again put afloat, opening thereby the upper seams or butts. To keep the ship, when taken out of the water, in precisely the same shape she has in it, the curve of the keel must be ascertained, and the keel-blocks be made to conform thereto.

"To *measure the curvature of the keel* we have devised an instrument, consisting simply of a bar, suspended at each end by a graduated chain. This bar, being long enough to reach across the ship, is passed under and across her centre at every five or ten feet, when the graduations on the chains will show the difference of depth at every point of contact from stem to stern. For merchantmen this precaution will not generally be necessary.

"A ship of 500 tons measurement will exert a pressure of 250 tons, and we have supposed the whole of this may have to be borne by the two extremities of the carriage, or by 10 feet at each end. The axles, therefore, are at the extremities, but nearest to each other. But as steamboats will bear heaviest in the middle, the axles must be near in the centre also, for their support.

"The axles will be two feet apart in the first 10 feet. Five axles will have to bear 125 tons, or 25 tons each; the bearings and wheels 12½ tons. The axles of the New York Dock are 3 inches diameter, and the square of the section is 7.071 inches. The bearings are close to the wheels in which the axles are fixed.

"*The strength of the rail* is deduced from experiments, from which it resulted that a rail of 1 square inch would be ample; but a rail of 1 inch is too narrow to be favorable to the duration of the wheels.

"The central axles of the New York Dock weigh but about 1 ton, and would together suspend 9,300 tons.

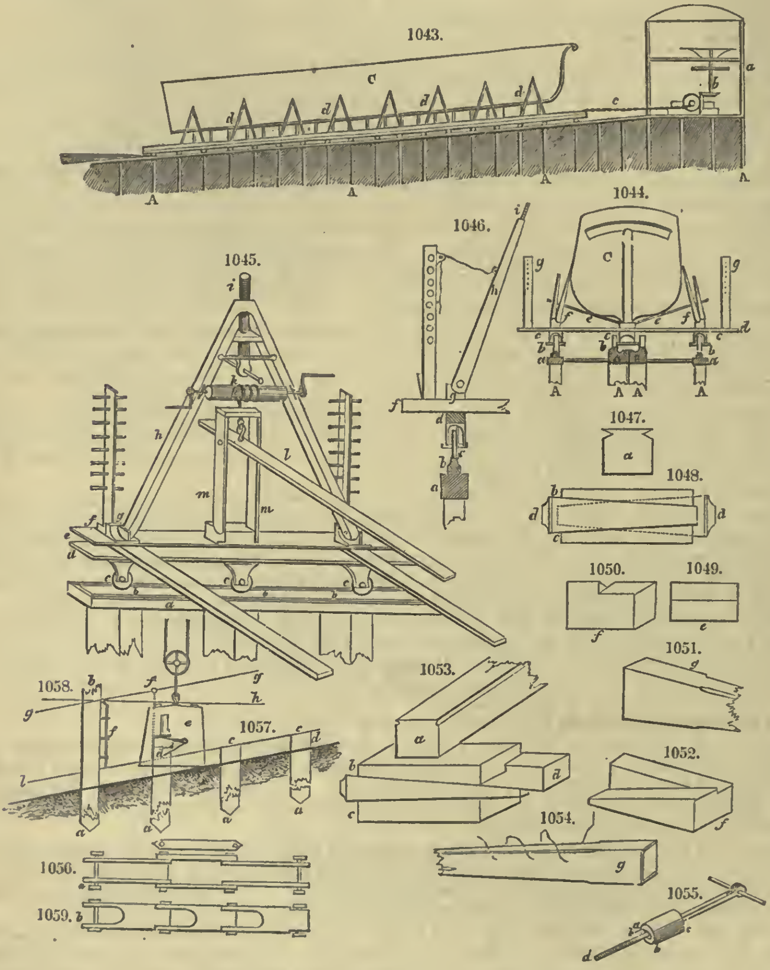
"The friction of the axles should be relieved by the intervention of brass bearings, as usual in machinery.

"*The side axles* will sometimes have a proportionate share of the ship's weight to sustain; though she will ordinarily be prevented from inclining on one side or the other by the *adjusting-screw* placed at the angles of the shear-shores; yet it is necessary to guard against the force of high winds, and the weight which a hogged ship may sometimes throw on the centre shores, before she is eased down at midships by the screws, if intended to be straightened. (Fig. 1045 *i.*)

"*The carriage* is combined in a very strong manner, though it appears to be rather a light structure for the purpose. In its construction the implement called the dowelling-bit is of great and essential use. (See Fig. 1048.)

"The *dowell* is a cylinder of some hard wood, generally lignum-vitæ, which is one half inserted into one, the other half into the other timber, where a joint is to be made of their surfaces, which the dowell prevents from moving or sliding on each other. The gouge and the screw, perceived on reference to Fig. 1055, are also improvements. An auger hole, a little smaller than the screw of the bit, being first bored, the thread will cause the bit to advance as fast as the chisel and gouge can conveniently cut, and thus the whole labor is confined to turning it.

"The instrument now makes it easy to dowell the frames of a ship, the knees to the timbers, the waterways to the beams, the thick stuff of the wales to each other, and generally to bind the ship by a solid connection of wood.



"By means of irons and the dowell, the *cross-ties* are secured to the sills in such a manner as to make it impossible that the carriage should spread; and by thus tying the sides to the centre, the cross-timbers convert the oblique force of the shores into vertical pressure; and care is taken in every instance *that a wheel shall stand directly under the base of every shore.*

"The shear-shores (Fig. 1045) have a form which gives them great stability in their places, and answers other purposes to be mentioned; they are bases in *hollow coin blocks*, either of wood or iron, divided across the middle of the hollow by a partition, which serves to hinge the two legs of contiguous shears. There is thus a continuity of solid material from the side of the ship to the foundation, from the moment she ceases to float till she is high and dry.

"The *shear-shore screws* will sometimes have the important office, when ships are old and tender, of taking a good share of the weight of the ship's side, and distributing it along the carriage side, taking it off from the floor timber-heads, futtocks, and beam-ends, where ships are most liable to be weak.

"The *bilge levers* (Fig. 1045) are levers of the second class. One end is lodged fixedly on the centre sill of the carriage, while the other end is hove up between the legs of the shear-shores by a windlass placed within them. The moving end is guided in a slot of the prop, and sustained, when up to contact with the bilge, by means of an iron pin passing through the cheeks of the prop.

"The *cradle* thus formed by the bilge levers it is evident *will fit every successive vessel equally well*, and may thus be removed singly, and replaced as the work progresses; and as they require to be hauled up with considerable force, nothing can be desired more convenient than these shears.

"The *common keel-blocks* are of course placed between the cross-ties, and are of such height as to allow ample room for the shipwright to work under the flat of the bottom, standing between and on the cross-timbers. But the bottoms of the keel will sometimes have to be repaired. To accomplish this end, the instrument called the lifting-plane has been devised, (Fig. 1046.) In the operation of this machine, two wedges are forced on by percussion; blows from opposite sides being simultaneously given, with the combined strength of a considerable number of men, when the resistance renders it requisite.

"The *lifting-planes* are composed of six pieces of timber, and for the navy may be made of cast-iron, or of wood faced with iron. To make them, let us suppose a block 4 feet long, and 16 inches square, halved horizontally, and each face of the cut marked lengthwise, and then shaped into two similar planes inclined in opposite directions. The two planes are then divided from each other by a bar of iron, let in edgewise till its edge is flush with the upper ends of the two planes, in order to guide the wedges. Now let the upper half be placed in its original relation to the under one, (over it,) and there will be space for two wedges, pointing in opposite directions parallel to each other, separated by the bar of iron before mentioned. The planes being eight, all at the same angle of inclination, the upper block, with whatever may be upon it, will be lifted perpendicularly by driving the wedges. These require heavy blows, and for this purpose battering-rams, swung each between two files of men, are necessary. (Fig. 1046.)

"In practice, one of these machines placed near a keel-block is easily made to take the pressure from it by the least degree of lifting, and thus several machines may be applied, so as even to take away all the common blocks, and they themselves may be readily withdrawn and shifted in position, so as to allow the bottom of the keel to be got at for coppering, shoeing, or renewing; and when done, the common blocks are to be replaced. To do this, when a ship is hove down, her keel must be hove completely out of water.

"The chain and compound windlass by which the ship is hauled out is an expensive and essential part of the machine.

"The *power to draw up a ship* of 500 tons, weighing, as before assumed, one half the same number of tons, is now to be considered. From the experiments made in different places, the weight which the chain must bear is 40,320 lbs., or 18 tons.

"The chain of a marine railway must be, however, exposed to accidental stress beyond this calculation. It has to ply around a ratchet-wheel, and animal force is often irregular. A steam-engine would therefore be the best.

"The shape of the chain, in order to give it a degree of strength proportionate to the material, is of importance, as it has to bear the stress of turning around the ratchet-wheel of the windlass.

"The windlass is also so geered as to adapt it to the power of a few horses. When they travel in a walk the ship moves up the plane about 3 feet a minute, and she is completely up in less than two hours. Four horses are a sufficient force for a ship of 500 tons. The horses work in the second story of a small building; they are attached to bars 14 feet in length, proceeding from an upright shaft, on the lower part of which is a bevel-wheel communicating with the rest of the geer.

"The end of the chain is strongly fastened to the centre of the carriage, with branches passing obliquely to the sides, so that the whole must move equally, and at once.

"The *reversal of the draught* at will is an essential provision, in order to draw the carriage out to the extremity of the ways, to which its own gravity would not certainly carry it, because to be able to give the carriage such a position as to afford just water enough for the ship to ground on the upper blocks is indispensable. To be able to refloat the ship, should she happen by bad management to ground otherwise than on the centre of the carriage, may, if on a falling tide, be of great consequence; we must therefore have the readiest means of drawing the carriage down the ways. With this view, the chain, after passing the *haul-up wheel*, is led to another ratchet with reversed teeth, and thence down along in a trunk by the centre timber of the ways till near their extremity; there it turns around a large and strong shiver, and fastens about 20 feet from the end of the carriage, which the chain follows, when drawn up, it being supported on rollers. The reversed movement, of course, draws the carriage down till it touches the stop-block at the outer end of the railway. The chain is thus disposed of without manual labor. The connection of the second ratchet with the first is by intervening geer, so that they move alike.

"The ship in descending requires a controlling power, that she may not acquire momentum, and injure the carriage by velocity. The friction for this purpose is produced by means of an iron wheel on the upright shaft, placed just below the floor. An iron band is made to clasp this wheel by the aid of a powerful lever. This is found to be quite sufficient, and very convenient.

"The manner of receiving a ship is this:—she is brought between the wharfs of the dock, head on; the carriage is drawn down under her, and perhaps up a little, till her forefoot grounds on the forward block, and as ships generally draw more water aft than forward, she is nearly aground aft also; the head-shores are applied, she is then moored up a few feet, until she is ascertained to touch aft also; the shores are now all applied and secured, and the bilge levers are hove up to their bearing; she is now ready to rise into the light and air.

"The wheels or sheaves running on the rails are made small, because it is an object to keep the carriage low, that we may not have to extend the ways further than is necessary to get the desired depth of water on the carriage.

"This structure, it is to be observed, is only accessible for repairs by the diving-bell. In all places exposed to the worms the timber must be coppered, unless the white gum tree is found to be unassailable, as some have represented."

At New York there is also a company called the New-York Screw-Dock Company, to whom belong

the screw-dock, and the hydrostatic screw-dock, which is an improved form of the invention, and with hydrostatic power brought to bear as the lifting force.

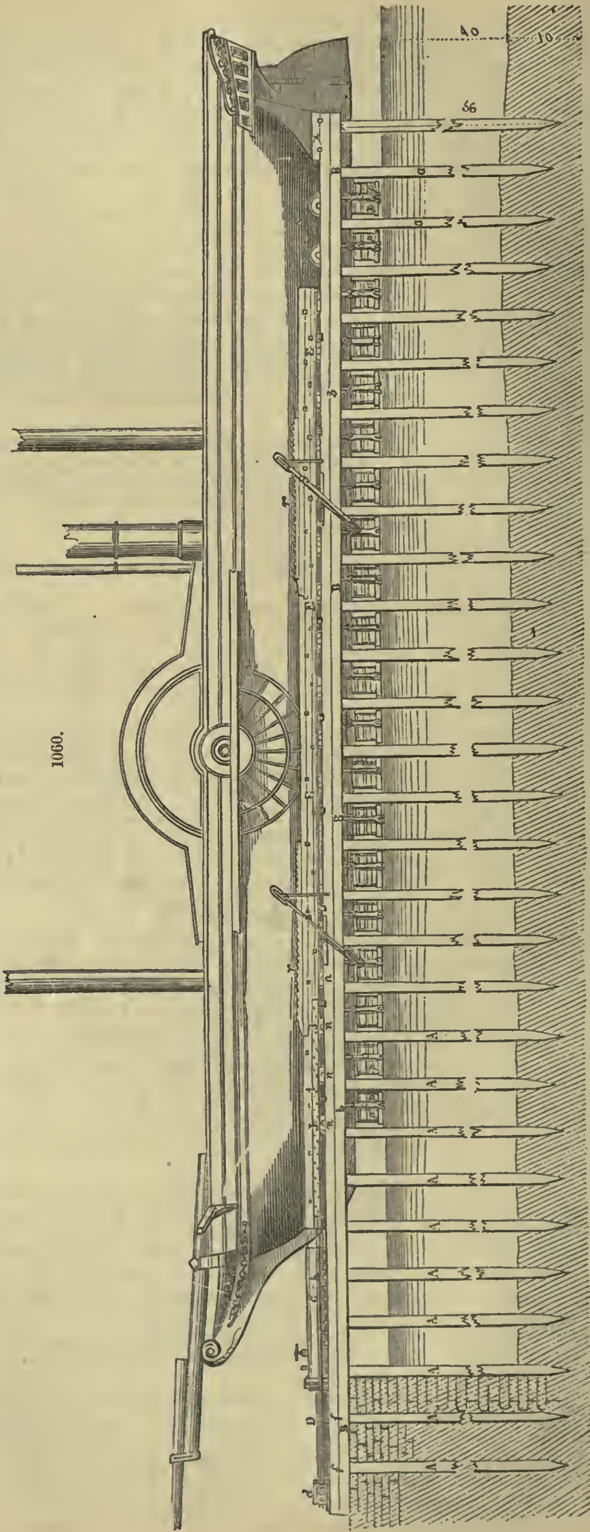
The screw-dock in general principle and form is the same as the hydraulic screw-dock. The vessel in the screw-dock is floated on to a timber platform, which platform is suspended from strong mainway pieces of beams on each side, laid on the quay walls, by eight suspending screws four and a half inches in diameter. The platform is capable of being sunk about ten feet below the surface of the water, to receive the ship.

This platform has several shores on its surface, which were brought to bear equally on the vessel's bottom, to prevent her from canting over on being raised out of the water. About thirty men were employed in working this apparatus, who, by the combined power of the lever, wheel and pinion, and screw, succeeded, in the course of half an hour, in raising the platform, laden with a vessel of 200 tons burden, to the surface of the water, where she remained high and dry, suspended between the wooden frames.

In a dock at Baltimore, of this kind, the platform is suspended by forty screws of about five inches in diameter.

The Hydrostatic Screw-Dock is a slip abutting on the shore, with a suspended keel, allowing the vessel to be raised up vertically, instead of being drawn up on an incline, as in the slip and the marine railway. It consists of two outer and parallel ranges of piling, each bearing a way at the top, from which are suspended chains, to which are slung transverse bearers or swing beams, over which the vessel to be docked floats; and having arrived over this moveable platform or grating, the chains are raised by means of a hydrostatic press, and the vessel brought to the level of the permanent way. The means by which the apparatus is worked are ingenious, and constitute the chief merit of the application.

The dimensions of the dock are about 165 feet long internally, and 35 feet wide. The distance from the outside of one mainway to the outside of the other is 51 feet. The mainways abut on the land, and run about 38 feet beyond the head of the dock on to the land, resting on a solid quay of masonry, to which they are bolted down, and which supports the machinery.



1060.

We shall first describe the construction of the two parallel mainways. These ways (B B, Figs. 1060 to 1069) are placed 35 feet apart, and each consists of a row of double piles A A, with every pair placed obliquely; thus, A. The piles are of the best Georgia pine, 56 feet long and 20 inches square, with iron shoes, and with their heads mortised into the mainway pieces, and bolted together with 1¼-inch bolts. The divergence of the double piles from the perpendicular is about 3 feet at the lowest extremity. The piles in the longitudinal direction of the ways are placed 4 feet 8 inches apart. The depth of water at the site of the dock is 40 feet, needing no excavation; and the piles are driven into the foundation soil about 8½ feet. Some of the piles are further apart than others, depending upon circumstances and contingencies, but the general distance is about 4 feet 8 inches. The total number of pairs of piles in each way is about 29, making a total of 116 piles. (Fig. 1060.)

The mainways B B are, as already mentioned, scarfed or mortised on to the top of the double piles, and secured by iron 1¼-inch bolts, Figs. 1060, and 1061. Each mainway is 182 feet in length, and is formed of Georgia pine logs, placed five together . . A . . , and bolted together by the same bolts which secure the heads of the piles. These ways are about 4 feet 10 inches broad and 2 feet 10 inches thick. Through the mainways, passages are left for the suspending chains. At the end of the mainways are chocks Z to prevent vessels from slipping off.

On each mainway, again, are mainside straps E E, Fig. 1060, being double, and each composed of three pieces of Georgia pine, the centre about a foot thick, and the others about 8 inches, making a total height of 2 feet 4 inches, and a breadth of about a foot. The mainside straps stand about 10 inches apart, and are secured together by strong bolts and square trenails of locust-wood z* The straps are 124 feet in length. The side straps are secured to the cylinder C, by side straps of wrought-iron, 32 feet in length and a foot broad, bolted in, and fastened to the side rods h of the cylinder by a large gib i, Fig. 1062. On each mainside strap are two ratchet-plates and pawls, hereafter to be described.

At every 6 feet 4 inches in the mainside straps, a wrought-iron cross-bar or distance piece l is fixed in, which is an eye or box u, to receive the head of the suspending chain k. This head consists of a screw m, secured by a nut, which regulates the height of each swinging beam so as to fit the keel of the vessel. From the screw m a chain k descends, passing between the mainside straps, mainways, and the spaces between the piles, and terminating in a wrought-iron linkhead and cross-bar o, sustaining the transverse bearers or swinging beams p. The chains are each about 24 feet long.

Between the two mainways B, Fig. 1061, hangs the platform of swinging beams, suspended by the chains k, which run over the sheaves n. The mainways are 35 feet apart, and the swinging beams p 44 feet long, consisting each of a double beam about 7 inches apart. The beam is of a flat triangular form, made up of large logs, fastened together by six iron straps. The pairs of swinging beams are twenty in number, and each single beam is of oak, about 15 inches broad, 3 feet 3 inches deep in the centre, and 18 inches at the ends. Each pair of swinging beams is suspended by a chain k at each end. On the centre of the swinging beam is a keel-block w, 3 feet long, 2 feet broad, and 10 inches deep, to receive the keel of the vessel. In it are boltheads also to receive blocks-tackle y, for managing the chock-blocks t. On every second swinging beam is a traverse frame q, raised on six short bearers. On this traverse frame is a ratchet-plate x, into which a pawl falls from the chock-blocks. On the ratchet-plate rests the chock-block t, 5 feet 3 inches high, 4 feet 10 inches broad, and 18 inches thick. These chock-blocks support the sides of the vessel, and are moved backwards and forwards on the swinging beam by blocks and tackle $y z$. This tackle it will be seen works both ways, and is also affixed to the pawl x.

On the quay or landside is the engine-house and pump-room, in which is the machinery of a 6-horse power steam-engine for working the hydrostatic press. In it is a tubular boiler A *, much like a locomotive boiler, 15 feet long, 3 feet broad, and 6 feet 3 inches high, with steam-pipe B * communicating with the horizontal cylinder C * and valve-box B *, which lie parallel to the boiler. This piston carries a connecting rod E *, which sets in motion the mainshaft F * at right angles, and in the direction of the mainways, by which four cranks G* G* are worked, each of which has a pair of pumps attached. Each pair of pumps has a separate cistern in the tank N *, which, instead of water, is filled with a fluid composed of equal parts of water and alcohol, to prevent freezing in the winter months. These are the pumps which produce the pressure within the hydrostatic cylinders C C. The diameter of the smaller pumps is 1 inch, and of the larger pumps 2 inches, and each set of pumps has its respective stop-valves for letting on and off to the hydrostatic cylinders C C, so that one or more may be worked at pleasure.

From the main-shaft power is also obtained for fleeting back the ram, by means of a pinion H * set in geer on the wheel J * by a clutch I *. The wheel J * is on a parallel shaft k *, carrying a pinion K *, from which a bevel-wheel M * takes the motion at right angles to another shaft M *, on which are the two pinions L L, Fig. 1062, which turn the bevel-wheels I of the parallel screws $j j$ of the hydrostatic ram, so that the power is brought to the back of the hydrostatic cylinders.

A hydrostatic cylinder C, Figs. 1060 and 1061, is attached to each mainway, secured, as already mentioned, by its side rods h through a strong gib i to the mainside rods E. The apparatus consists of two strong wrought-iron parallel side rods $h h$, 44 feet long and 6 inches diameter, united by a cross-head d, 4 feet 8 inches long and 2 feet broad, at the upper end. Within this framing is the cylinder C and ram D. The cylinder, including the glands, is 18 feet long, 18 inches internal diameter, and 2 feet 3 inches external diameter. On the top of each cylinder, Fig. 1061, are pipes o * communicating with the pump-room. The ram or plunger is 1 foot 2 inches diameter, and made sufficiently long to admit of a direct motion forward of 15 feet. The outer end is fitted with a collar x * into the crosshead d. The crosshead d, Fig. 1061, travels backwards and forwards by means of rollers e on a cast-iron way f, laid on the mainways B. At the dock end the mainside rod h is crossed by the fleeting shaft M * from the engine-room, already mentioned, and the pinions L, on which work the wheels I of screws j, secured by a box K to each of the side rods h, Fig. 1062. At the extremity the side rod h carries a roller M and handle N.

We shall now proceed to describe the process of taking a vessel into the dock. The hydrostatic

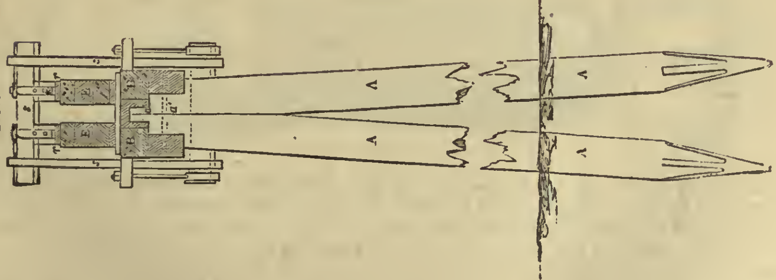
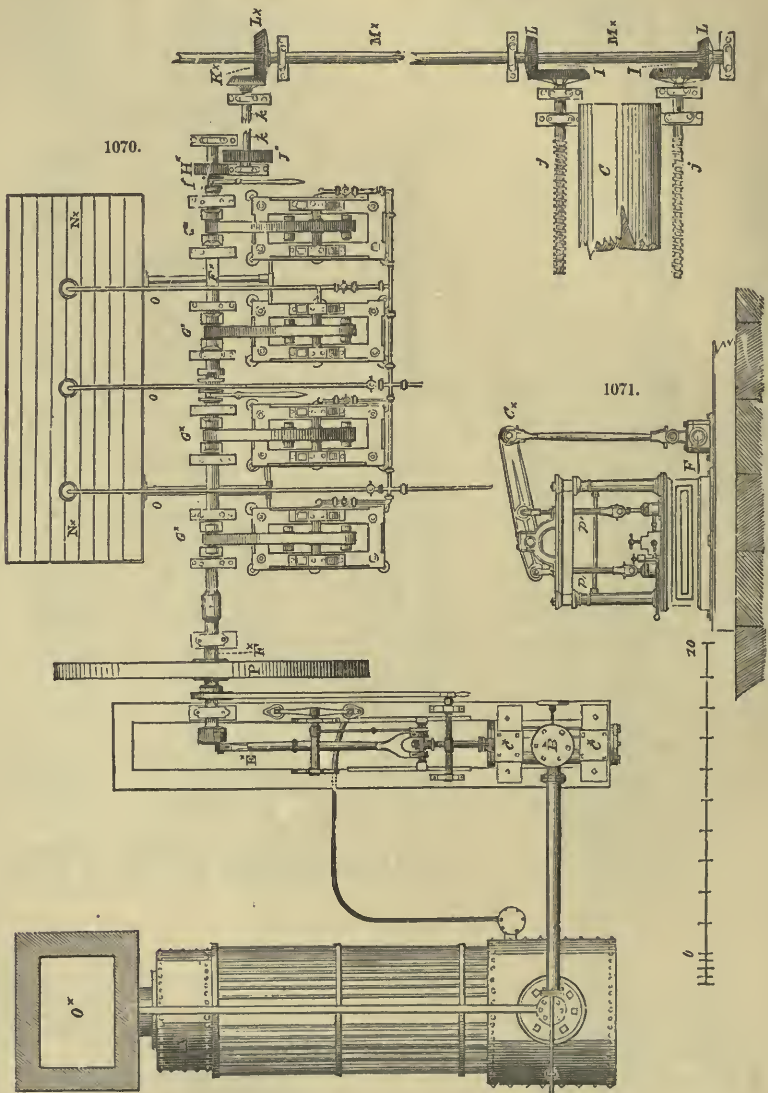
1067.



engines are charged with water, and the rams D forced out to the full extent of their stroke. By this means the mainstraps E are drawn towards the head of the dock, and the cradle of swinging beams lifted up, so as to allow of the adjustment of the keel-blocks *w w* and chock-blocks *t*, and of the swinging beams, by means of the adjusting-screws *m*, to the suspending chains. The cylinders are then discharged, the rams fleeted back, the pawls loosed, and the cradle of swinging beams sunk again by its own weight, the mainstraps being checked from running over the mainways by the chocks Z*. It will be observed that the cradle may be stopped at any required depth by closing the escape-valves, and by lowering the pawls-bars *s* on the ratchet-frames *r*.

1070.



1071.

The vessel to be repaired is then floated into the dock, brought over the keel-blocks, and the hydrostatic engines and pumps set to work until sufficient pressure is created to raise the swing beams up to the keel. The motion is then stopped, and the traverse frames *q* and chock-blocks *t* hauled in by the tackle towards the centre of the cradle, so as to take a uniform bearing under the body of the vessel. When they have done so, the pawls *x* are let fall on the rack so as to fix them in their places, Fig. 1066. The vessel is now shored up and the engines again started, when by the hydrostatic pressure the rams are forced in a few minutes out of the cylinders, dragging the mainstraps E, which take the chains along with them, and the vessel is raised on the cradle of swing beams, as represented in Fig. 1060 high and dry above water, so as to allow of the inspection by the shipwrights of every part of her bottom. The cradle is supported on the platform by the pawls and racks *s r*.

When the vessel is to be released, pressure is again put upon the cylinders, and then, the escape-valves being opened, and the pawls and racks *s r* released, the cradle sinks as the water escapes from the cylinders; the traverse frames and side chock-blocks are removed, and the vessel allowed to float out.

The mode of fleeting back the rams, Fig. 1062, is to detach the side rods *h*, by drawing out the gib *i i*, and turning round the roller M, by the handle N, which supports the end of the side rod *h*. The side rod having a little play on the crosshead *d*, allows it to be passed back with ease. The clamps and boxes K K are then attached to the side rods, and the screws *j* turned by means of the bevel-wheel and pinions I and L, the motion of which is taken from the mainshaft F* of the pump-room, Fig. 1070, by putting on a clutch I*.

Another dock company at New York, is that called the *Sectional Floating Dock Company*. The docks of this company are the most powerful, being capable of lifting vessels of 2000 tons burden.

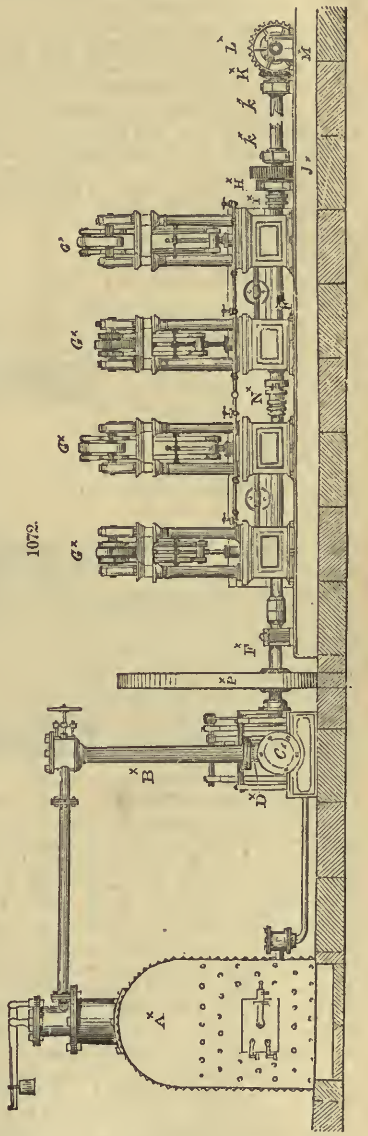
This dock is executed at a comparatively small cost, being chiefly of timber, and being more powerful and efficient, is esteemed preferable to all the others.

The entire safety of this system is another advantage, as it is scarcely possible that an accident can arise either to the vessel raised or to the workmen employed in the repairs. The dock, also, instead of being fixed, and in one position, like the marine railway and screw-docks, may be towed to any vessel within a convenient distance.

Suppose that a ship is sunk, say in 5 fathoms water, it may be raised to the surface by hogsheads, or slung by any of the usual modes; and once got up to the surface, the sectional floating dock can be readily introduced beneath it, and the whole towed together to the landing or shipwright's wharf.

Although this dock has many facilities, it has, however, some of the inconveniences of dry-docks, as the vessel is hidden between the towering sides and the machine sheds on them; and the whole forms a damp structure of wood.

The sectional floating-dock derives its name from its consisting of distinct sections of timber framing in the form of a floating-dock, into which ships can enter. In the sections on each side are balance-tanks, raised and lowered by means of a rack and pinion, and also tanks, which, by being filled with water, cause the dock to sink, and by the water being pumped out, enable it to be raised to any required height out of the water, the ship resting on the platform within. On the top of the sections is machinery for working the racks and pinions and pump-work.



1072

Such is the general principle of the contrivance. Now to detail the construction. According to the size of the vessel to be raised, any number of sections, more or less, may be used, as convenience suggests. Each section is 92 feet broad externally, and 64 feet internally, and 23 feet long; the total length of the seven sections being 165 feet. The section is 38 feet high externally, exclusive of engine-house, and 28 feet high internally to the top of the standards. The dock, it will be seen, is neither more nor less than a large floating timber vessel, and is constructed of beams strongly bolted together.

Each section may be considered as consisting of three parts—two lateral scaffoldings or framings of standards within which the balance-tanks run, and a central platform connecting them. The object of the lateral framing is to enable the balance-tanks B to be run up and down, and to prevent the machines from coming in contact with the water. Each lateral portion consists of two external standards 36 feet high and 12 inches square, and of four internal standards 37½ feet high and 12 inches square. These standards are at the bottom secured to the outside truss-girders, and on their tops carry a platform on which the engine apparatus is placed. The standards are bound together by proper tie-pieces, and are further secured to the outside truss-girders by a 12-inch beam, 44 feet long. At the bottom of each lateral framing is a flooring on which rests a balance-tank B, 19½ feet long, 10 feet broad, and 8 feet deep, being of a capacity of about 1,500 cubic feet. The total capacities of the fourteen tanks would therefore be 21,000 cubic feet. Besides these are water tanks within the platform in which the pump-rods work.

The platform is about 10 feet deep, and on the upper surface consists of two outside truss-girders

being about 70 feet long and 17 inches across, composed of two beams scarped together. Between these are a cross-beam, 7 inches square in the centre, secured to the keel-beam; and a cross-beam on each side 9 inches square, for carrying the chock-blocks, and secured to the keel-beams. These cross-beams rest on joists or tie-pieces 10 inches square. In the centre across are the two keel-beams, 24½ feet long and 12 inches square, and which carry five keel-blocks. This upper platform rests on the foundation truss-girders, by means of posts and timbers scarfed in, and is further secured by four stout iron ties. The bottom truss-girder is 93 feet long, and formed in three portions, well scarped, tied, and bolted together. These bottom truss-girders extend under the lateral framings, knitting together the whole structure.

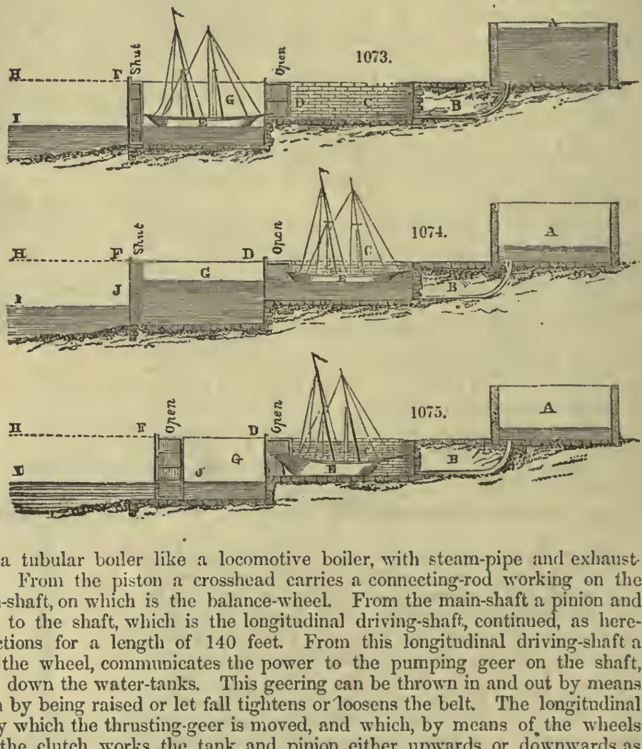
The sections are connected together, in case of need, by the double tie-beams, which can be readily slipped out, by withdrawing the nuts and screws by which they are secured.

On the cross-beams on each side is a rack and pawl, enabling the chock-blocks to be readily moved, and secured by means of tackle. The chock-blocks are 4 feet high and 3 feet 9 inches wide. These receive the bottom of the ship; but in order to steady the sides there are side supports on each side, worked by block and pawl, so as to make the ship firm to the inner standards.

The object of the balance-tanks is to keep the dock steady and in an upright position. They contain no water, and it is only necessary to keep them depressed to the level of the water, either in sinking or raising the dock, and their resistance keeps the whole dock, with the ship, perfectly steady.

The lateral framings are furnished with two stationary spuds 34 feet high and 7 inches square, provided, on one side, for 27½ feet, with a rack-plate. This spud is secured into the framing at top and bottom, and is for the purpose of working the tank up and down by machinery, subsequently to be explained, and part of which is seated on the top of the tank B. Each lateral framing is also provided with a ladder, and an upper stage for the workmen.

On each side of the centre section is an engine-house, which contains the machinery for working the thrusting and pumping apparatus, and from which shafts run along the sections on each side. It should be observed that the machinery on all the sections is covered in.



1073.
1074.
1075.

The engine-house contains a tubular boiler like a locomotive boiler, with steam-pipe and exhaust-pipe, cylinder and valve-box. From the piston a crosshead carries a connecting-rod working on the crank, which drives the main-shaft, on which is the balance-wheel. From the main-shaft a pinion and bevel-wheel carry the motion to the shaft, which is the longitudinal driving-shaft, continued, as hereafter explained, along the sections for a length of 140 feet. From this longitudinal driving-shaft a wheel, working by a belt on the wheel, communicates the power to the pumping geer on the shaft, crank, and pump-rod, running down the water-tanks. This geering can be thrown in and out by means of the moveable pulley, which by being raised or let fall tightens or loosens the belt. The longitudinal shaft also works the shaft, by which the thrusting-geer is moved, and which, by means of the wheels and pinions, put on or off by the clutch, works the tank and pinion either upwards or downwards as may be required. The shaft is connected at each end by means of the universal joint, and by the small circular shaft, with the longitudinal shafting on the end sections. By this means the different sections may be placed at such distance from each other as the length of any ship may render necessary. It is to be observed, that a necessity constantly occurs for sinking one or more sections lower than the others. This is also provided for by the slip and universal joints.

The thrusting-geer for raising and lowering the tank takes its motion, as mentioned, from the shaft, by means of the bevel-wheel, which moves the pinion, the head of the square vertical shaft. On this shaft is a moveable socket, with a square hole in it, and four friction rollers, so that the vertical shaft may easily pass through it. Beneath the friction rollers is a pinion working into the bevel-wheel. This bevel-wheel is on the horizontal shaft, secured into a framing on the top of the platform of the tank. The horizontal shaft carries a worm, working into the worm-wheel, the shaft of which carries a pinion at each end, working into the spud, which is kept in geer by the friction roller. The number of spuds is twenty-eight, four on each section, or two for each tank. On the end sections the machinery consists merely of the longitudinal shaft, the thrusting and pumping geer.

The process of taking a ship into the sectional floating-dock is as flollows:—The dock is sunk to any required depth by opening the gates or valves with which each water-tank is furnished, and the dock necessarily sinks. The dock sill being at the required depth, the ship is then introduced between the

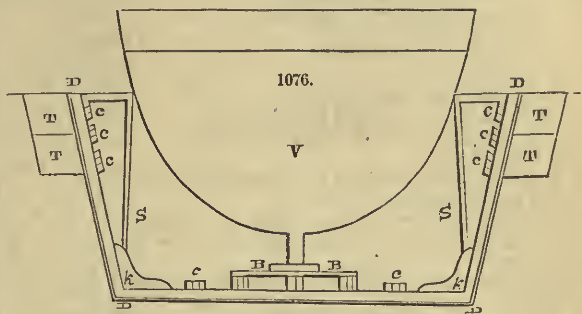
vertical side-framing, rests on the keel blocks, and when supported on the sides by the chock-blocks and side-supports is ready for lifting.

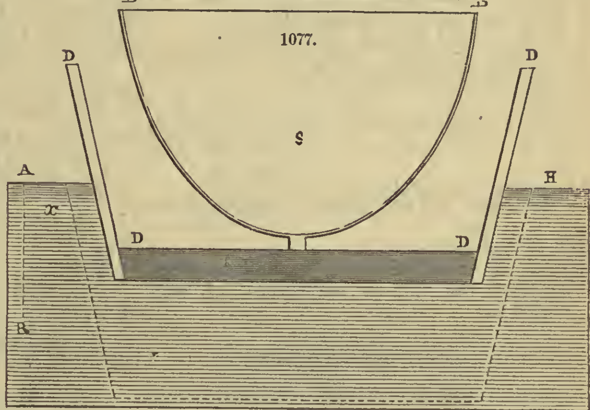
The valves which have previously admitted the water into the water-tanks are now closed, the water is pumped out, and the air again fills the tanks, and they rise, bringing with them the vessel to the height necessary for repairs.

The vessel is taken out of dock by a repetition of the process of admitting water into the tanks.

The patent is for the general arrangement in the construction of the side-balance tanks.

Besides these several kinds of dock apparatus in actual working at New York, many plans have been proposed in the United States, and nearly fifty patents taken out within the last twenty years, for the invention and improvement of slips, marine railways, floating, and other docks.





In 1826, Captain Thomas Caldwell proposed a system of dock without pumping power. He proposed to construct a dry-dock of about twice the usual length; to be divided into two compartments by gates situated near the centre of the structure; an additional pair of gates being placed at the extremity, opening a communication with the harbor. The vessel was to enter the first compartment, the external gates being closed, and the internal gates being opened. The bottom of the second compartment would be above the level of the water in the first or outer compartment, and consequently at this period dry. The water was then to be permitted to flow from an elevated reservoir, through a pipe, into the dock. When by this means the surface was sufficiently elevated, the vessel was to be hauled into the second compartment, constructed in all respects similar to a common dry-dock. The central gates being closed and secured, the water was to be discharged into the adjacent harbor, Fig. 1073.

In 1826, Commodore Barron, of the United States Navy, invented a floating dock in the form of a large scow. (See Fig. 1076.) It will be seen that it is a large flat-bottomed boat, furnished at one end with a pair of gates, and having on each side two air-tight trunks T T, to preserve the buoyancy of the dock when filled with water. In the sides are port-holes, like those of a man-of-war, so as to allow of being opened when the dock is above water, and admitting light and air, and the introduction of materials. In case of being used in salt-water, it was proposed to copper the outside of the dock as high as the float-line of the dock when it contained no water. As the dock would not be exposed to much friction, the Commodore was of opinion that very thin sheets of copper might be used.

When the gates are open the dock fills with water, and sinks to a depth sufficient to allow vessels to enter therein, and of course to displace their weight of water from the dock, when the gates are closed and secured. The vessel is then shored, and secured by the shores N and S in the usual way. The water is next to be removed from the docks by common pumps, the Archimedean screw, or by a pump forcing the water out through the bottom, which latter plan was preferred.

Letters D D D, Fig. 1077, represent the floating dock containing the vessel S. H A is the surface of the water in the harbor, which would coincide with the surface of the dock, supposing it to be sunk to the dotted line, which is its situation when full of water. This depth is also supposed to be 20 feet, or equal to A B. At the commencement of the operation of pumping the water from the floating dock, it resembles the common dock, in not requiring any power to exhaust it; but as the pumping proceeds the dock becomes lighter, and of course the bottom does not remain in the same relative position to the surface of the water in the harbor, but rises in proportion to its buoyancy.

In the figure the dock is represented as having risen. It is now immersed to the depth of about 5 feet. It is not necessary to remove the water from the space occupied by the ballasting, shaded dark in the lower part of the figure. As the water is forced out through an aperture in the bottom, the greatest resistance to be overcome is equal only to the pressure of a column of water equal in height to the line A B, (5 feet;) half of this, or $A\,x = 2\frac{1}{2}$ feet, will be the average resistance during the whole operation. Therefore, the power required to remove the water from the floating dock by a forcing-pump, will be to the power required to remove the water from a common dry-dock on the usual plan, as, $2\frac{1}{2} : 10$, or as $1 : 4$; viz. as $A\,x$ Fig. 1077 $=$ to $2\frac{1}{2}$ feet is to $A\,x$ dry-dock $= 10$ feet. If, however,

lifting or forcing pumps be employed to pump the water up, and discharge it over the sides, then, of course, the same power will be required for Barron's dock as for the fixed dock.

Commodore Barron's dock was proposed to be moored in a slip between two wharves or breakwaters, to flank and protect it from injury, and with a raft or floating breakwater moored in front of the dock-gate, to preserve it from storms.

DRAWING MACHINE.—*Lowell Machine-Shop.*

Fig. 1106 is a front elevation, with cans A removed.

Fig. 1107 is an end elevation, showing geered end of rolls.

Fig. 1108 is an end elevation, showing pulley end of rolls.

A is the tin cans into which the slivre is deposited.

B is cast-iron end, or support for frame.

C is the plungers or crowders that press the slivre into the tin cans A A, after it has passed through the rolls.

D is an upright shaft for driving-cam b^1, and giving a rotary motion to the cans A A.

E is a stand attached to *r* for support to upright shaft D.

E^1 is a pair of calender-rolls, resting upon the table D^1, by means of stands J, through which the slivre passes before entering the tin cans.

G is a bushing or bearing-in floor, to guide lower end of upright shaft to plungers.

G^1 G^1 and W are weights for weighting top rolls.

D^1 is a table of iron, sometimes of wood, to support calender-rolls.

Z Z Z Z are steel rolls fluted: there are three and four, and sometimes five, rolls, which increase in velocity from the first to last sets, making the draft.

S^1 are stands to support rolls Z Z, &c.

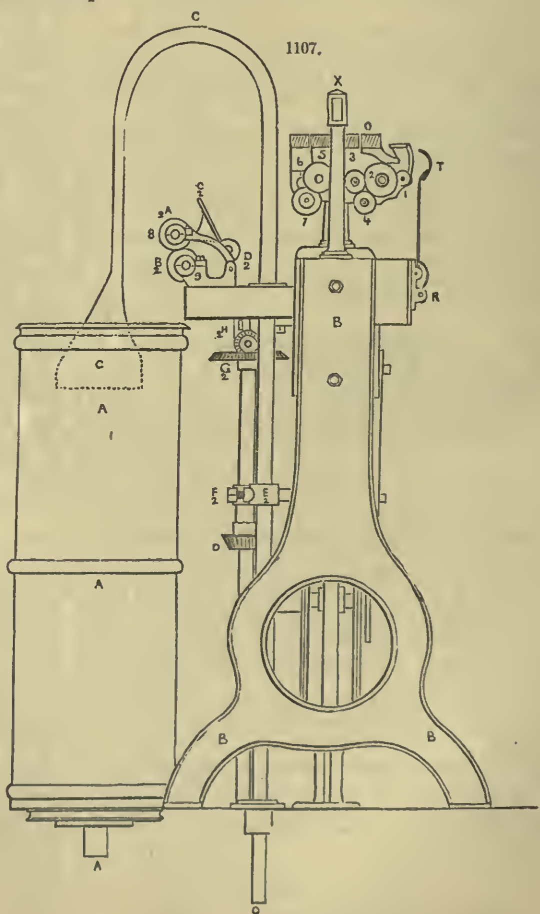
A^1 is a stand to support the end of driving-roll.

X X are stands to hold belt shipping-bar, which is wood, sliding in the stands.

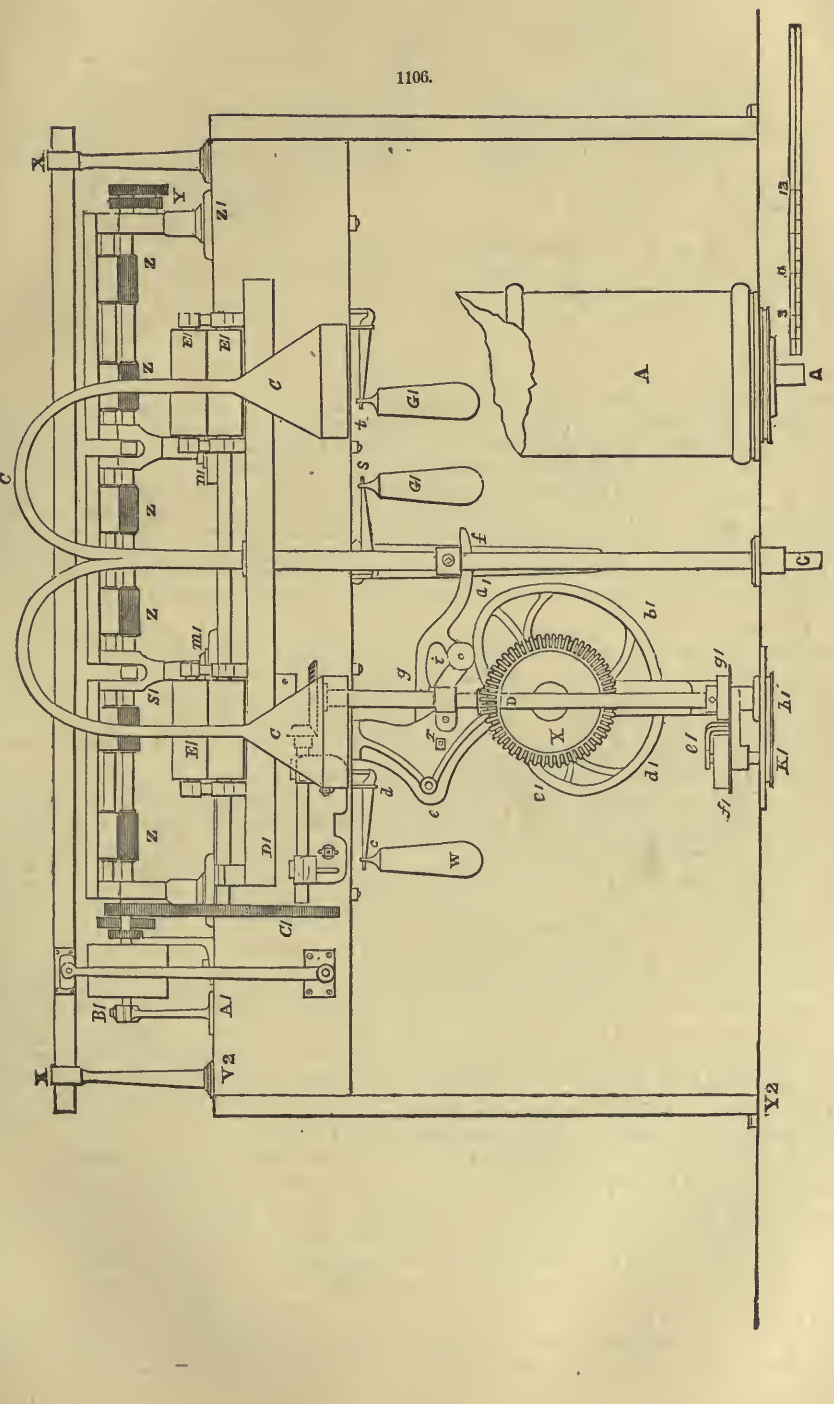
X^1, bevel-geers on cam-shaft.

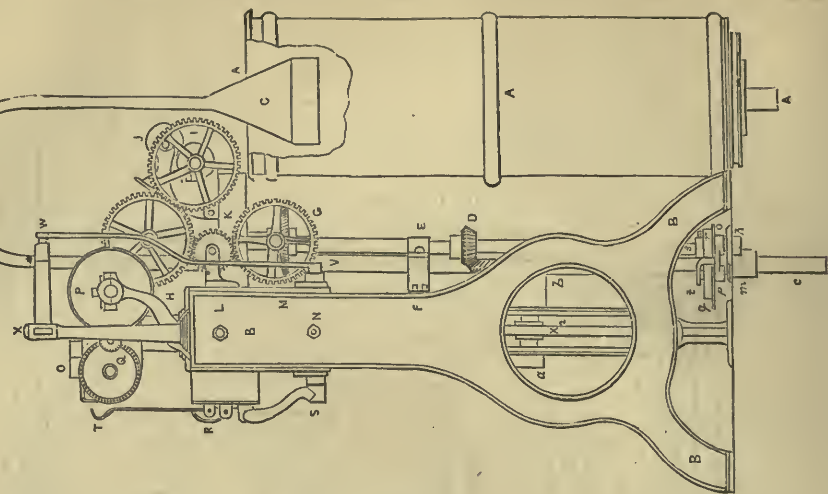
b^1, cam for producing up and down motion on the crowders C C.

1107.



1106.





1108.

K^1 is a mangle-wheel, which gives an alternate circular motion to the cams A, which are driven by a pulley and shaft $f\,l$, which has a pinion on the lower end geering into the mangle-wheel. The pulley f^1 is driven by a belt from the upright D. i is a friction-roll attached to a lever g, which raises and falls the crowders $c\,c\,c$. Y, Fig. 1106, represents the edge view of roll-geers. O O, wooden clearers, which are covered with cloth for clearing top rolls from waste cotton. P are driving-pulleys, tight and loose. Q, geers on back roll. S is an arm operated by a stop-motion R T, which moves arm W, that is attached to shipper-bar in stands X X. T is a light tin trumpet, over which the slivre passes in entering the rolls. In case the slivre breaks or runs out, this trumpet falls back, which throws out a ratch, and lets the slide, by means of a spiral spring, press against arm S, which works arm W, and stops the machine. The roll-geers are made to vary in size to suit the operator on No. of yarn which may be required.

DRAW-BORE. The pinning a mortise and tenon, by piercing the hole through the tenon nearer to the shoulder than the holes through the cheeks, from the abutment in which the shoulder is to come in contact. *Draw-Bore Pins.* Pieces of steel in the shape of the frustrum of a cone, somewhat tapered, and inserted in handles with the greatest diameter next to the handle, for driving through the draw-bores of a mortise and tenon, in order to bring the shoulder of the rail close home to the abutment on the edge of the style: when this is effected, the draw-bore pins, when more than one are used, are taken out singly, and the holes filled up with wooden pegs.

DREDGING AND DREDGING MACHINES. Dredging is effected in various ways; either by drags, or scoops, or rakes, or machines. There are two sorts of hand-drags, one for raising mud, the other sand: the first consists of an iron box pierced with holes, open in front as well as at the top; to this is attached a slightly flexible handle, of a length proportionate to the depth it is to work in: when this is made use of, the men in a boat make the iron box enter the sand, sustaining the handle on the shoulder, and when it is filled they raise it, and if there be any large stones, they are disengaged by means of hooks: a man will raise in this manner, where the depth is not more than 4 or 5 feet, a cubic yard in the course of a day, and sometimes more.

The Drag for Mud is differently formed; it is an iron ring, to which a canvas bag is attached, by passing a cord through holes made in the ring purposely to receive it: that point of the iron rim which is intended to touch the ground and enter the mud must be sufficiently strong: two men in a boat or punt are required to manœuvre it, and in the course of a day they will raise from 12 to 14 cubic yards, if the depth does not exceed 6 feet: when the boat is made use of, it is first moored in such a manner that it cannot drift; such a drag allows the water to flow out of it, and retains only the solid matter.

The Louchette, a kind of spade, or a collection of them, is used for cutting or extracting turf under water, without the necessity of first pumping it dry: this consists of a light iron frame, which is armed all round with a cutting-blade, in length about 3 feet; the part between it and the handle is open, being formed of four horizontal rods, and two vertical ones; these receive the turf after it is cut and detached, and enable the workmen, by means of a rope and windlass, to pull it up; these cutting instruments have a variety of forms given them to adapt them to the peculiar work they may have to perform.

The Box Shovel consists of an open box fixed at the end of a long handle, usually made of iron; the cutter traverses in a groove, and is worked by another handle; by this the turf is cut and detached, and each successive piece falls into the box: as many as four turfs may be thus drawn up at one time.

Dredging machines have been constructed in various ways, and of iron or wood, according to the nature of the service. Some machines have been arranged so that the system of chain and buckets should work through a channel in the middle of the vessel; others with one system on each side; and others with the buckets working over the extremity of the vessel. But, in general, the modern practice is to place the machinery towards one extremity of the vessel, to allow of the working of the ladder (which holds the buckets) freely on either side of the vessel. By this arrangement barges can be laid along both sides of the vessel, and the material raised by the machine be taken away more easily.

Perhaps the most popular form of machine for dredging purposes is the spoon dredger; similar in all essential particulars to the excavator invented by Otis, and used for land purposes; when placed upon a proper barge, with strong posts at either end, which, sliding in grooves, may be lowered vertically to serve as anchors. This machine is one of the most economical in use, and as a full description of it is given under the head of excavator, we shall confine ourselves to the chain and bucket dredging machines.

The best adapted boilers and engines for dredging purposes, are those upon the marine principle, as in them compactness and stability are combined; and for which reasons, they of that description are invariably applied; but in practice it is found disadvantageous to the profitable working of the machine, if the engine be not of a proportionate power to the depth of water, the buckets of a suitable number, and the bucket-frame of sufficient length to lie at a proper angle. Hence the following arranged proportions are annexed as the best adapted for working at or about the various specified depths from which the material is to be raised:—

Nominal Power of Engine.	Length of Bucket-Frame.	Number of Buckets.	Depth of Water in feet.
20	59½	34	18
25	63	36	20
30	78¾	45	25

The boat requires little or no peculiarity of form, otherwise than that of proper stability; it must be strong and well put together, or a constant tremulous motion is created by the action of the machinery, and the proper effect of the machine in a measure destroyed. It must also be of magnitude sufficient for the receiving of the machinery with a proper clearance for the buckets, according to the depth of water, and different positions in which, on that account, they are so frequently required.

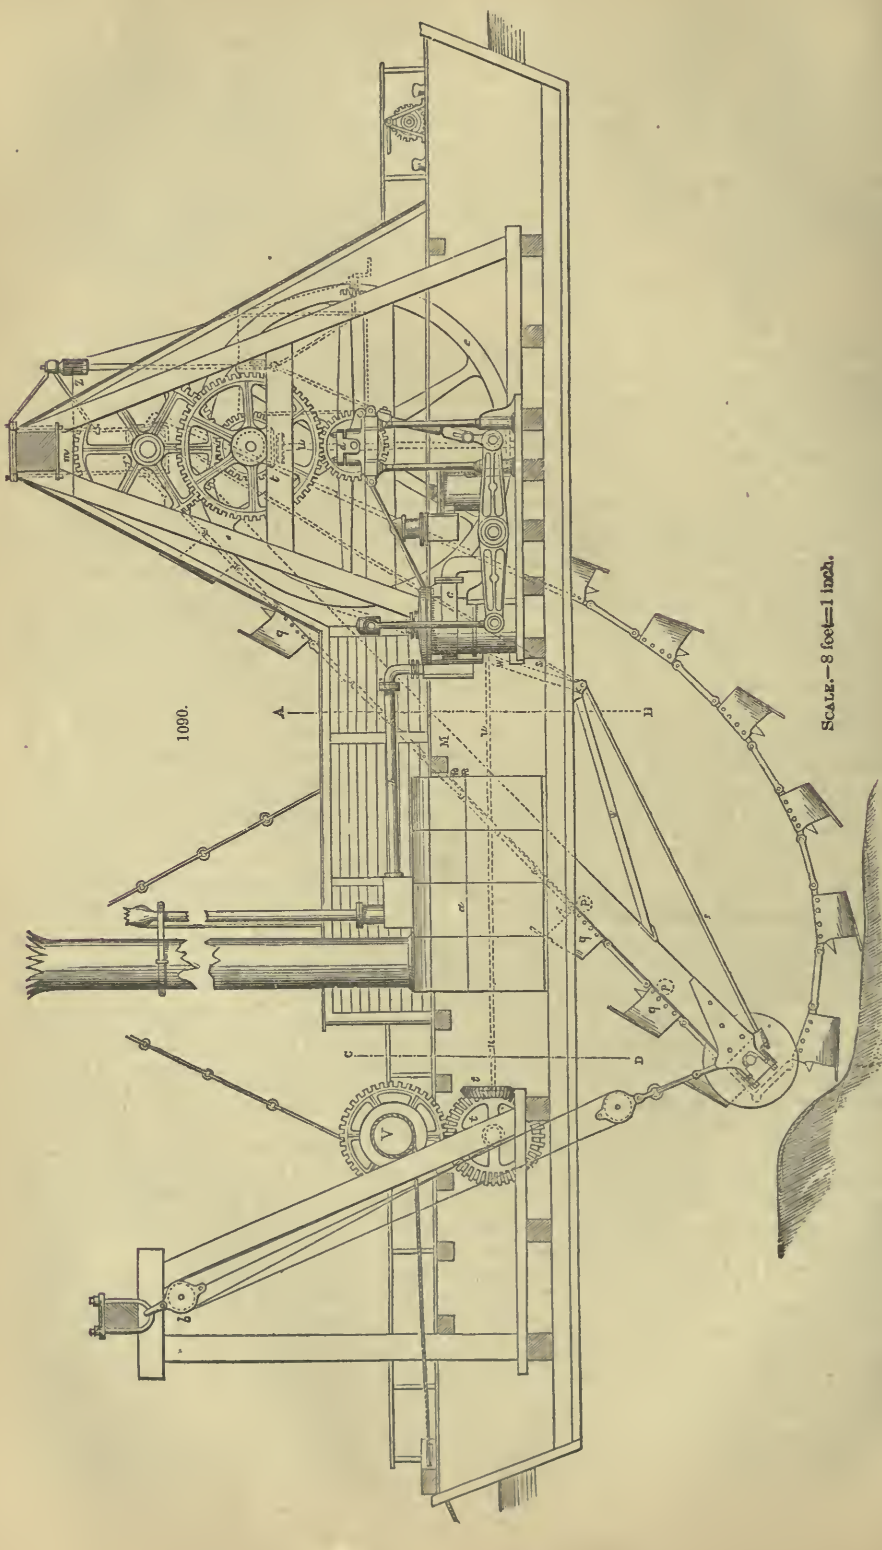
Description of the Machinery in the Dredging Vessel constructed by Summers, Groves and Day.—The objects which were chiefly kept in view in arranging the machinery of this dredging-engine, were simplicity of construction with efficiency and facility in adapting it to the work it would have to perform; and after some consideration, it appeared to the makers that a marine steam-engine, with side-beams, was the best kind of engine for this purpose, as it enabled them to convey motion to the buckets with less wheel-work, shafting, and machinery than is generally required in dredging-engines, whose works are frequently complex, and require considerable skill in their management.

Figs. 1090 to 1099, show an elevation, plan, and section of the vessel and machinery.—*a* is the boiler, constructed with internal fire-places and flues similar to the boilers commonly used for marine engines. *b*, steam-pipe leading from the steam-chest on the boiler to the engine. *c* is a condensing engine of 20 horse power, the cylinder being 27 inches diameter, and the length of stroke of piston, 2 feet 9 inches. The engine is constructed with side-beams on the marine principle, and the motion is communicated to the fly-wheel shaft *d*, by a connecting rod in the usual way. *e* is the fly-wheel. *p* is a friction-hoop, which fits lightly around a drum or sheave keyed fast on to the fly-wheel shaft. The use of this contrivance being to prevent accidents to the machinery, in case the buckets should get entangled with any thing during the process of dredging, as when the resistance increases beyond what is necessary for raising the soil, the drum or sheave slips round inside the hoop, and the buckets cease to work, whilst at the same time the steam-engine may continue its motion without injuring the machinery. *g* is a pinion bored to fit the fly-wheel shaft, (but not keyed fast to it,) having two strong stops or carries cast on one side of it, which come in contact with corresponding stops on the wrought-iron ring or hoop. *h* is a spur-wheel which is driven by the pinion *g*. *i* is a pinion keyed on the intermediate shaft, which drives the spur-wheel *j*, keyed on the tumbler-shaft. *l l* are clutch couplings for the purpose of connecting one or both sets of buckets to the steam-engine, or disengaging them when required. *m m m m* are cast-iron carriages, forming joints or hinges for supporting the bucket-ladders independent of the tumbler-shafts. *n n n n* are the tumblers over which the chain and buckets work. *q q q q*, &c., are the buckets made of boiler-plate, and bolted securely to the links of the chain in a peculiar way, more clearly described in figs. 1094 to 1096, where the buckets and links are shown on an enlarged scale, and in which, on the front of the buckets, will be observed a kind of spade that is of steel, and attached to the bucket by rivets, consequently easily renewed at any time when worn away: the bucket-chain runs on cast-iron rollers *p p*. The bucket-ladders are made partly of wood, having wooden sides with cast-iron king-posts and transverse trusses; with wooden struts and wrought-iron tie-bolts, with screws at the ends, so that they may be tightened up when required. These ladders are remarkably strong, with comparatively light materials.

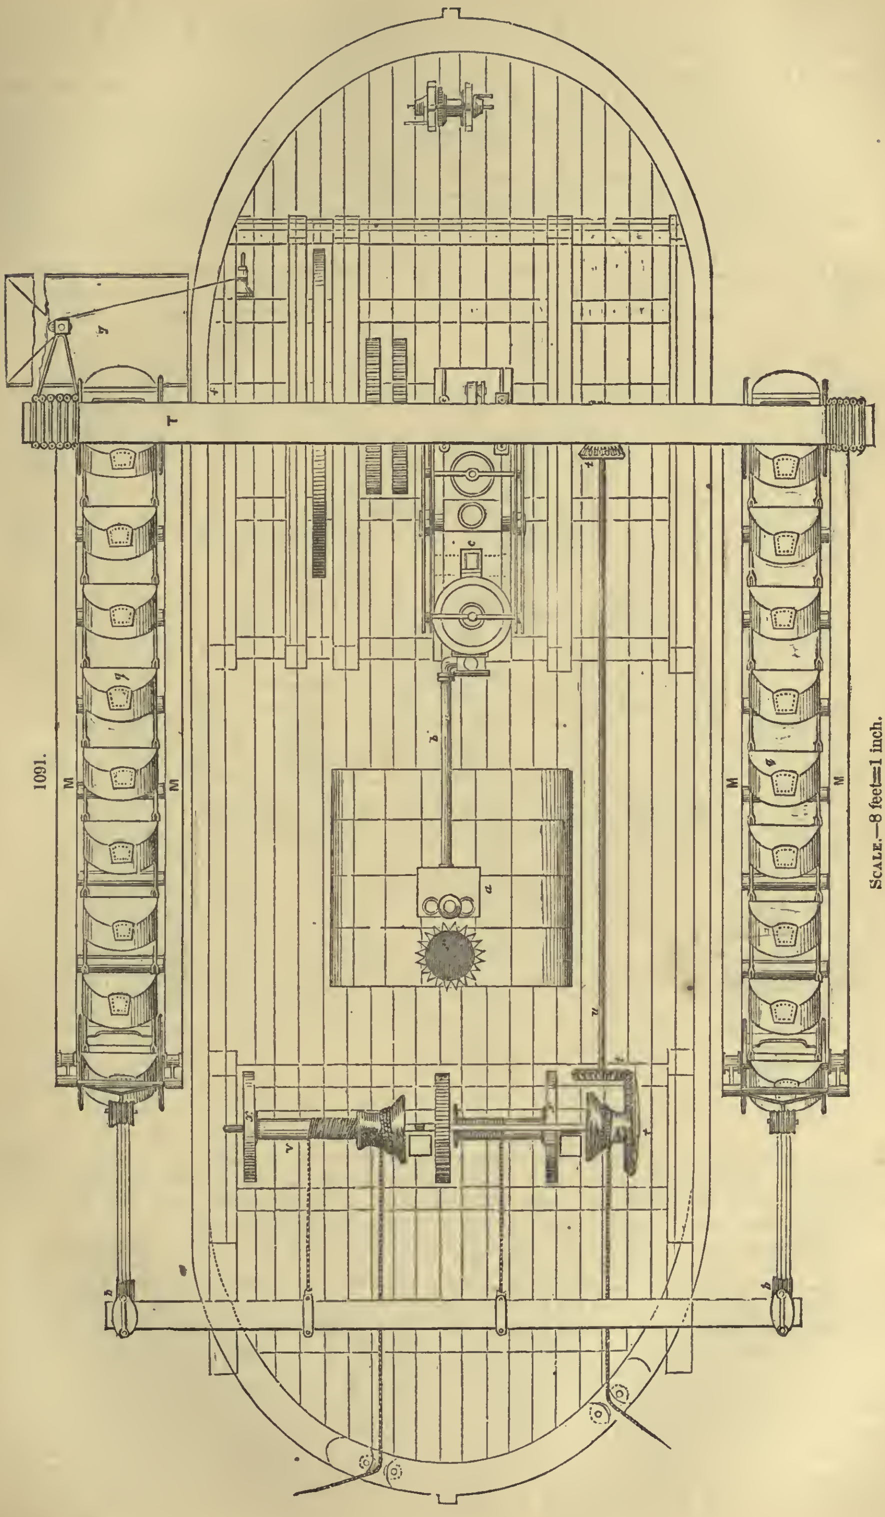
The spout *g* is of wood, lined with sheet-iron, and has a joint at *r* to allow of the punts or barges being equally loaded on both sides without turning them round. As when the outer end of the spout is raised by means of the purchase *z*, the soil will escape at *r*, near to the side of the barge which is close to the dredging-machine, on lowering down the outer end of the spout, the soil will be carried over to the other side of the barge, thus insuring its being equally loaded. The bevel-wheels *t t t t tt* and shafts *u u*, figs. 1091 and 1092, convey the motion from the steam-engine to the apparatus on deck for propelling the vessel to and fro, raising or lowering the bucket-ladders, &c. The ladders are raised by chains passing round the barrels *v v*, and working in the sheaved blocks *b b*, which are suspended from the timber framing. The operation of raising the ladders is effected by connecting the barrels to the shafts by the clutches *w w*, which are worked to and fro by levers that pass through the deck of the vessel. When the ladders require lowering, the clutches are drawn back and the ladders run down of themselves to any depth which is desired, being regulated by a brake attached to the drums at *x x*, as shown in figs. 1091 and 1093.

The apparatus for propelling the vessel to and fro is fixed on the deck. *y y* are two curved cast-iron barrels. By taking two or three turns of a rope or chain round these barrels, one under and the other over, one of the ropes will draw the vessel ahead, whilst the other pays off the slack, and *vice versa:*

1090.



SCALE.—8 feet=1 inch.



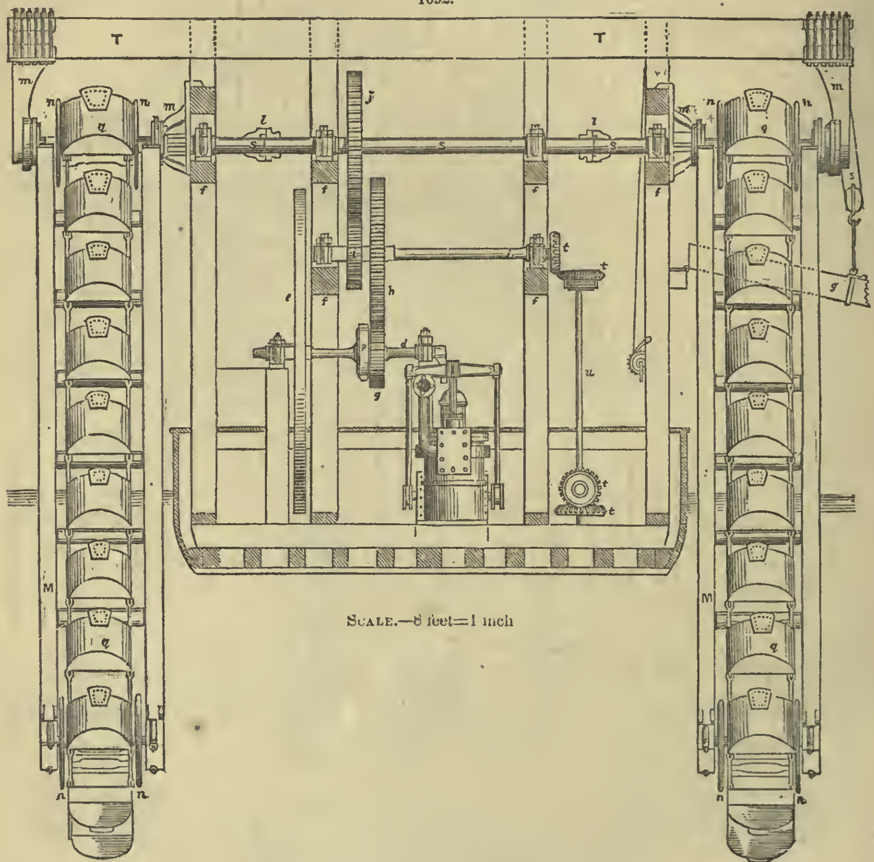
1091.

SCALE.—8 feet=1 inch.

or by putting both ropes or chains the same way round these barrels, they will both act in pulling the vessel in the same direction. It should be named that there is a friction-sheave placed between the propelling machinery and the steam-engine, similar to that which is fixed upon the fly-wheel shaft, to prevent the chains or ropes being broken in case of any obstructions.

The bucket-ladder, Fig. 1090, is composed *partly* of timber framing; the main timber M (which runs the whole length) being eighteen inches deep and eight inches broad, connected by strong cast-iron crosses, (*not* shown in the drawing, as it was thought they would only confuse the adjacent parts.) To give it strength to bear the weight of the buckets with their contents, it is furnished with a cast-iron king-post k, having two inch tie-bolts $s\,s$ connected to its lower extremity by a single and double forked joint, through which joints and the king-post a pin passes, thus firmly uniting them at this point. The *other* ends of the tie-bolts pass through snugs, cast on the top and bottom carriages at ends of ladder, and are

1092.



SCALE.—8 feet=1 inch

furnished with a screw for the purpose of setting them up, by means of a nut, should they at any time become slack. There are also two *wooden* trusses $w\,w$, which take the strain of the framing, midway between its centre and either end. This ladder is found sufficiently strong, and well adapted for sustaining a heavy weight; at the same time it is extremely light in appearance.

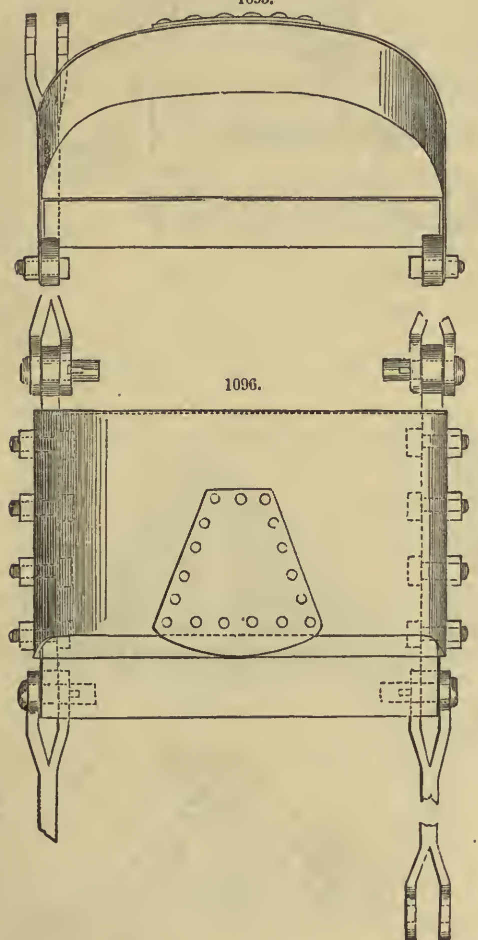
The buckets are made of boiler-plate, the back being half an inch thick. The back plate rises considerably above the other parts of the bucket, and slopes forward at an angle of about 25° towards the front or lip of bucket, for the purpose of retaining the soil and preventing its being spilled during its progress, after receiving it from the excavation, until it deposites the same in the barges alongside. The form of this back plate prevents a great loss of mud or other material, which would otherwise be the result, and consequently a loss of time would follow, and the quantity of soil delivered would not be adequate to the power of the steam-engine. All the other parts of bucket, (exclusive of the back plate before mentioned,) are three-eighths of an inch thick. The buckets at present dig to a depth of 24 feet, but greater depths may be obtained by merely lengthening the timber framing of ladder, and adding a greater number of buckets and links, proportionate to the extended length.

As the bucket-links are given in the same drawing with the bucket, further description is deemed superfluous; it may, however, be remarked, that the links pass over the tumblers with perfect ease, and *without noise*, owing to there being no projections on their *lower* sides, as the requisite strength round the pins is carried *above* the centre of the link, and not on *each side*, as is frequently the case.

The upper or tumbler shaft *s s s*, Fig. 1092, is in three lengths, having *two* coupling-boxes *l l* fitted to them, for the purpose of working either *one* set of buckets or *two* sets simultaneously; the bearings or journals of the shafts are four in number, seven inches in diameter and nine inches in length, and working in plummer-blocks, resting on four timber frames *f f f f*. The intermediate or middle shaft *i i* has bearings five inches and three-quarters diameter and eight inches in length, working also in plummer-blocks, which rest on wooden framing *f f*; and the lower or fly-wheel shaft *d*, has bearings five inches and three-quarters diameter and eight inches in length, one bearing of which rests on the engine-frame, and the other on the timber framing. These timber frames are severally connected at their tops by a strong transverse beam T T, 20 inches deep and 18 inches broad, the *outer* ends of which support carriages (to be hereafter described) for carrying the ladders, &c. By this arrangement, and by being securely fastened at their bases, the four upright timber frames are firmly kept in their perpendicular position. The form of these frames will be clearly understood by reference to the elevation, Fig. 1090.

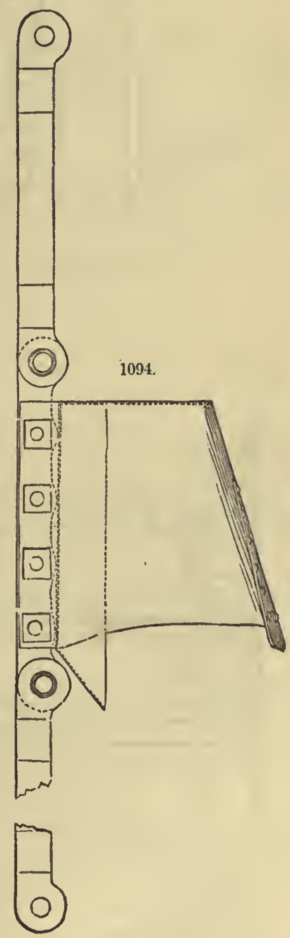
It will be seen that the outer or hanging carriages *m m*, Fig. 1092, are connected to the ends of the transverse beam in rather a novel manner; the hanging part, or part *beneath* the beam, being attached to the

1095.



1096.

1094.



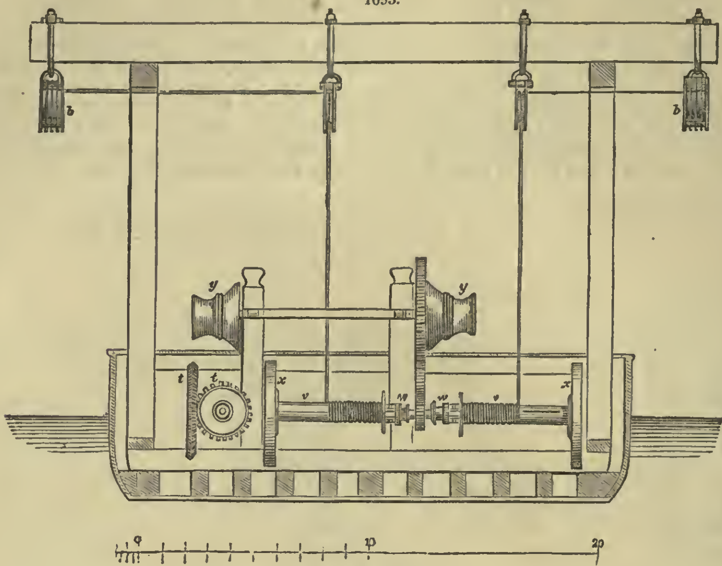
SCALE.—4 feet=3 inches.

cap or top plate by means of twelve 1¼-inch bolts, by which method it can be securely fastened to the before-mentioned beam, and adjusted so as to accommodate the tumbler-shaft, by means of packings being introduced between the cap and top of timber, and which can easily be removed at any time when required.

Figs. 1097 to 1099 consist of a detailed plan and section of top and bottom tumblers; they being of essential consequence to the efficient working of the machine, are therefore minutely delineated in an extended scale, thereby rendering the design more easily understood than by a lengthened description, which it would otherwise require. It may be observed, however, that they are of cast-iron, and the corners only being liable to derangement, are separate pieces, consequently easily removed when required.

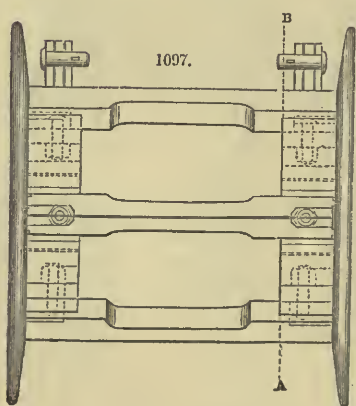
The engine with its machinery *has raised* 160 tons of soil per hour, upon an average *one* set of

1093.

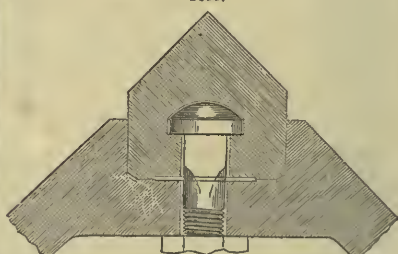


SCALE.—8 feet=1 inch.

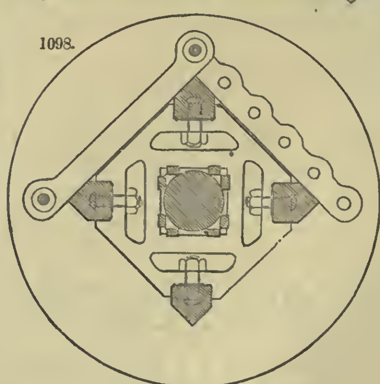
1097.



1099.



1098.



SCALE.—4 feet=3 inches.

buckets only having been employed in the performance, with a weight of three pounds and a half per square inch upon the safety-valve of the boiler.

It may be remarked, in conclusion, that the boat is supplied with a bilge-pump for discharging the bilge-water, and a deck-winch for moving the boat *by hand* when the engine is *not* working. The chain for raising the lower end of the ladder, is five-eighths of an inch in diameter, of the description called "*short* link." The draught of water is three feet six inches, with *every thing on board*, and the bottom is perfectly flat, and *both* ends are of the same form.

Specification for a Dredging Vessel of the following dimensions.

	Ft.	In.		Ft.	In.
Length of deck	80	6	Depth in hold	5	4
Breadth, extreme	22	1	Tonnage $169\frac{84}{94}$.		

The scantlings as follows:—

	In.		In.
Chine, elm, or beech	12	by	14
Floor timbers, elm or birch	$9\frac{1}{2}$	—	10
Kelson timbers, elm or birch	12	—	11

Stems, oak, sided 8 inches, moulded 9 inches.	1 deck hook, oak, at each end sided 9 inches.
Aprons, " 8 " " 8 "	1 breast hook, " " $7\frac{1}{2}$ "
Timbers, " 6 " head 6 "	Stancheons, " " 5 "
Stemson knee, at each end sided 7 "	Winch-bits " " $6 \times 7\frac{1}{2}$ "
Deck beams, oak, sided $7\frac{1}{2}$, moulded $8\frac{1}{2}$ "	Propelling gear-bits, oak $9 \times 11\frac{1}{2}$ "
Deck knees, " 5	

Plank:—

Bottom	$3\frac{1}{2}$ inch elm.	Deck	$2\frac{3}{4}$ inch yellow pine.
Outside	$2\frac{1}{2}$ " "	Bulwark	$1\frac{1}{4}$ " "
Clamps	$4\frac{1}{2}$ " "	Roughtree rail	$4 \times 2\frac{1}{2}$ " oak.
Plank-sheer	$2\frac{1}{2}$ " "		

Iron work:—

Butt bolts in bottom and sides . . . . $\frac{3}{4}$ inch.
Stemson knees and breast hooks . . . . 1 inch.

6 pair of iron knees in the wake of boiler and engine $\frac{3}{4}$ cwt., each fastened with 1-inch iron.
Deck, 5-inch spikes.
Deck fastenings all of iron.

The vessel to have both ends alike, with a break in the deck both fore and abaft.

The platform of 2-inch yellow pine round the boiler for the stowage of coals, and $1\frac{1}{4}$-inch yellow pine in the engine-room and cabins.

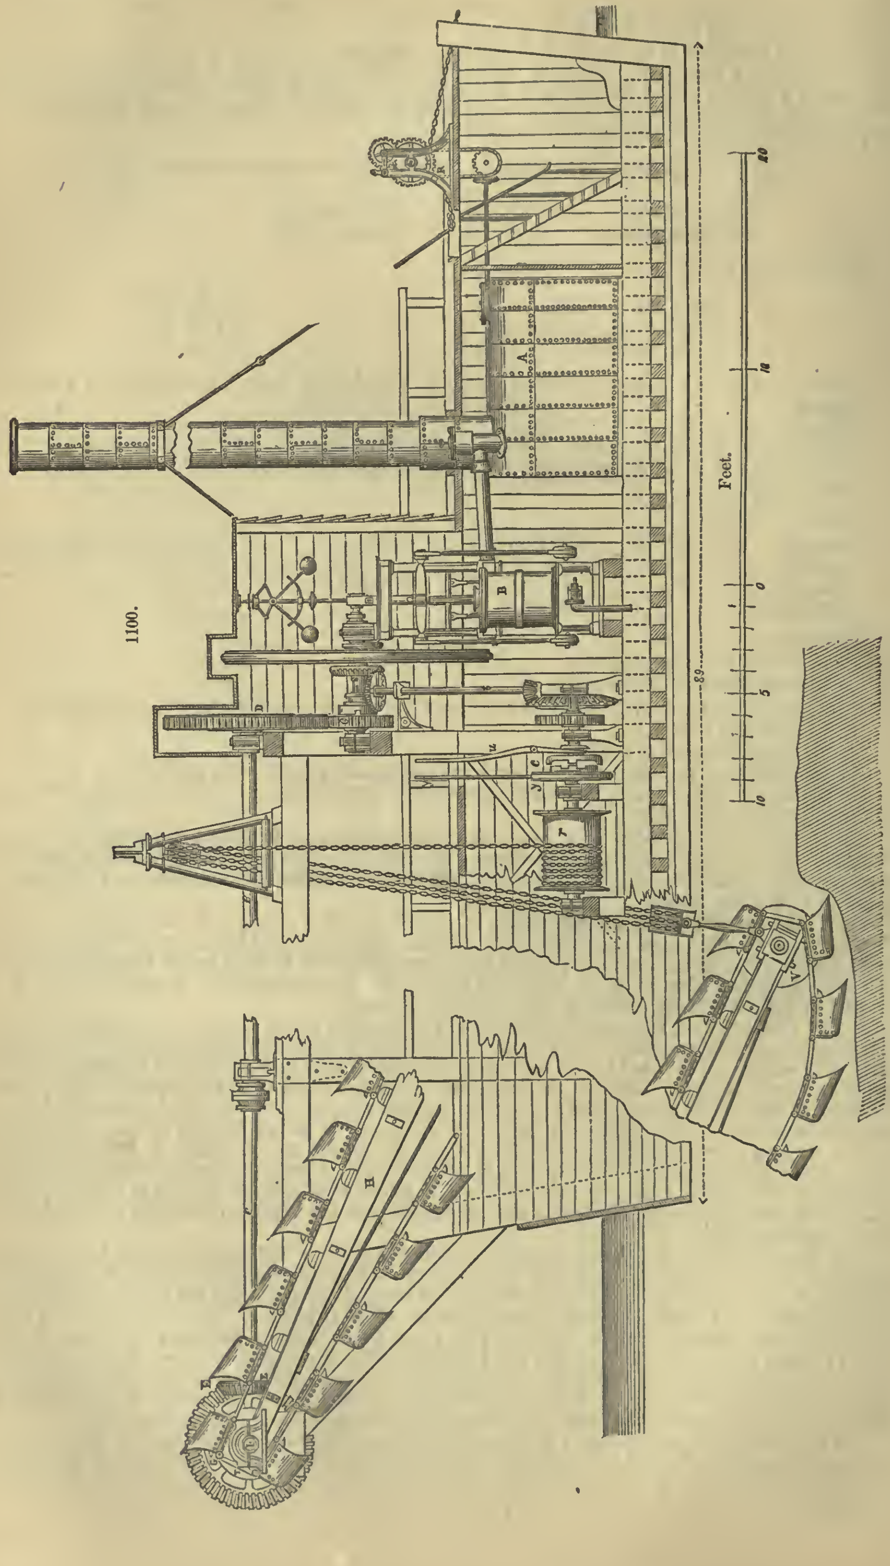
Description and specification of a Dredging-machine, constructed by Messrs. Girdwood and Co., of Glasgow, for the excavation of the River Clyde. Figs. 1100 to 1103, exhibit an elevation, plan, and section of the engine and dredging apparatus, the letters of reference corresponding in each figure or separate view of the design.

The timbers of this vessel are all exactly similar in specified variety and dimensions to that by Messrs. Summers and Co., as already minutely detailed, but the external dimensions of the vessel are a little different, viz.: entire length on deck 90 feet; extreme breadth 22 feet; height from ceiling to ceiling seven feet; and when all is on board and in complete working condition, the draught of water is about four feet. Six is the number of men employed on board.

A, Figs. 1100 and 1101, represents the boiler, and B the engine; both of which are of the usual construction adapted to marine purposes. The cylinder of the engine is 26 inches diameter; length of stroke $2\frac{1}{2}$ feet; number of strokes per minute 44; and requires about 2 cwt. of good coal per hour for the generating of a sufficient supply of steam. In effect, the engine will lift, from a depth of 18 feet, about 110 tons of mud or clay per hour, or 160 tons of sand or gravel in the same time; but in very hard ground, and intermixed with stones, no proper data can be given. The vessel is moved forward by the power of the engine, through means of the bevel-wheels, shafting, pitch-chain, &c., as shown in each design, and which communicates motion (when required) to, and by means of the double-acting winch R, and when the buckets are working in mud or clay, the vessel is caused to advance at the rate of about four feet per minute, when in gravel or sand at $2\frac{1}{2}$ feet per minute, and the number of buckets delivered is 14 in that space of time.

With regard to the movement of the buckets, motion is given to the wheels C and D by the crank-shaft S of the engine, and communicated by the line of shafting *e e e*, &c., to the wheels F and G; from thence to the buckets by the barrel or tumbler T, that being made fast upon the spindle I, which is of malleable-iron, eight inches diameter, and on which the wheel G is fixed. The small wheel C is three feet three inches in diameter; the cog-wheel D is seven feet diameter; the shafts *e e*, &c. are of cast-iron, $6\frac{1}{2}$ inches diameter in the bearings; the bevel-pinion F is two feet three inches diameter, and the bevel-wheel G is six feet, and makes seven revolutions per minute; the top or upper tumbler T has four sides, and the bottom tumbler V five; as when they are thus formed, the motion of the buckets is found in practice to work more steady, and, consequently, the effects rendered more complete.

The bucket-frame H, acting upon I as a centre, is also regulated to a proper depth of water by the power of the engine; the bevel-wheel K upon the crank-shaft S gives motion by means of the wheels *l m n*, to the barrel *r*, and round which the chain of the tackle passes, as shown distinctly in the elevation.

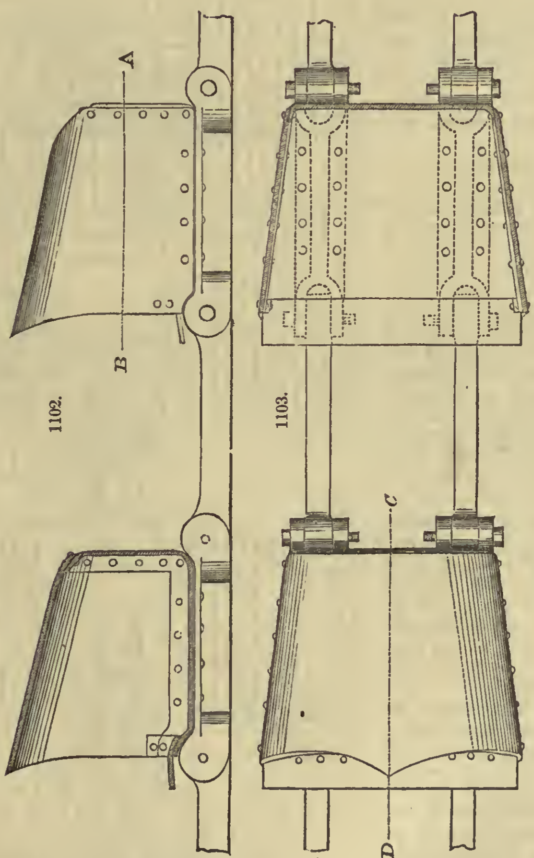


1100.

The wheels K and l are each two feet four inches diameter; the pinion m on the bottom of the shaft l is 10 inches diameter, and the wheel n four feet two inches. On the same shaft with the bevel-wheel n is fixed a spur-pinion g, of one foot seven inches diameter, which gives motion to the wheel o, of three feet three inches; the motion is communicated (when required) by means of the clutch $c\,c$, and, when the frame H is raised to a sufficient height, and placed at the requisite depth of water, farther motion of the barrel is prevented through disengaging the clutch by means of the lever W, and the barrel rendered stationary by the lever and friction-pulley $y\,y$. The clutch is two feet four inches diameter; the friction-pulley is three feet eight inches diameter, and its breadth of strap $3\frac{1}{2}$ inches. The length of the chain-barrel r is $4\frac{1}{2}$ feet, and its diameter two feet. The shaft t is $4\frac{3}{4}$ inches diameter, and the barrel-shaft $5\frac{1}{2}$ inches, each being of cast-iron.

The following is the number of teeth that each of the preceding named wheels contains, also the pitch and breadth upon the face:

Wheel or Pinion.	Number of Teeth.	Pitch.	Breadth.
Spur-pinion on crank-shaft C	49	$2\frac{1}{2}$ in.	$8\frac{1}{2}$ in.
Cog-wheel on end of laying-shaft D	112	$2\frac{1}{2}$	$8\frac{1}{2}$
Bevel-pinion, marked F	27	$3\frac{1}{8}$	8
Bevel-wheel " G	72	$3\frac{1}{2}$	8
Mitre-wheels " K and l	44	2	$4\frac{1}{2}$
Bevel-pinion " m	15	$2\frac{1}{8}$	$4\frac{1}{2}$
Bevel-wheel " n	75	$2\frac{1}{8}$	$4\frac{1}{2}$
Spur-pinion g on shaft with u	35	$2\frac{3}{8}$	5
Spur-wheel o on chain barrel-shaft	51	$2\frac{3}{8}$	5



1102.

1103.

The Bucket-Frame, Buckets, Links, &c.—The bucket-frame is of the best red pine, strongly trussed and strapped with iron, and in form and dimensions similar to the bucket-frame already described in the preceding machine; in length it is 55 feet 4 inches, and the number of buckets thirty-four, each bucket being $26\frac{1}{2}$ inches wide, 16 inches broad, 17 inches deep, and formed of the best plate-iron $\frac{3}{8}$ inch in thickness; on the back or sole plate p, of each bucket, and immediately beyond its formation, is an attached piece or continuation of the plate, so as to form a covering to the joints of the links, and so prevent any injurious effects from the constant liability of contact with the excavated materials; also

on the front of the buckets are fixed pieces of iron shod or edged with steel, for the purpose of increasing the strength of that portion of the bucket, and the better adapting of the same for coming in contact with hard materials; likewise that of being easily removed when required for repair.

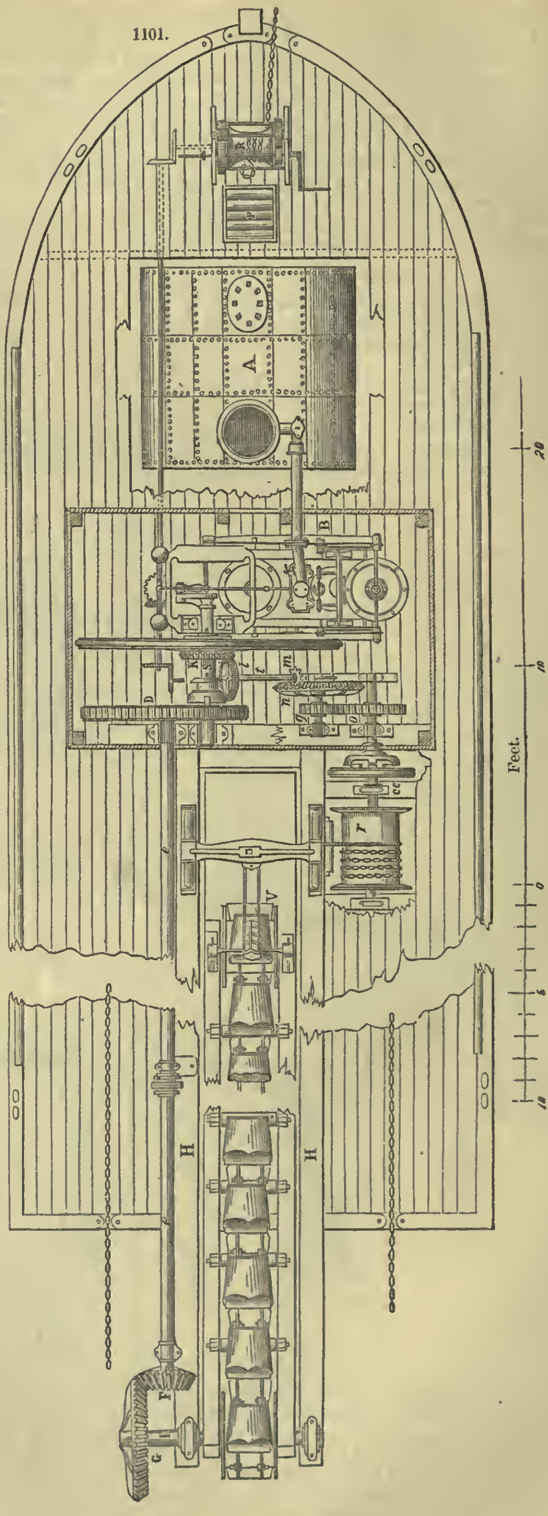
The links *x x x*, &c., that connect the buckets, are of wrought-iron, each link being 21 inches from centre to centre of joint; flanges are formed on the double links, as shown in the design, 2¼ by ⅞ths of an inch, and to which the buckets are fixed by ⅞ths of an inch rivets; the diameter of the joints is 3⅜ inches with ¼ inch projecting on each side, to increase the surface of bearing for the pins: all the joints and pins are cased with steel and properly hardened.

The rollers *r r r*, &c., are for the proper conducting of the buckets along the frame H, and are of cast-iron 8 inches in diameter, with axles or bearings of wrought-iron, 1½ inch diameter, and which revolve in cast-iron receptacles or bushes. The ends of the tumblers also revolve in cast-iron bushes, that metal being found more durable, for this purpose, than any hitherto tried.

It may not be out of place here, as being through the means of the action of the buckets and bucket-frame, to remark an idea or system given by a correspondent in the "Civil Engineer and Architect's Journal," which he calls *radius cutting*, in distinction to that of the common practice called *trench cutting*, and which no doubt in various instances must be of considerable advantage. In the ordinary method called *trench* cutting, the power applied to lead the machine ahead into the cutting, has also to resist the reaction of the buckets. Now, in *radius* cutting, the chain from the bow of the vessel is not wound up while it is cutting, but is only shortened at each return of the machine, and which causes a swinging motion of the vessel to take place, the machine being led laterally to the cutting by the side chains; and which are comparatively easy to work, as the reaction of the buckets is mostly against the *bow* or *radius* chain.

In respect to any inconvenience attending the use of these lateral chains, in a harbor or narrow navigation, it is no more than in the ordinary method, as corresponding chains are then required to keep the machine in line, and these are necessarily used on both sides at once; whereas, in the other system, these lateral chains are only tightened on one side, namely, that on which the machine may happen to be traversing; and where it is required to lower them, to allow vessels to pass, they only again require to be tightened up sufficiently to let the buckets fill.

1101.



It may be contended that, to cut or trench a bank in the proper current, will, by changing the currents and eddies, remove it by a natural process; but, as this is a point so difficult to hit upon, it is generally allowed that, to get large stones and rocks taken up, and to cut the surface fair, is the surest way of reducing a bank, and of leaving it in the condition least liable to "slit up."

The difference of construction in the machine is trifling, so as to adapt it to the radius principle, being only the doing away with the flanges on the bottom tumbler, and substituting in their stead "snugs" on the tumbler between the chains or links, to prevent their getting off. But it must be borne in mind in the constructing of dredging-machines for whatever kind of cutting, that a proper means be effected for preserving the chains employed in taking the vessel ahead, when the power of the engine is applied; and the best method that I am at present aware of is that of "conical friction."

The excavated material from the dredging-machines is carried away by punts, or large rectangular boxes of plate-iron. In dimensions, they are each 32 feet in length, 14 in breadth, and 3 in depth; through the deck of which is an opening 27 feet 8 inches by 10 feet 4, and around this opening is a cooming 10 inches in height, as a prevention to the stuff getting over upon the deck; each punt carries on an average 20 to 22 tons, and a small steam-tug of 70-horse power takes from 18 to 20 loaded punts at one time.

DREDGING AND RAISING MACHINE, by J. Hart, of Middletown, Connecticut.

Fig. 1104 is a horizontal plan of the mud dredging-machine.

Fig. 1105 is a vertical section.

A is a large flat vessel for receiving the boilers, fuel, engine, and principal parts of the machinery.

B is a small vessel for stores, &c., strongly connected to the larger one with the vibrating ways c for the buckets, strongly hung between the two vessels in a gallows-frame.

A is a crank, by which the power is to work the whole machinery, fixed on one end of the shaft b, which is strongly mounted in framing c.

On the shaft b is the fly-wheel e, and between that and opposite bearing is the clutch f, sliding on the shaft b, into or out of the clutch part of the driving pinion g, which geers into the larger tooth-wheel h mounted on that end of the bucket-shaft i; on this the chain-wheels $k\,k$ are fitted, each wheel made with four shifting-studs to lock into the long links of the bucket-chain. This chain is made so that each flat link has a curve to fit the wheels $k\,k$.

The edge link has a strong iron brace l^2 put in given lengths.

A connecting link is inserted, made with an open side turned up to receive a doubled-eyed collar.

In this mode of making a chain in sections, and using only four spurs or teeth, a chain can be worn one inch at each end, and not ride or turn on the teeth or spurs; each end of the links is lined with steel.

When worn or broken a section can be taken out to be repaired and replaced by another.

The chain-wheel $k\,k$ is a skeleton cast wheel to receive a shifting sectional stud or spur, with bolts to hold them in, which takes the strain off the chain, and allows them to be taken out and replaced by others when worn.

The friction rollers and water chain-wheel run on sleeves.

The raising and lowering of the buckets is effected by the slings and yoke in i, Fig. 1105, and chain h^1, which goes over the sheeve o, mounted on the double davit p, thence under the chain-wheel g to a sheeve at the head of the gallows-frame, and having at its inner end a counter-weight.

The chain-wheel g, fitted with a groove and studs to match the chain h^1, is mounted on a shaft fitted in bearings, and having the tooth-wheel w on one end, where it geers into the pinion x, which is fitted to a shaft mounted on bearings, and carrying on it the raising or lowering wheel E; this is made so that it serves as a hand-wheel by the spokes y^1, and as a drum by the flanged rim x^1, and through it the ways are regulated by the directing workman, who stands on the deck.

Immediately over the fly-wheel e, Fig. 1104, a frame i, Fig. 1105, is laid, to receive the bearing of the shaft t^1 on one part, forming a winch k^1, Fig. 1104.

At the other end, the drum s^1 is mounted, and over this is placed the belt, so that it hangs loosely around and below the fly-wheel e, and is kept from contact with it by the small rollers $q^1\,q^2$, mounted below the drum s^1, when not required in use in the pit. Formed by the frame which carries the drum s^1, are the two tightening drums $p^1\,p^2$ shown in Fig. 1104, as set over the fly-wheel e; these are hung in the swing-frames $o^1\,o^2$.

The upper part of each of these frames terminates in arms $u^2\,u^3$, and at one end of the frame u^1 is the vertical davit and sheeve m^2; a rope l^1 goes from the arm u^2 round the sheeve m^2 and returns and fastens to the arm u^3, and thence leads to the frame over the deck w^1.

The winch k^1, Fig. 1104, receives one end of rope i^1, the other end of the rope being attached to the drum x^1 on the wheel E; and the tooth-wheel is fitted with a pawl h^1 to retain it in its place as wanted. This part of the apparatus is to be used as follows: when the buckets are to be lowered, the attending laborer lifts the pawl h^1 back and turns the ways-wheel E in the direction of the arrow 1 by the spokes y^1; this lowers the ways, and at the same time is winding the rope i^1 off the windlass k^1: the belt r being slack does not hinder the operation of lowering.

When the bucket and ways are to be raised, the attendant laborer leaves the wheel E and simply hauls on the rope l^1, which pulls the arms u^2 and u^3 outwards, and forces the drums $p^1\,p^2$ inwards against the belt below in contact with the rim of the fly-wheel e, whose motion round drives the raising-wheel E round in the direction of k^1, raising the ways and buckets easily and rapidly.

Near the machinery in the smaller vessel B, projecting over the end, is a frame forming a slide, carrying the anchor-post. This is raised by a chain running through sheeves; then by taking a turn around the end of the bucket-shaft i, the end forms a windlass barrel for that purpose. This anchor-post holds one end of the machine; the other end is moved the width of the buckets at a time by a pawl, windlass, and lines.

1104.

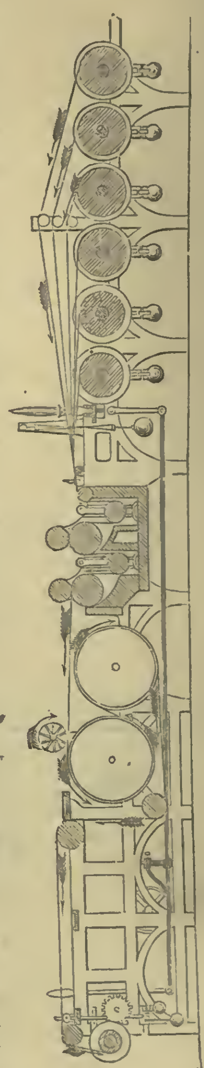
SCALE.—25 feet=3 inches.



DRESSING MACHINE. Fig. 1108 is a section of an English Dressing Machine as constructed by Hornby and Kenworthy. Six beams are placed in bearings so that they will revolve, having retaining weights upon their pivots; the six threads of yarn are then passed through an ordinary comb-bar and thus divided equally until passed through the healds, which in this machine are situated at the left end, for the purpose of effecting the cross-shed, and thereby taking the "lease," previously to the yarns being submitted to the sizing process. The lease now being taken, and the cross-band or threads being introduced for the purpose of "looming," or drawing in of the weaver's beam, the threads of yarn are passed over a comb-bar, formed by a row of teeth or pins, for the purpose of laying the threads in parallel breadths, side by side, and forming each division of threads (of any required number) into distinct bands (of any desired width), each thread being laid parallel, side by side, and thus in lateral contact, the comb-bar being allowed to vibrate or oscillate freely as the threads proceed. The bands are now passed over a conducting roller, and immersed into the trough containing the sizing material, which is here kept in a heated state by steam pipes, and thus boiled into the warp threads as they are passed through it and under the adjustable tension roller. The threads are then passed forward through a pair of squeezing-rollers, and again similarly immersed in the trough containing the size to finish the yarn, from whence they are passed around the drying cylinders, also heated by steam, and now assume the form of tapes, (the sizing material, by its adhesive properties, causing the threads to adhere slightly together). A circular revolving brush is placed above the threads as they proceed over the drying cylinders, for the purpose of dressing or laying the fibres. They now proceed in a sized, dried, and finished state, being conducted by two rollers through a similar comb-bar, but of much finer pitch, and by passing through which the bands of threads are passed edgewise and again similarly divided by the oscillating or vibratory action of the comb-bar, and laid over the tension roller at the right hand end of the machine in a proper state to be received and wound upon the warp beam ready for the operation of drawing in.

Fig. 1109 represents a side view of the dressing-machines used at Lowell and its vicinity. A A is the centre-frame, B B B are the section frames, containing the section-beams H H H H. The ends of the section-beams are of cast-iron, with a square groove for receiving a friction-strap, and a weight represented at *v v v v*. The sizing-rollers are represented at *y y y y*.

The yarn as it leaves the section-beams, passes through a raddle of small pieces of hard wood, *u u u u*, through between the sizing-rollers,—through a brass wire reed at *o o o o*,—through a copper-plate supported by *b b*,—through another brass wire reed at *d d*,—and under the measuring rollers N N,—at which place the yarn from the four beams on each section are brought all into one horizontal plane. From the rollers N N, the two sections of dressed yarn pass up through heddles at *k*, called the lease-harness, and are wound on to the centre-beam *a*. The lease-harness may be shifted to either side of the frame by means of a screw at *k*, and only one section of the yarn goes through heddle-eyes in the lease-harness; so that when a full beam is to be removed, a lease-rod is introduced between the two sections of yarn above the harness; then, by drawing the harness to one side, another lease is formed, into which a rod is introduced.

F are the fast and loose belt-pulleys, driven by a belt from the room below; *n n* are two cones, that to the right being driven from the one to the left, by the cross-belt R. On the axis of the cone to the right hand, there is a small bevel-wheel working into another on the bottom of the upright shaft *r r*. On the top of the upright shaft there is a small bevel-wheel working into the wheel *c*; and on the axis of the wheel *c*, there is a small spur-geer, not seen in the engraving, working into the wheel E, on the centre-beam *a*. Motion being thus given to the cone on the left hand, (by the belt-pulley F which is fastened on the same shaft,) it is next communicated by the belt R to that on the right, and from it to the beam on the top, containing the dressed yarn; hence the speed of the centre-beam *a*, on the top of the centre-frame, may be increased or decreased, by shifting the belt R, on the cones *n n*.

The brush-motion is next to be considered. D D D are the brush-racks, or brush-frames; they are not fastened to the section-beam frames B B B, but are fitted so as to move up and down, short spears *z z* being fixed to the top and bottom of each side of the brush-frames, which slide into the eyes of studs, and serve to keep them in their proper position, as well as to let them move freely up and down: *s s s s* are small blocks of cast-iron, which are fitted to slide freely on the polished steel-rods *h h h h*; the dotted lines represent straps or belts passing over small pulleys on each side, and descending down to the large wooden pulleys G G, to the surface of which the belts are fastened: the blocks *s s s s* are fastened to the belts by a small nut and screw on the under side, whilst the brushes rest on the blocks above. The feathers represented on the blocks at *s s s s*, fit into slits in the ends of the brushes. W W represent two beams of wood, (one at each side of the machine,) about four inches broad, and three inches thick, called sweeps; these are supported in the centre at *f*, and at the end towards the left hand, they are attached to the lever P P, the under point of which supports the whole brush-frame the other end of the sweeps being attached to the block *i*, towards the right hand: the block *i* is a

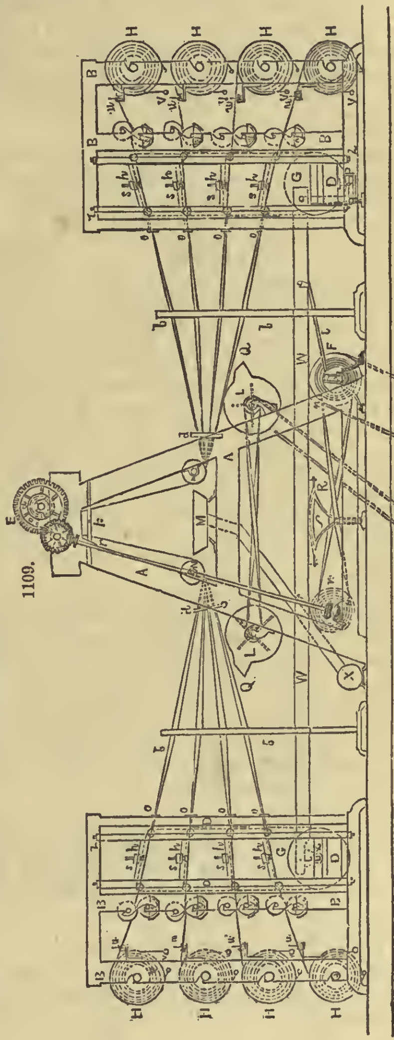
CHAS HUTTON, L.L.D. F.R.S.

N Y D Appleton &

projection from a shaft, extending across the machine at each section, the axis of which is seen at x, and the pulleys G G are fastened on each end of this shaft. By carefully examining the engraving of the various parts of the machine, the reciprocating motion of the brushes, together with the up and down motion of the brush-frames, will now be easily understood. The lever J is connected with a sliding-crank on the axis of the cone n, towards the left hand; consequently, the revolving of the crank moves the sweeps alternately, from section to section; and the end of the sweeps to the right hand, being attached to the block i by a strap of belt leather, the alternate motion of the sweeps moves the shaft x, and with it the pulleys G G, about one-fourth of a revolution each way: this reciprocating motion of the pulleys, draws each end of the straps represented by the dotted lines, and thereby produces the necessary reciprocating movements of the brushes upon the yarn; while, at the same time, the other end of the sweeps towards the left hand, by means of the lever P P, raises the brush-frame, and with it the brushes, up and down at every alternate stroke. Thus, when the brushes are at $h\ h\ h\ h$, the frame is down, and they are then in a proper position for moving along the surface of the yarn, (which has just been coated with size, in passing through between the sizing-rollers,) and having made one full stroke, they are then at the opposite side of the frame, which is immediately raised by the lever P P, connected with the sweeps; and in raising the frame, the brushes are lifted out of the yarn, until they return to their former position at $h\ h\ h\ h$. The whole movements of the machine commence at the cone n, towards the left hand. From it, motion is communicated by the belt R, to the opposite cone, and from it, to the centre-beam a at the top; and from it, (the cone n,) motion is also communicated by the sliding-crank, and the connecting-lever J, to the sweeps W W, of which there are two, and the one end of each moves the brushes alternately from side to side, whilst the other end produces the up and down motion of the brush-frame. The whole machine is extremely simple, and all its different movements so contrived, that they can easily be adjusted so as to operate with the most perfect accuracy.



1109.

Scale.—4 feet=1 inch.

L L represent the fanners enclosed in wooden boxes, open only at the centres for admitting a current of air, and at the mouths Q Q, for throwing it out: by this method of confining the air, it rushes out with much greater force, and the mouths Q Q are made so as to direct it right up amongst the dressed yarn. The fanners here represented have four wings each, but some have only two or three: that to the left hand, is driven by a belt from the room below, and from it, a cross-belt communicates motion to the one on the right. X is a hot-air pipe, with a branch extending up to the hot-air box M, placed between the two rollers N N. The cover of this box extends till within one half-inch of each side, which leaves a small opening for the escape of the air, which issues out at each side upon the yarn, and being entirely hot air, it has a peculiar effect in absorbing any remaining moisture upon the yarn, before it is wound on to the centre-beam a, on the top. Instead of the hot-air box M, some dressing-frames have a centre fanner, similar to those used about Manchester.

The sizing-rollers $y\ y\ y\ y$, are generally made of soapstone, with an iron axis; the under roller only is covered with cloth: one of these rollers, when finished, costs about eight dollars.

The two sections of these dressing-machines may be extended out as far as may be thought necessary. In order to diminish the size of the plate, the distance from the centre of the section-beams to the centre of the frame, is represented as only 9½ feet; some, however, extend to 17 or 18 feet. As the greater the distance from the sizing-rollers to the centre-beam containing the dressed yarn, more time will be gained for drying; but when the section-beams are stretched out too far, the yarn is more liable to break with the drag of the centre-beam.

On one end of the axis of the measuring-rollers N N, there is a screw or worm working into geers, connected with an index which points out the number of yards of dressed yarn on the centre-beam; every 33 yards is marked with paint, which allows 30 yards of cloth to each piece, the 3 yards (equal to 10 per cent.) being allowed for shrinkage in the weaving, &c.

The measuring-rollers, in general, are common wooden cylinders, about eight inches in diameter some are revolving steam-cylinders, which, when properly packed at the journals so as to prevent the steam from escaping, has the best effect of any thing that has yet been tried for drying the yarn speedily.

The average produce of these machines is very variable. In some factories, their average produce will be about 14 pieces per day to suit a 9^{00} reed; yarn, Nos. 14's to 18's. In other factories, on the same kind of work, these machines will dress 20, in others 30, 40, 50, and 60 pieces per day. Some of those fitted up with revolving steam-cylinders, are said to produce even 70 pieces on the same kind of work, viz., coarse 9^{00s}, yarn No. 14's. One great cause of this difference in the quantity produced from the dressing-machines, arises from the different temperatures in the apartments where they are in operation, as well as from the mode of applying the heat to the dressed yarn. In some factories the dressing-machines are in the same room with the looms, where the temperature seldom exceeds 75°. Those mounted with steam-cylinders, in place of wooden measuring-rollers, generally produce the greatest quantity of work; next to these, are those with the hot-air pipes; and next to the latter, are those with three fanners, that is, one at each side, and one in the centre. Those with only two fanners, produce the least quantity of work.

The size used for dressing is generally made of potato starch for all coarse work; and of flour for the finer goods, or such as are intended for printing. The mode of preparing the starch for size requires particular attention; and although different places may have different methods, the two following have been found to suit the purpose remarkably well.

1. *Method of making Size from Potato Starch for coarse Goods.*—2½ gallons of yeast, and 2 quarts of vinegar, to be well mixed with about 9 gallons of water, which has been previously heated to 120°, or as hot as the hand will bear to work in it. To these are added 125 lbs. of potato starch. The whole is then allowed to stand in a warm place about 10 or 12 days, or until it is perfectly fermented; then 3¼ lbs. of common clean tallow is dissolved in 75 gallons of water, heated to 160°, to which are added 75 lbs. of the fermented starch. The whole is well stirred until all the ingredients are perfectly incorporated. The size is then to be used immediately before, or after it is perfectly cooled down. To the above some add about 2½ lbs. of the sulphate of copper, to prevent mould.

The above makes a very superior size. It is smooth, clean, and entirely free from any offensive smell; and although about the same price as flour, it is found to answer the purpose much better for coarse goods; very little of it adheres to the yarn, yet quite enough to make it weave well.

2. *Method of making Size from Flour for the finer Goods.*—300 lbs. of flour mixed in 45 gallons of water, and allowed to stand for four or five days at blood-heat, until it is perfectly fermented; this is called yeast. To the above are added about 140 gallons of water heated to 180°. The whole is then boiled by steam from 30 to 45 minutes. At first it boils thick, but by continued boiling it becomes thin in the middle, when it is considered done; after which it should stand over one week, and be reduced with cold water when used.

The following mode of making Size from Flour is practised in Glasgow for various kinds of Goods:—One barrel of flour is soaked in water which had been previously heated a little over 120°, and allowed to stand in this state about a week, or until it ferment thoroughly. It is then mixed with about 110 gallons of water in a copper boiler, with a cast-iron casing; and by introducing steam into the boiler, as well as into the vacant space between the casing and the boiler, it is gradually heated until it boils; after which the steam may be admitted at any pressure, and the boiling process continued about an hour; during which an agitator, driven by the engine, moves round with a slow motion, until all the concretions or lumps are completely dissolved, when a wooden roller being dipped into it, if the small portion which adheres to the roller has a thick, smooth, glutinous appearance, it is then ready to be emptied out into narrow deep vessels to cool, in which it is allowed to stand for three or four days before using it.

Besides the kind of dressing-frame just described, there is another made at Providence, Rhode Island, and generally used throughout that part of the country, known by the name of Pitcher and Gay's dressing-frame. The principal difference between it and the one already described, is, that the former has four pairs of sizing-rollers on each section, while the latter has only two; that is, the yarn from the two upper beams passes through between one pair of sizing-rollers, and that from the two under beams through another pair.

DRESSING MILLSTONES, *Machine for.* We have had occasion to notice, in our descriptions of corn-grinding machinery, the frequency with which it is found necessary to renew the grinding surfaces of the stones, and the great care and accuracy to be observed in thus preparing them for their work. The operation consists in roughening the surface of the stone, when worn smooth, by cutting delicate and very regular furrows between each of the radial grooves and parallel to them, and depressing the latter to a degree corresponding with the amount of the grinding surface removed. Skilful and experienced workmen are employed for this service, which they accomplish by the help of hammers, provided with chisel-edges, of well-tempered cast-steel.

Simple as this operation may appear, the attempts hitherto made to perform it entirely by machinery have proved abortive; and we need not be surprised at this, when we consider the various degrees of hardness and compactness presented by different parts of the same stone, as well as the differences in the nature of the grain which is to come under its action. To accommodate itself efficiently to such circumstances, a machine would almost require of itself to possess intelligence. But although it may safely be pronounced impossible to dispense with manual labor in this process, it may be accomplished with much greater dispatch and precision by the use of the simple machine, or more properly *instrument*, which we have represented in Figs. 1110 to 1121.

This instrument serves simply to guide the hand of the workman, and to restrict the cutting edge of the hammer into a perfectly parallel and rectilinear course; the force and number of the blows being left entirely to the discretion of the workman. By a simple contrivance, it is also made available for

regulating with the greatest nicety the degree of fineness, or in other words, the distance between the furrows, of the grinding surface of the stones, according to the nature of the work on which they are to be employed.

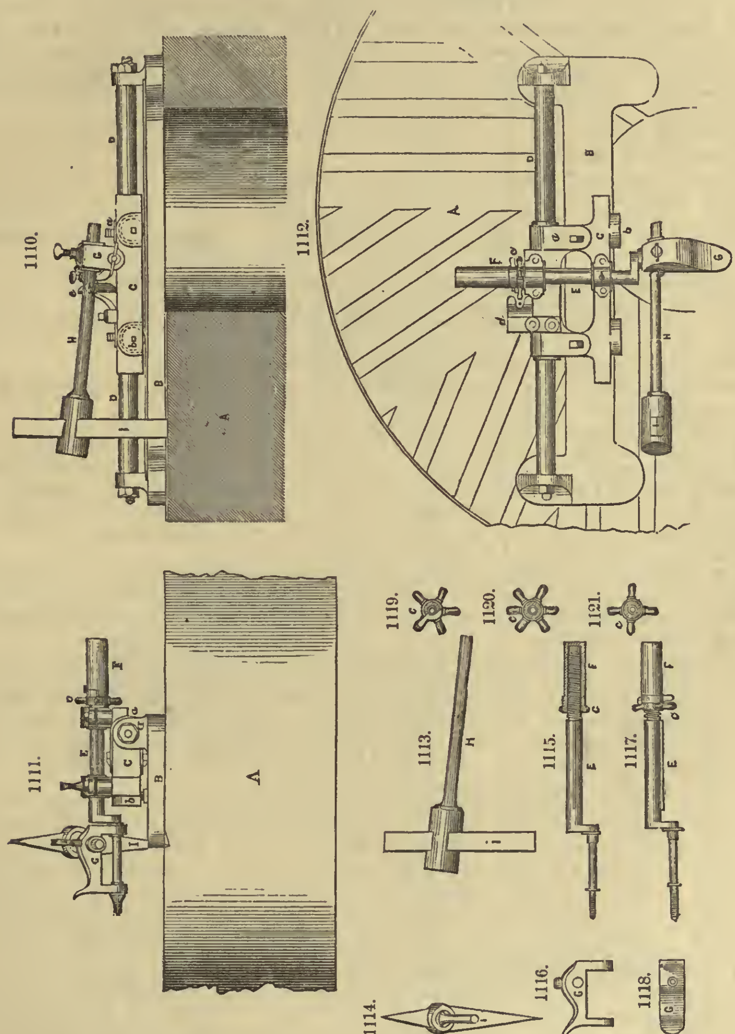
Fig. 1110 is a side elevation; Fig. 1111 an end view; and Fig. 1112 a plan of the entire machine.

Figs. 1113 and 1114 are views of the hammers and cutting tool detached from the machine.

Figs. 1115 and 1117, a sectional view and corresponding plan of the axis E, and its screw and nut.

Figs. 1116 and 1118, detached views of the saddle or guide for the hammer.

Figs. 1119, 1120, and 1121, represent the various handles used for varying the distance between the cuts the first having five, the second six, and the third four rays or points.



Scale.—1 foot=1 inch.

The base of this machine, which simply rests, without being fixed, upon the dressed surface of the millstone A, consists of a narrow cast-iron plate B, also dressed on its under surface, and of sufficient weight to retain it in the position in which it is set, without at the same time impairing its portable character. On this sole-plate a carriage C is fitted to traverse longitudinally; being supported at one side by a smooth cylindrical rod D, bolted to the sole-plate, and passing through the brass-mounted sockets *a a;* while, at the other side, it is provided with small friction-rollers *b b*, resting on the sole-plate. At right angles to the direction of this motion, an axis E is fitted to slide on bearings cast upon the carriage C; the outer extremity of this axis is formed into a screw, worked by the nut F; and the opposite end, which is cranked, carries the saddle G, into which the hammer-handle H is inserted, and which guides the action of the cutting-tool. The nut F is elongated so as entirely to enclose the screw and protect it from injury; it is also provided with a set of star-handles *c c′ c″*, either of which may be affixed to it according to the degree of fineness which it is required to give to the stone. The first has

six rays, and gives the greatest degree of fineness, the distance between the cuts being only one-sixth of the pitch of the screw; the others, having fewer rays, give correspondingly increased roughness to the stone. A species of index *d*, fixed to the carriage, serves to regulate the exact amount of motion given to the nut. The cranked form given to the axis E is for the purpose of adapting the machine to the length of the cutting-tool I. The manner in which this adjustment is accomplished will be obvious from inspection of the drawings.

Action of the Machine.—This instrument being laid upon the surface of the stone, with the edge of its sole-plate exactly parallel to one of the great radial grooves, the carriage C is pushed by the hand of the workman towards the circumference of the stone, until the cutting-tool I reaches it.

He then begins his strokes, varying the number and intensity of them according to the hardness of the stone, and the depth he wishes to give to the furrows; and drawing the carriage C slowly with his left hand towards the centre of the stone, until the whole grinding surface is traversed by the tool. The hammer is then set into the position for making the next adjacent furrow, by turning the handle *c* through another of its divisions; the carriage is again slid towards the circumference, and the operation continued as before. Thus the requisite straightness, regularity, and parallelism of the grooves is ensured and the operation of dressing materially facilitated.

A, the millstone to be re-cut.

B, the base-plate of the machine.

C, the carriage or support of the working parts of the machine.

a a, straps of iron binding the carriage to the cylindrical rod D.

b b, friction-rollers between the carriage and sole-plate.

D D, a cylindrical horizontal rod, turned smooth, for guiding the carriage C into a rectilinear movement.

E, an axis sliding transversely in bearings, and carrying the guide for the hammer.

F, nut by which the position and motions of the axis E are determined.

c c c, star-handles for regulating the fineness of the cut; the first having six, the second five, and the third four rays.

d, an index for regulating the exact amount of travel given to the nut F.

G, a cast-iron saddle fitting to the cranked end of the axis E, and serving as a guide to the hammer.

H, the wooden handle of the hammer.

I, the chisel or cutting-tool inserted into the head of the hammer.

DRILLING-MACHINE, *by Messrs. Joseph Whitworth & Co., Manchester.* This machine answers all the purposes for which tools of this kind are intended, and is made self-acting in all its motions.

Fig. 1122 is a vertical section in the plane of the axis of the driving-cone and work-table.

Fig. 1123 is a front view of the machine, agreeing in its letters of reference with Fig. 1122.

The other figures are drawings of the parts of the machine, which are necessary to a full description of its construction and motions, and have the same letters of reference.

A A A A indicate the form of the cast-iron framing of the machine, upon which all the working parts are carried, as also the work-table and its motions. This framing is formed of a single casting, and is fixed by three strong bolts upon the sole-plate T T, intended to rest solidly, and without any fastening, upon the floor of the workshop.

On the upper portion of the main frame a strong bracket is cast, which serves to carry the outer ends of the cone-spindle *b*, and back-speed spindle of the machine. Upon the spindle *b* is the driving-cone B of three speeds, the spur-wheel C, and the bevel-pinion D. The speed-cone B is loose upon the shaft, and only communicates motion to it by means of the spur-wheel C, which is keyed upon the spindle, and to which the cone *can be attached* by a stud-pin and nut at *c*. This wheel geers with the pinion E, on the same spindle which carries the wheel M; this in turn geers with the pinion N, which is fast upon the end of the cone B, but runs loose upon the cone-spindle *b*.

This arrangement is in every respect the same as the ordinary back-speed of a lathe, and serves the same purpose. Supposing the back-speed removed, the cone being driven by its belt causes the spindle *b* to revolve, in consequence of its attachment to the fast-wheel C, and at the same time gives motion directly to the bevel-pinion D on the end of the spindle. This again geers with the bevel-wheel F, on the drill-spindle G G, which is free to slide vertically in the eye of the wheel, while at the same time it is prevented from revolving in it by a sunk feather. By this means three different degrees of quick speed may be communicated to the drill. But let the back-speed be in geer, as represented in the drawing, Fig. 1122, and let the stud-pin *c* be removed, and the cone thereby loosened from its attachment with the wheel C, the motion being communicated to it will not drive the shaft *b*, directly as before, but the pinion N being fast upon it will give motion to the wheel M, upon the same spindle with the pinion E. This last will therefore make the same number of revolutions as M, but being less in diameter will convey a proportionally less velocity to the wheel C, with which it geers, and which it consequently drives with a speed diminished in the ratio of the geering pairs. Now the wheel C being fast on the shaft *b*, conveys through it to the bevel-pinion D the same diminished speed, and this again to the drill-spindle G G. This reduced speed may, of course, be varied as before, by placing the belt on one pulley or other of the speed cone.

Behind the pinion E there is a recess cast in the framing, to allow it to enter when the back-speed wheels are to be thrown out of geer; and it may be remarked that this speed-geer is only required to be in action when the machine is employed in boring holes of upwards of an inch and a half in diameter.

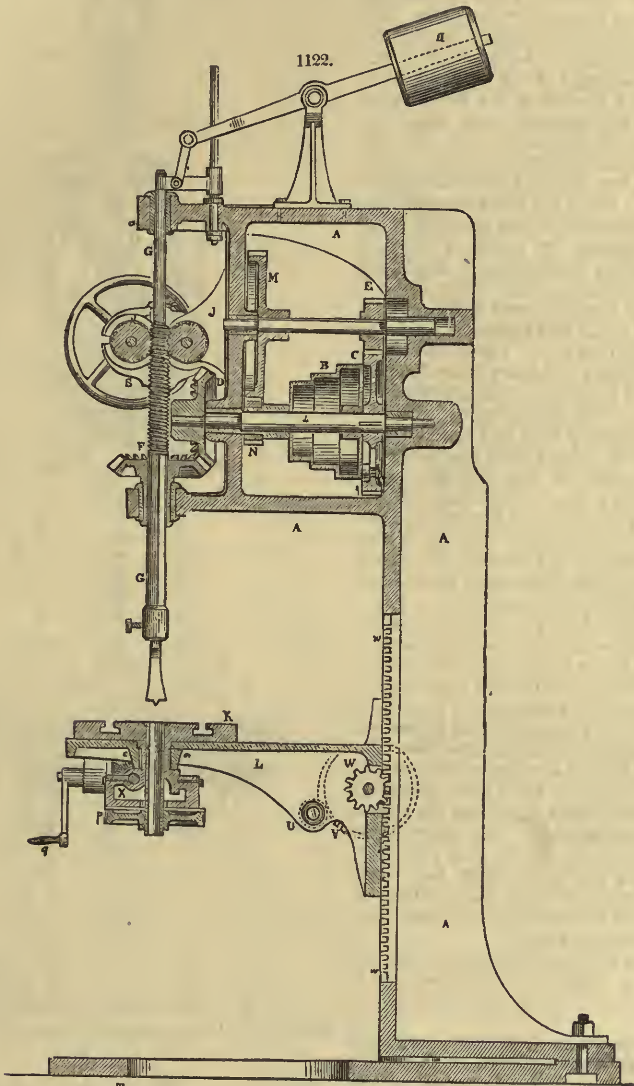
The wheel F is cast with a long hollow boss, which is turned and fitted into a brass collar in the lower branch of the carrying-bracket, as seen in Fig. 1122. This collar is kept in its place by a cover bolted over it, as shown in Fig. 1123.

As already observed, the drill-spindle passes through the wheel F, which thus serves as its lower guide. The upper end of the spindle is at the same time guided in a collar similarly fitted into the

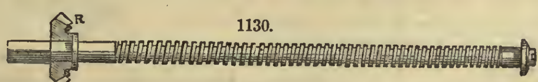
upper branch of the bracket at *a*, and is thus guided vertically in ascending and descending. (In the drawings it is shown at the lowest limit of its travel.)

To the top of the drill-spindle is attached the back-weight H by a jointed lever and guide link, which embraces the top of the spindle and moves upon a vertical guide-rod, kept firm in its place by having its lower end held by a screw-nut, in a socket cast in the bracket, in the manner of a bolt, a ruff forged upon the lower end of the rod answering to the head of the bolt.

1122.



1130.



SCALE.—12 feet=7 inches.

The drill-spindle is itself screwed towards the middle of its length; it is there embraced by two screw-wheels J J between which it turns, and which serve the purpose of a nut to feed down the spindle in the operation of drilling, by an arrangement which will presently be described.

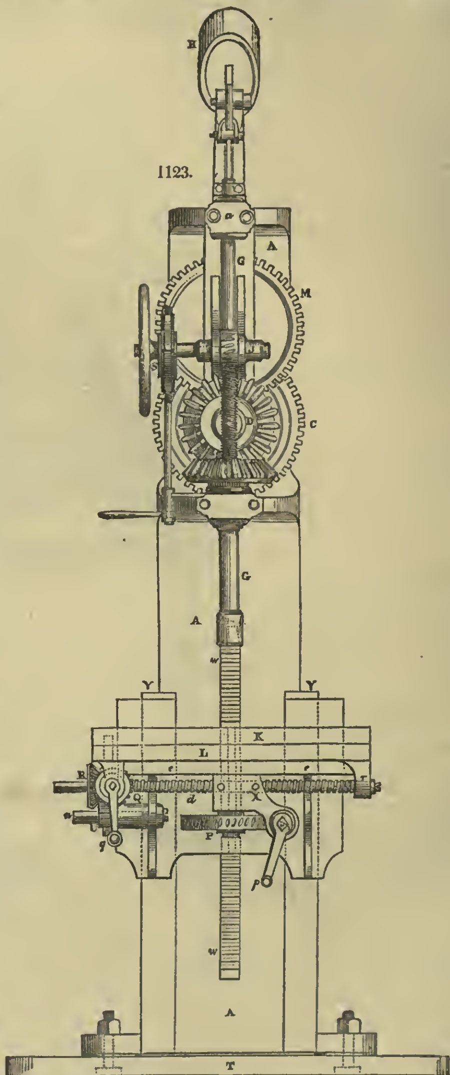
K, is the table upon which the article to be bored rests, and to which it can be firmly held down and adjusted by T-headed bolts and glands in the usual way, when thought necessary. The table, it will be observed, is recessed and grooved to receive and retain the T-heads of the holding bolts, as fully shown in the horizontal section, Fig. 1124, and the side view, Fig. 1125. When the article is much smaller in area than the surface of the table, the fixing bolt-head can be entered at any convenient point

of the surface by the recesses k k, and slid forward until it passes below the projecting ledges of the recess, where it is retained.

The common mode of running two sets of inverted dovetail-grooves at right angles to each other lengthwise and across the table, seems, however, preferable to this mode of partially recessing the surface.

The table is itself supported upon the sole of the large carriage-bracket L, which is strengthened by two strong ribs cast on its under side. This bracket is attached to the framing A A by two pieces Y Y, which are bolted upon it and planed true to the angle of the inverted bevel edges of the broad face-rib of the main frame. These edges are also planed where they meet the oblique faces of the pieces Y Y. By this means a joint is formed which allows of a sliding motion vertically, but does not admit of any deviation laterally. When the slides become loose by wearing of their surfaces, the pieces Y Y admit of being tightened by means of pinching screws fitted against them through continuous snugs cast on the bracket. This arrangement is fully explained by Figs. 1124 and 1125.

1123.



This bracket is raised and depressed by means of a hand-crank applied at u. Upon this spindle is fixed the spur-pinion U, (shown in combination by Figs. 1122 and 1123, and separately by Figs. 1132 and 1133.) This pinion geers with the spur-wheel V, (partially seen in Figs. 1122 and 1123,) on the same spindle with the pinion W, Fig. 1122, which geers in turn with the rack w set into the frame A A of the machine, so as to form an integral part of it. By turning the hand-crank on u, it is thus manifest that the motion will be transmitted to the bracket, which will either be raised or lowered according as the crank is turned in one direction or the other.

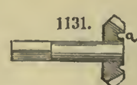
The table K has a double movement upon the sole of the carriage-bracket; one movement is circular and the other is in the direction of the length of the table. The circular movement is effected by means of the hand-crank p upon the spindle y, carried in bearings formed on the box X, which thus serves as a centre of rotation. On the spindle y is formed a worm, which, geering with the worm-wheel P on a stud projecting downwards from the table K, conveys the motion of the handle p to the table. This arrangement is well shown separately by the plan Fig. 1127, and the elevation Fig. 1126. This last corresponds to the view given in Fig. 1123. Opposite views of it are also given in Figs. 1122 and 1125, the last on an enlarged scale.

It will be observed that the stud on which the worm-wheel P is fixed, is cast hollow, and is fitted into the table K by a key at o, shown in Fig. 1124.

1133.

1132.

1131.

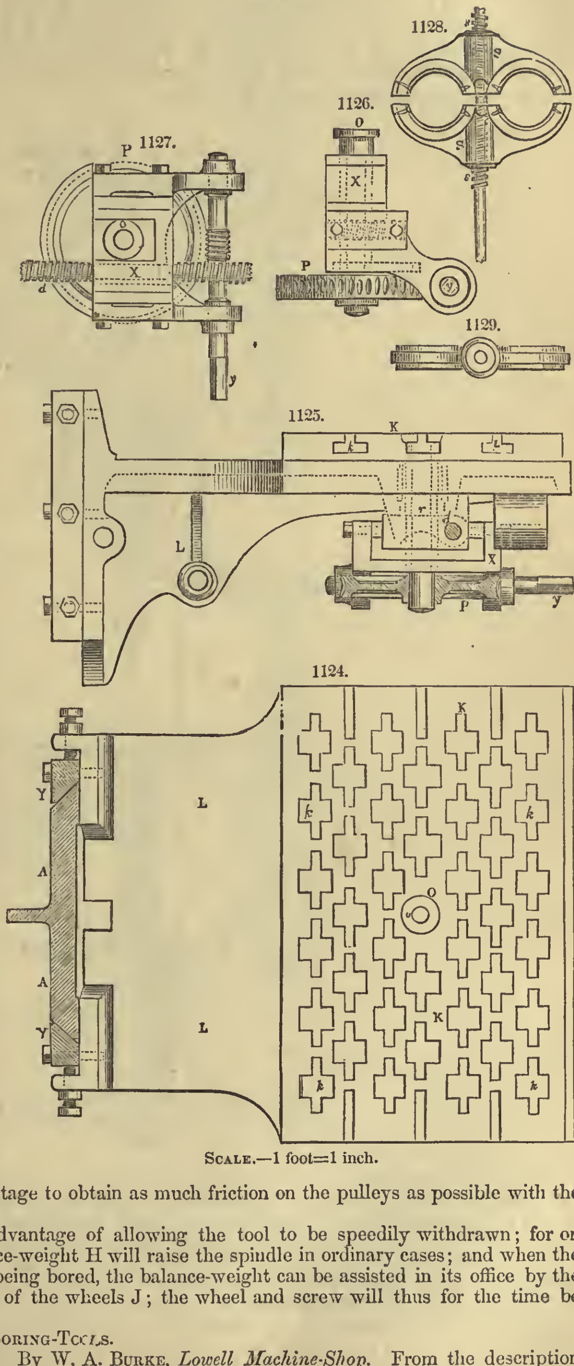


SCALE.—12 feet=7 inches.

The lateral movement of the table is effected by a different arrangement. A recess in the form of a parallelogram is cast in the sole of the carriage-bracket L, with projecting ribs $e\,e$ on its under side to serve the double purpose of giving strength to the sole-plate and of forming guides against which the cover of the travelling-box X may slide, the surfaces in contact being planed true for that purpose. The motion is communicated by means of the handle q, (Figs. 1122 and 1123,) upon the spindle which carries the bevel-wheel Q, (seen in Fig. 1123, and partially in Fig. 1122; also separately in Fig. 1131;) this spindle has its bearings attached to the bracket L, and its wheel-geers with the equal wheel R upon the end of the screwed spindle d, which has its bearings r also attached to the sole-plate of the carriage-bracket, and works in a long nut or internal screw formed in the cover of the travelling-box X, (see Fig. 1123 for the general arrangement, also Figs. 1125, 1127, and 1130.) By turning the handle q it is thus clear that the piece which serves the purpose of a nut on the screw d, will be carried along in the direction of the length of the screw; but the nut being attached to the table K, the whole will be moved simultaneously in that direction.

By means of these two motions any point of the table K can be brought under the axis of the drill and by means of the vertical motion it can be placed at any convenient height.

The feed of the tool during the operation of boring is obtained, as before stated, by means of the two screw-wheels J J, by an arrangement of parts which forms the chief novelty of this machine. On the axes of these wheels are placed two pulleys, the circumferences of which are embraced by the friction collars S S, (shown in combination in Figs. 1122 and 1123, and separately by Figs. 1128 and 1129.) The bearings of the axis being attached to the framing A A of the machine, it is obvious that the machine being in motion, if the pulleys be prevented from revolving, the wheels J J will likewise remain at rest; but the screwed part of the drill-spindle revolving between them, they will act as a stationary nut, and cause the spindle to descend through a space equal to one thread of its screw during every revolution. Again, suppose the pulleys and wheels free, the screw of the spindle, instead of descending will simply cause the wheels J J to revolve on their axes through a space equal to one tooth during every revolution of the screw. Now, between these extremes any amount of feed or downward motion of the drill-spindle may be obtained by simply retarding the motion of the wheels, by means of the friction-collars S S, which embrace the small pulleys on their axes; for the friction of the collars being less than to prevent entirely the motion of the wheels, and, at the same time, greater than to allow a tooth to pass during a revolution of the spindle, a downward motion of the spindle must thus be produced equal to the retardation of the pulleys produced by the friction-collars. Thus, any degree of feed can be produced at pleasure by the contrivance of the friction-collars shown separately in Figs. 1128 and 1129. These collars are formed in two halves S and S, with bosses joining the segments, pair and pair; these bosses are reverse screwed internally, the thread of the one to the right, and that of the other to the left; and being placed on a rod *s s* correspondingly screwed right and left, they are made to approach or recede according as this rod is turned to the right or left, and to embrace more or less closely the surface of the pulleys upon which they are placed. This screwed rod is prolonged, and has a handle placed on its under end, by which the required degree of friction can be adjusted at pleasure, (see Fig. 1123.) The friction-collars are lined with copper, for the purpose of increasing the friction; for it is manifestly of advantage to obtain as much friction on the pulleys as possible with the least amount of pressure.



SCALE.—1 foot=1 inch.

This arrangement has also the advantage of allowing the tool to be speedily withdrawn; for on slacking the friction-collars the balance-weight H will raise the spindle in ordinary cases; and when the tool has a hold in the hole which is being bored, the balance-weight can be assisted in its office by the hand-wheel placed on the axis of one of the wheels J; the wheel and screw will thus for the time be converted into a pinion and rack.

DRILLING-MACHINES. See BORING-TOOLS.

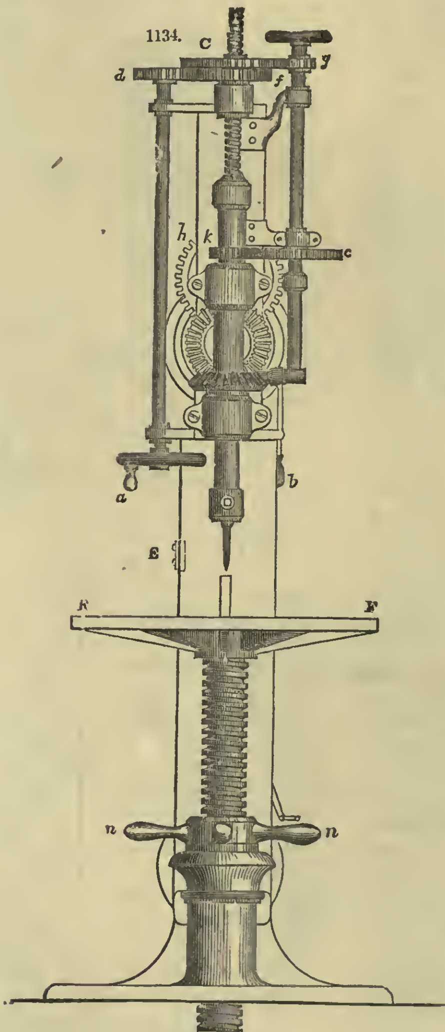
DRILLING-MACHINE, *Vertical*. By W. A. BURKE, *Lowell Machine-Shop*. From the description already given of Whitworth's drilling-machine, it is needless to enter minutely into a detailed descrip-

tion of this very complete machine. Fig. 1134 is a front view of the machine. Fig. 1135 is a side elevation in the plane of the axis of the driving-cone and work-table.

The frame of this machine is of iron, cast in one piece, having a broad base or sole-plate at the bottom, by which it can be properly fastened to a stone or other suitable foundation.

Fig. 1135. N is the loose and fast driving-pulleys. D, on the same shaft, is a set of cone-pulleys which communicate the power by a belt to a corresponding set of cone-pulleys. T, near the top of the frame *r r* and *h h*, are geers for decreasing the motion of the drill, similar to the back geering of turning-lathes. Upon the shaft which carries the cone-pulleys T is a bevel geer, which drives another bevel geer made fast on the spindle-tube B. This tube runs loose in gun-metal bearings, and carries round the steel spindle to which the drilling-tool A is attached, by means of a long splice in the spindle and a corresponding groove in the tube.

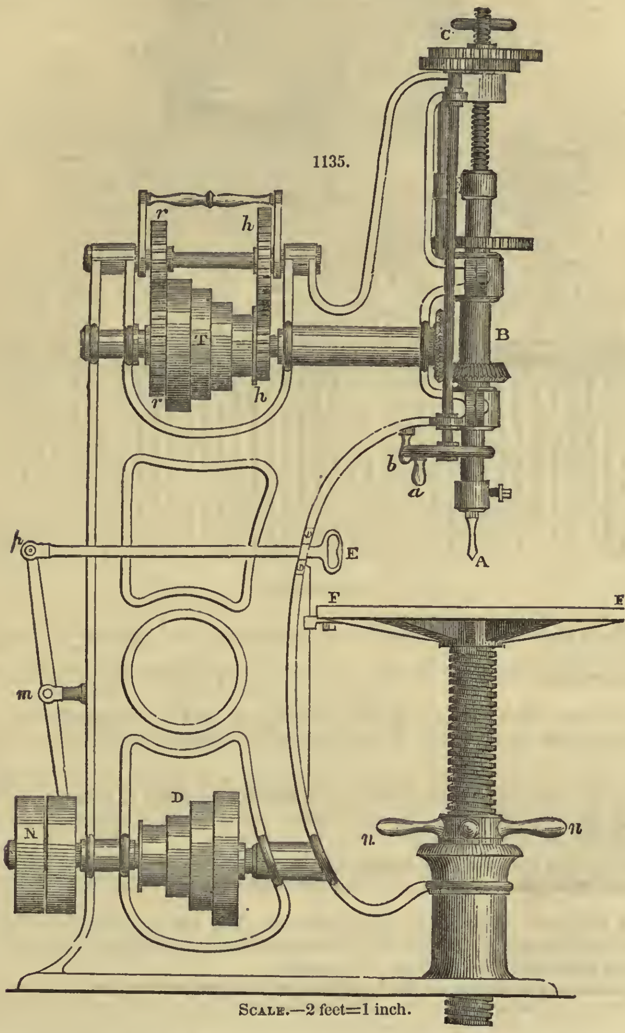
1134.



The machine is adapted to feed the drill down by hand, or it can be made self-acting. When feeding the drill by hand, by turning the hand-wheel *a*, Fig. 1134, motion is communicated through the geer *d* to the geer *f*, which is fastened to a revolving nut which moves the feeding-screw up or down as wanted. The screw is prevented from turning round by means of a coupling which connects the screw to the spindle, and slides on a parallel rod lying back of the screw. When the feeding is to be self-acting, the geer *k*, which is fastened to the tube B, drives the geer *c*, fastened on its shaft by a splice and groove. This shaft admits a motion upward sufficient to raise the geer *g* on its upper end from driving *c*. When the feeding is done by hand, this upward motion is produced by moving the handle *b*, which is on the end of a bell-crank lever jointed to the end of the shaft. By means of friction-collars each side of pinion-geer *g*, pressure to which is given by a small hand-wheel, the quantity of feed can be raised so as to suit the size of the hole to be drilled. The circular table F F on which the work to be

drilled is laid, is prevented from turning round by means of a stop which slides on a rib cast on the frame. *n n* are handles projecting from a nut, which, on being turned, elevates or depresses the table F as may be required. E, Fig. 1135, is the handle to the shipper.

1135.



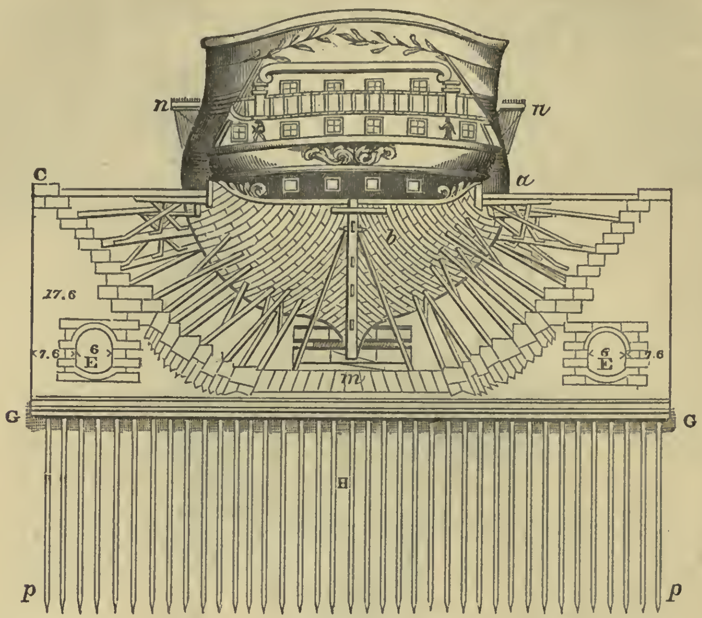
SCALE.—2 feet=1 inch.

A machine of gigantic dimensions has been constructed by Nasmyth for the Great Western Steam Navigation Company.

In this machine, the entablature carrying the upper end of the boring-bar is supported on two massive pillars of masonry, placed one on each side of the boring-bar. The feed motion of the cutters is novel and ingenious in the extreme; it consists, primarily, of an internal screwed collar fixed on the upper surface of the entablature, and surrounding the boring-bar. A train of geering, terminating in a pinion working into a rack running down the side of the boring-bar, is attached to the latter and revolves with it. The first wheel of the train is a species of crown-wheel, its teeth being set at right angles to its axis of motion; this geers with the internal threads of the screwed collar before-mentioned, so that by this means the train is set in motion by the revolution of the bar, and the cutter-boss, which is attached to the lower end of the rack, is raised and lowered at pleasure.

Mr. Walton, of Leeds, has introduced a highly effective boring-machine, with columnar framing intended principally for boring the apertures in the tube-plates of locomotive-engines. The machine is capable of drilling a series of parallel holes on a surface of five feet square, without refixing the object under operations, the tool-holder and the table being moveable at right angles to each other. This boring-machine may be considered as a magnified drill, as the spindle is fed longitudinally, no cutter-boss being attached. The framing consists of two plain columns, coupled at the top by a suitable entablature, and carrying two other transverse beams for the support of the drill-spindle and driving-geer. The self-feeding motion may be worked by hand.

1136.



Section on *b*.

DRY-DOCK, U. S., Brooklyn. *History of the Commencement and Progress of the U. S Dry-Dock at the Navy Yard, Brooklyn.*

New York was originally selected in 1794, as one of the points for the establishment of a naval depot.

In 1826, Col. Loammi Baldwin, a civil engineer of great skill and science, examined the harbor of New York, to ascertain the feasibility of constructing a dry-dock of sufficient size to receive a ship-of-the-line.

Locations for a similar purpose were examined at Boston and Norfolk, which led to the commencement of dry-docks at both of those places in 1832, and their completion in 1836.

In March, 1835, Congress authorized an examination for a site for a dry-dock at New York, and appropriated $100,000 for commencing it.

In the following June, Col. Baldwin examined the vicinity of the Navy Yard, and reported very favorably upon the facility for constructing such a work, nearly on the site where the present dock has been built.

In March, 1841, Congress made an appropriation of $50,000 for commencing a dry-dock at New York, and in August, Edward H. Courtenay, professor of Civil Engineering at the National Academy at West Point, was appointed chief engineer of the work.

Mr. Courtenay remained in charge of the work one year, during which time there was expended the sum of $35,264.75 on the coffer-dam, and erecting workshops, and providing tools, &c., for carrying on the work.

The succeeding Congress failed to make a further appropriation for the dock, and all operations were suspended in August, 1842.

At the close of this session Congress appropriated $100,000 for the construction of a floating dry-dock at New York, if the plan should be approved of by the Secretary of the Navy.

A commission was formed of naval officers and engineers, to investigate the merits of the different plans of floating-docks, as compared with the walled stone-dock, and also to determine the best plan of a floating-dock.

They reported in favor of the walled stone-dock as the best, and the "balance" as the best of the floating-docks.

In the naval appropriation bill of 1843, Congress directed an examination of a project for constructing a dry-dock in the city of New York, on the plan of using the Croton water as an elevating power, and an investigation of the best plan of a floating-dock.

W. P. S. Sanger, the Engineer of the Bureau of Yards and Docks, was directed to examine and report on these subjects, which he did adversely to the project of using the Croton, and the "Sectional" as the best plan of a floating-dock.

In February, 1844, Hon. Henry C. Murphy, a member of Congress from Kings Co., N. Y., took up the subject with great interest and energy, and presented the matter to Congress in a very able report.

To his exertions at this time may be mainly attributed a law that was passed in June following,

directing a resumption of the work on the site and plan previously determined upon, appropriating the unexpended balance of a former appropriation, amounting to $129,100.

In August, 1844, Gen. Wm. Gibbs McNeil, formerly an officer of the army, and then a distinguished civil engineer, was appointed chief engineer, and the works were resumed in October following.

Under this gentleman's direction considerable progress was made in the construction of the coffer-dam, and the removal of the excavation, and in preparing the plans and arrangements for conducting the work.

In March, 1845, Congress appropriated $150,000 for continuing the work, and it was placed under the direction of the Engineer of the Bureau, Mr. Sanger, until February, 1846, when Wm. J. McAlpine was appointed engineer in chief.

Congress has made the following appropriations:—

March, 1835	$100,000
Do. 1841	50,000
Do. 1845	150,000
August, 1846	250,000
March, 1847	275,000
July, 1848	350,000
March, 1849	490.000
Total,	$1,665,000

The progress of the work has been much retarded in consequence of the frequency with which its officers have been changed.

In 1835, Col. Baldwin expended the sum of $5,000. From August, 1841, to August, 1842, Mr. Courtenay expended $35,264.75. From August, 1844, to March, 1845, Gen. McNeil expended $114,675.83. From March, 1845, to February, 1846, Mr. Sanger expended $115,951.81; and from February, 1846, to the present date, (October 1st, 1849,) Mr. McAlpine has expended $1,147,310.39—making the whole amount of expenditure $1,418,198.78; and contracts have been made amounting to about $250,000 more.

A description of the Location *and* Construction *of the Dry-Dock.*—The dry or graving dock is a walled basin sunk below the level of the sea, to allow vessels to float in and remain while undergoing repairs. The water is removed from the basin, and the vessel is supported by shores resting on the bottom and sides.

In many parts of the world the rise and fall of the tide is sufficient to allow the vessels to float in at high, and become dry at low tide. When the tide is not sufficient for this purpose, it is necessary to remove the water by pumping.

The tide in the harbor of New York rises four feet seven and a half inches above mean low-water. The highest tides during the heaviest gales do not exceed eight feet above this mark, and the greatest range between low and high tide does not exceed ten feet.

The government dock-yard occupies the Wallabout bay, an arm of the East River, between the cities of Brooklyn and Williamsburg, on Long Island, and directly opposite the private dock-yards in the city of New York. The bay forms a fine harbor of sufficient capacity and depth of water to receive a large navy.

The dry-dock which is just being finished, and which it is now proposed to describe, is situated on the convex side of the channel of the Wallabout, near the northwest corner of the Navy Yard. It has been chiefly excavated, but the lower end of the dock was built on the edge of the channel.

This part of Long Island is a diluvial formation, composed of a coarse, sharp, red, and yellow sand and gravel, interspersed with boulders of trap and greenstone rock, some of which are of an enormous size, and will weigh several thousand tons.

The site selected for the dock is of more recent formation. The superstratum is formed chiefly by vegetable decomposition; below this, for a depth exceeding one hundred feet below tide, is a quick-sand formed by the debris of the rocks in the vicinity, brought down and deposited with alluvial matter by the East River, which at this place is expanded to three times the width it has above and below, and the velocity of the water correspondingly reduced.

This material is an almost impalpable sand, containing a large proportion of mica. When confined and undisturbed, and not mixed with water, it is very firm and unyielding, and presents a strong resistance to penetration. When saturated with water, it becomes a semi-fluid, and is moved by the slightest current of water passing over or through it.

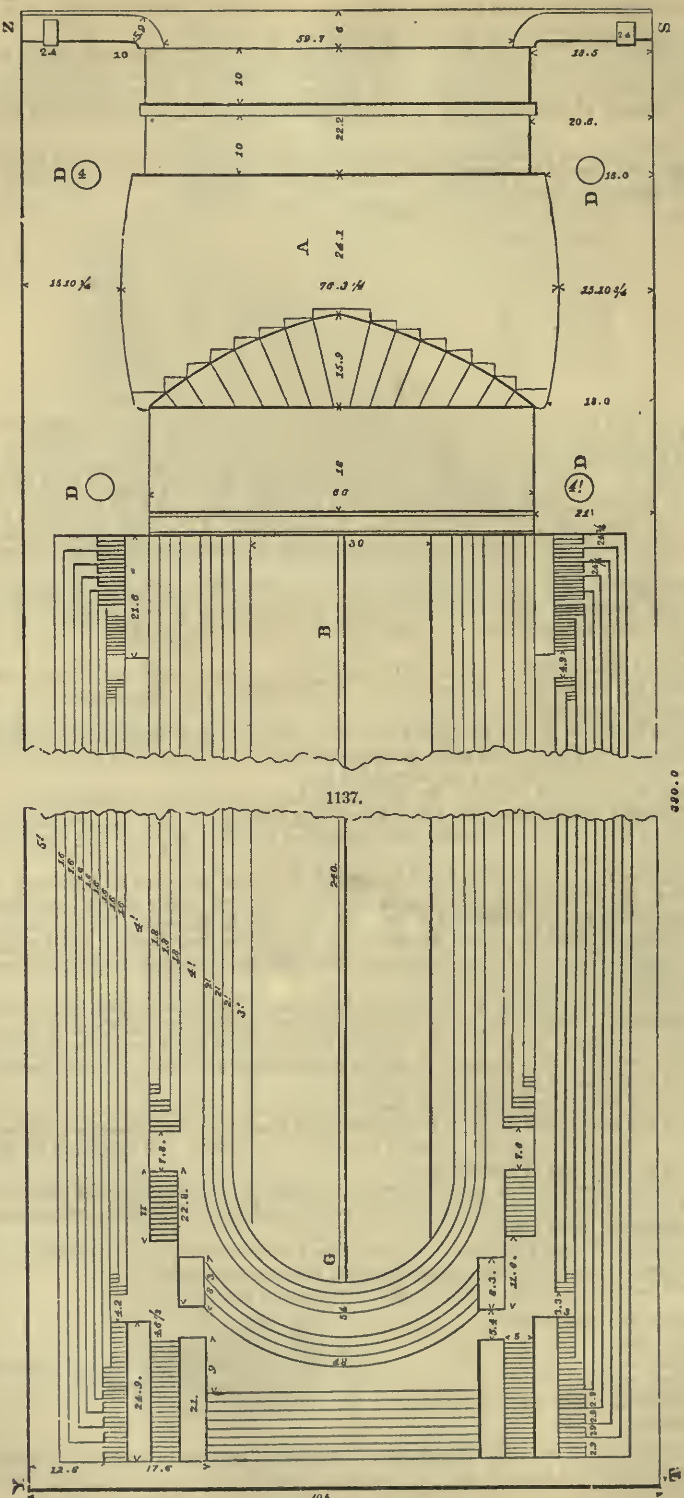
Borings were made to a depth of sixty feet below the level of the foundation, and the same material was found to extend to that depth. Small veins of coarse sand were occasionally encountered, through which flowed springs of fresh water.

It was on this material that the coffer-dam was to be constructed, to exclude the tide-waters, and a foundation prepared to sustain the enormous weight of the superstructure.

The work will now be described under the following general heads, viz:—

Dimensions of the structure
The coffer-dam.
The earth-work.
The bottom springs.
The foundation, apron, and pile-driving.
The masonry.
The gates.
The pumping engines.
The pump-well, culverts, and engine-house.
The machine and tools used; and
The cost of the work.

Dimensions of the Structure.—The pit which was excavated covered an area of over two acres at the top, and over one acre at the bottom. It was sunk about forty-two feet below the surface of the ground, and thirty-seven feet below mean high-water.



1137.

The coffer-dam in front was four hundred and seventy feet long, and from sixty to one hundred feet wide. The wings were one hundred and seventy-five feet long, and from fifteen to thirty feet wide.

A double row of sheet piling protection-timbers were extended entirely around that part of the pit which was not protected by the coffer-dam.

The foundation is three hundred and ninety-two feet long, and one hundred and sixteen feet wide.

The main chamber is two hundred and eighty-six feet long, and thirty feet wide on the bottom, and three hundred and seven feet long, and ninety-eight feet wide on the top; and by using the floating-gate instead of the folding-gates, an additional length of fifty-two feet may be obtained. The least width is at the hollow quoins, where the walls are sixty-six feet apart at mean high-water line. The least depth of the dock is over the mitre-sills, where there is twenty-six feet of water at mean high-tide. The whole height of the walls is thirty-six feet.

The Coffer-Dam.—Before the excavation could be extended below the surface of the water of the bay, it was necessary to exclude the tide, and to provide for the removal of the water which would collect in the pit.

As the excavation was required to be carried to a great depth, (thirty-seven feet below mean high-tide,) it became necessary to provide a strong and tight barrier to resist the pressure and percolations of the tide-water.

The original dam was built as follows:—

Three rows of contiguous square piles were driven entirely around the lower end of the proposed excavation, leaving two intervals of ten and twelve feet between them. These piles were secured at the top, and at the level of low-water, by horizontal wales and iron tie-bolts.

The dams were filled with the silt which was taken from the excavation.

The piles were of yellow-pine timber, thirty-five to forty feet long, fifteen inches square, and sawed to parallel sides. A portion were tongued and grooved; but on examination it was found that from the difficulty experienced in driving, the piles swerved aside, and fractured or drew out from the tongues. The wales were of oak, twelve inches square, bolted once in ten feet, with bolts two inches in diameter.

On the first trial of this dam, (in February, 1846,) it was forced inwards by a pressure of less than ten feet head of water, and by the time the excavation was taken down, so as to bring a head of thirty feet of water against the dam, the water of the bay forced its way through the sand beneath the piles, and burst into, and filled the pit.

This breach occurred in July, 1846, at the northeast angle of the dam. It was repaired, and in September following, a similar breach occurred at the northwest angle of the dam.

The first breach occurred without warning, after the workmen had left. The first indication of the September breach, was an increased flow of water in one of the bottom springs, which was situated fifty feet from the nearest part of the coffer-dam.

The water flowing from this spring had previously been fresh; it was observed to change alternately from fresh to salt, several times within a few minutes, and in less than an hour had increased to five times its former quantity, and soon after brought up volumes of the black mud which overlays the quicksand in the channel of the bay. The direction of the breach was soon developed by the sinking of the coffer-dam, some of the piles in which settled down vertically from five to six feet.

After the occurrence of these breaches, it became necessary to reconstruct a dam.

This was done with piles from ten to fifteen feet longer than had been before used. The new dam which was placed on the outside of the old one, was made from thirty to forty feet wide, so that the weight of the earth would break down into any passages which the water might form through the loose soil on which the dam rested.

In the narrow dams it was found that the earth adhered to the timber on the sides, and that the cavities formed by the filtering of the water, became very large before any of the earth broke down to fill them.

The new dam was filled with gravel, containing loam, sand, and coarse stone. The gravel was filled in water thirty feet deep, and to prevent the stone from separating from the other materials in the descent, it was discharged in large quantities from boats with drop bottoms which contained one hundred tons. A row of piles was driven on the inside of the original dam, to a depth from twelve to fifteen feet below the proposed level of the foundation. A heavy bank of coarse gravel was filled on the inside of the dam, extending up to the lines of the foundation.

The material on which the dam rested, was so unstable, that although the piles penetrated it from fifteen to twenty-five feet, yet the dam continued to yield to the pressure, and was only sustained by the closest watchfulness, and the most prompt application of remedies.

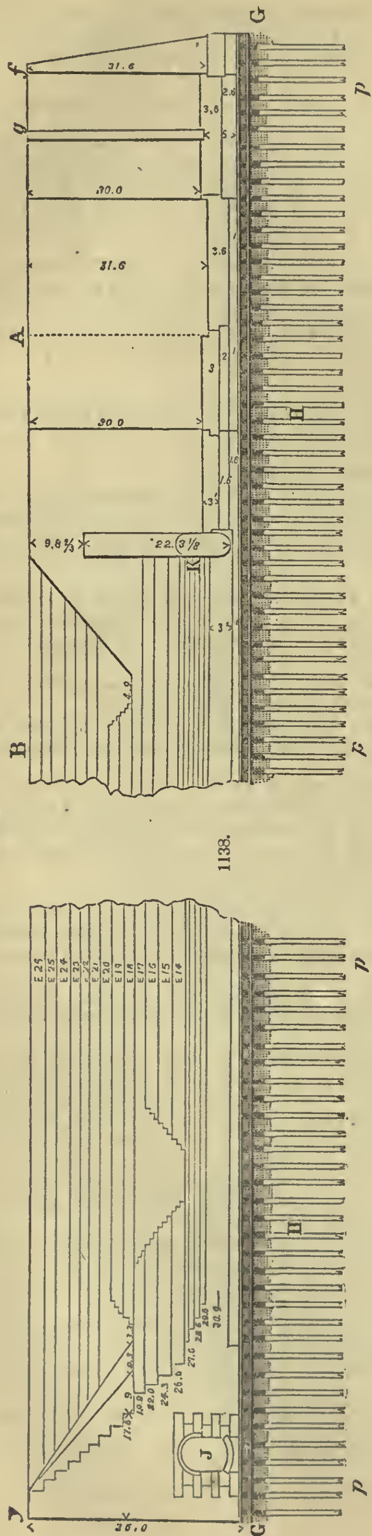
As long as the excavation was in progress, there was no opportunity to obtain any support from the inside, and whenever it could be done, chain cables were attached to the dam, and secured to mooring blocks on the shore. These cables, made of iron two inches in diameter, were repeatedly broken. On one occasion six of them broke during one night.

The removal of the excavation adjoining the dam was not effected any faster than it could be followed up by the foundation piling, and this was done in trenches, leaving abutments of earth on each side. Timber shores were extended from the foundation to the dam, before the intermediate sections of earth were removed.

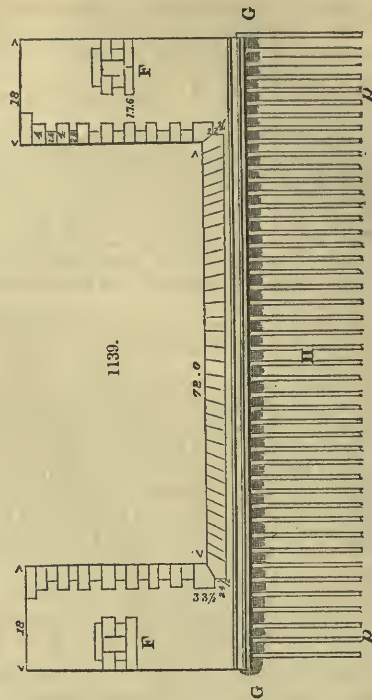
In like manner the rear work of the masonry on the foundation was at first laid in sections, and braces extended from it to secure the dam.

The thrust upon these braces at one time was so great, that it moved a mass of masonry exceeding two hundred and fifty tons weight.

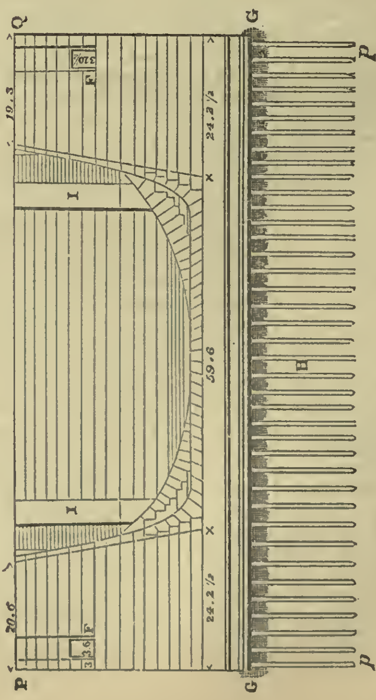
The earth in the dam was subject to a continued waste on the side adjoining the bay, by the action



1138.



1139.



1140.

of the water flowing through the joints of the piling; but this waste gradually decreased, until it became of but little importance.

The whole number of piles driven for the coffer-dam is 3,504.

Earth Work.—That part of the excavation of the pit which was above the level of low-water was taken out before the coffer-dam was constructed. There was also about ten feet of the earth below the water dredged. The semi-fluid state in which the material was found after the water had been pumped out of the pit, rendered its removal very difficult and tedious.

When the excavation had been extended to a depth within about six feet of the level proposed for the foundation, springs of fresh water burst up through the crust, and discharged very copiously.

It was found necessary to use tight vessels in removing the earth, because when the water mixed with the sand, it became so fluid, that it would escape almost wherever water would flow. Boom derricks were used to some extent in the removal of the excavation from the pit. Dumping tubs were suspended from the end of the boom, which, when filled, were hoisted to the level of the ground by steam-power. The chief part of the excavation, however, was taken out in cars, which, when loaded, were hauled up the inclined planes by steam-power. These cars possess an advantage over the earth-cars commonly used for this purpose, as they were hung very low, not above thirty inches from the top of the ground to the top of the box. This saves the labor of shovelling the earth twice to load the cars. They dumped between the axles and between the rails.

The walls were backed up with gravel, as fast as the masonry was laid.

Puddle walls were extended from the sides of the masonry to cut off the passage of water along the walls.

The Bottom Springs.—These were met with, as before stated, when the excavation had nearly reached the level proposed for the foundation, and were the cause of the greatest difficulty which was encountered in laying down the foundation.

The water which flowed from them was entirely fresh, and evidently came from a source higher than the tide-water. The temperature was 53° in January, and 55° in August. The temperature of the water in the bay at the same time was 43° and 46°, and that of the atmosphere was 40° and 90° at the same dates. The flow was not affected by the rise and fall of the tides.

The strata through which the springs flowed, were evidently at a great depth (not less than thirty feet) below the foundation, and the veins of water of the different springs, even those contiguous, had no connection with each other.

The difficulties caused by these springs did not proceed from the mere flowing of the water; but this, as it came up, brought with it large quantities of sand, so fine and impalpable, that it would insinuate itself through the smallest interstices, and if allowed to flow in this manner, would soon have endangered the surrounding works. Nor could the water be checked with safety, as the pressure was sufficient to raise the foundation, however heavily it could be loaded. It became necessary, therefore, to provide for the flow of the water, and at the same time check the removal of the sand.

After repeated trials, it was found that the level of the outlet of the springs could be raised to a height which would not disturb the foundation, and would yet be sufficient to check the velocity of the water so much, that it would not disturb the sand through which it flowed.

The largest spring discharged (in 1848) ten gallons per minute. When the water was allowed to flow at a level, twenty-six feet below low-water, it discharged thirty-eight gallons per minute, which contained twenty-seven ounces of fine sand; at a level twenty-two feet below it discharged thirty-three gallons, containing seventeen ounces of sand; at a level nineteen feet below, it discharged twenty-two gallons, containing four ounces of sand; and at a level seventeen feet below low-water, the water flowed unmixed with sand.

One of the most troublesome and refractory springs was encountered at, and near the pump-well, at the northeast corner of the dock.

The first evidence of its effect was the undermining and settling of the piles driven to support the pumps and engine, and rendered it necessary to change the pump-well; but the spring followed, and compelled another change of the well. The spring was driven out of the old well by filling it with piles, but it immediately burst up among the foundation piles of the dock near by. In a single day it made a cavity in which a pole was run down to the depth of fifteen or twenty feet below the foundation; one hundred and fifty cubic feet of cobble-stone were thrown into this hole, which settled ten feet through the night, and fifty cubic feet were thrown in the following day, which drove the spring to another place, where it undermined and burst up through a body of concrete two feet thick. This new cavity was repeatedly filled with concrete, leaving a tube for the water to flow through, but in a few days it burst up in a new place, where it soon undermined the concrete, and even the foundation piles, so that they settled from one to three inches. These piles were thirty-three feet long, and had been well driven by an average of seventy-six blows from a hammer weighing two thousand two hundred pounds, falling thirty-five feet at the last blow, which did not move the pile over half an inch.

These alarming results rendered paramount the adoption of the most thorough and speedy measures to prevent any further injury from this source. Accordingly, as many additional piles as could then be put in the space were driven, and those put in before were then driven from eight to twelve feet lower, by means of followers. The old concrete was removed to a depth twenty inches below the top of the piles. An area of about one thousand square feet around the spring was planked; a floor of brick was laid in dry cement; and on that another, also of brick, was set in mortar, made of Roman cement; the space was next filled with concrete, and the foundation completed over all in the usual manner, and with the greatest dispatch. Several vent-holes were left through the floors and foundation. After a few days' interval, when the cement had become well set, the spring was forced up about ten feet, at which level it ever after ran clear, and without discharging sand, and gave no further trouble.

The other bottom springs, some forty in number, have been of a like character, but the successful result obtained in the treatment of that above described, led to the adoption of the same plan with each, and with similar results.

Two of the springs were accidentally closed by freezing in 1848, and forced up, in one case eight hundred, and in the other twelve hundred square feet of the foundation. The rising took place between the lower timbers and the planking, lifting also the first course of the stone floor, which was from twelve to fifteen inches thick.

None of the springs were closed until the inverted arches of masonry and side walls had been laid, and the cement had become well set. The pressure on the bottom of the floor is so great that the water sweated through the joints, but did not disturb the stone.

The arrangement proposed to be accomplished, was to bring up all of the springs through the foundation, and have no pressure upon it, until the masonry was laid, and the cement had become well set; but there were many minute veins of water that were unnoticed when the foundation was laid, which exerted a force upon the cement joints, and rendered its setting very slow and tedious. These joints will require a twelvemonth or more to become impervious to the water.

The whole amount of water which came into the pit for the last year was from these springs; none leaked through the dam. The quantity which flowed in was seven hundred cubic feet per hour.

The water was removed from the pit by a steam-engine of twenty-five horse power, driving two plunger pumps of fifteen inches diameter, and five feet stroke, which discharged six hundred cubic feet per minute.

Foundation, Apron, and Pile-Driving.—In 1835, Col. Baldwin examined the proposed site of the dock by borings, which he extended in several places to a depth exceeding eighty feet below tide. These borings brought up sand and clay, and also fresh water, but touched no rock.

Col. Baldwin remarks, "Upon careful examination of these circumstances, I have no doubt a dry-dock may be safely founded at Wallabout bay. Should piling for the foundation be thought necessary, which can best be determined in the process of excavating, the piles cannot be driven deep in such soil, and will have similar or better resisting materials than those hitherto used. The construction of a dock in the yard, however, will be more difficult than either of those built before, (at Charleston and Norfolk.")

In 1842, Mr. Courtenay commenced driving the piles for the coffer-dam, and remarks, "During the progress of the work we were enabled to form a very satisfactory opinion, as to the character of the soil upon which the dock was to have been founded, and the frequent examinations then made resulted in the conviction, not only that the substratum was sufficiently firm to resist, without danger, the pressure arising from the weight of the contemplated structure, but that the nature of the soil was far better adapted than had been supposed, to resist the percolation of water through the dam."

A deposite of clay mixed with a large proportion of very fine sand, which covered the northeast portion of the pit, for several feet in depth, probably led to the favorable conclusions of these gentlemen.

The soil, as was developed by the excavation, is as has been previously described, and there is but a very small portion of clay in any part of it.

The borings which were made during the progress of the work extended to a depth forty feet below the foundation. Specimens have been preserved of the soil taken from various parts of the dock, and at every change in depth, including that which was brought up by the borings. Sets of these specimens have been deposited in various public institutions through the country.

A trial-pile was driven in June, 1846, to the depth of forty-five feet below the foundation. It was a round stick of spruce, twenty inches diameter at one end, and fourteen at the other, and forty-nine feet long. It was shod with iron, and was driven by a hammer weighing two thousand and twenty four pounds, falling from its greatest elevation, thirty-five feet.

For the first hundred blows the hammer fell but a few inches; the next two hundred and sixty blows drove the pile thirty inches in forty-six minutes; the next two hundred and sixty-five blows occupied an hour, and drove the pile from half an inch to one and a half inches at each blow; the next one hundred and ten blows in an hour, averaged one and a quarter inches at each blow, the hammer falling at the last blow thirty-four feet. The pile subsequently received about two hundred blows through the medium of a follower, which drove it an average of half an inch to each blow.

In June, 1847, a pile was driven forty-three feet by Nasmyth's steam pile-driver; and then another pile fifteen feet long, driven on top of the first, making a total depth driven into the earth of about fifty-seven feet.

The first pile was driven forty-two feet, by three hundred and seventy-three blows in seven minutes, as follows: Four blows, four inches each; eight blows, three and a half inches each; twenty-two blows, three inches each; twenty-five blows, two inches each; forty blows, one and three quarters inches each; fifty-six blows, one and a half inches each; thirty-two blows, one and a quarter inches each; sixty-four blows, one and an eighth inches each; seventy-three blows, one inch each; the last forty-nine blows, half an inch each blow.

The second pile was driven fifteen feet by two thousand four hundred blows in forty-three minutes, as follows: Thirty-three blows, three-eighths of an inch at each blow; seventy-three blows, one-fourth of an inch each; one hundred blows, one-eighth of an inch each; eight hundred blows drove it together eighty-eight inches; three hundred blows, twenty-four inches; three hundred blows, twelve inches; four hundred and fifty blows, eleven inches, and the last three hundred and forty blows together drove the pile five and a half inches.

The movements of these piles indicated the continuance of the same material to the depth which they reached; and the uniformly increasing resistance, as the pile penetrated the earth, gives very favorable evidence of the support which the piles afford, when they are thus driven to the point of absolute resistance.

The soil required very hard driving to force the pile into it, and as long as the material was undisturbed, the subsidence of the sand around it added greatly to the firmness of the foundation. Yet the springs were liable to disturb and loosen the soil around the piles, and, as has been previously stated, destroy their value as supports.

To prevent the wasting effects of the springs, it became necessary to put down the foundation in small detached pieces, and frequently to drive the piles at a level, sometimes to the extent of six feet above the proper plane. When one of these pieces was taken in hand, the earth was removed, and the concrete, timber, &c., put in without a moment's cessation; for the springs would in a few hours render the earth semi-fluid, which had before been compressed to great firmness by the insertion of the piles.

It was originally supposed that piles driven at distances of three feet from centre to centre, and twenty to twenty-five feet long, would afford a sufficient foundation to the superstructure; but from the fear that changes might take place after the foundation was put down, it was determined to drive as many piles as could be forced into the earth. The chief part of the piles were driven to the point of absolute resistance, and whenever a hammer of two thousand pounds weight, falling thirty-five feet, drove the pile for the last few blows exceeding three inches per blow, another and longer pile was driven alongside.

Great care was taken in registering the performance of all the piling engines used in constructing the foundation of the dock; the depth driven by every blow that has been given to every pile was recorded, and from these data the following averages have been made. The average number of blows received by the piles was seventy-three; the average depth driven by the first five blows is eight inches each; by the middle five blows, six inches each; and by the last five blows, one inch each blow.

The whole number of bearing-piles in the foundation is 6,539, besides 1,744 sheeting-piles, which serve also as bearing-piles. The piles are chiefly round spruce timber, from twenty-five to forty-five feet long, averaging fourteen inches diameter at the head. The average length of the piles as driven, is thirty-two feet.

The sheeting-piles were yellow-pine planks, five inches thick, and from twelve to twenty-five feet long. They averaged fifteen and a quarter feet long. They were tongued and grooved, and were driven entirely around the foundation, and four rows across the pit.

The piles were protected at the head by a band of wrought-iron, three by one inch, made of the toughest iron that could be procured. One ring would generally drive two piles before it burst, and by welding it could be used three times. Occasionally the point was shod with iron, but this did not increase the facility of driving, as the resistance was caused by the friction on the sides of the pile.

The hammers which were used were generally about twenty-two hundred pounds weight. Several were used from three thousand to four thousand five hundred pounds, with economy and effect. The arger hammer did not injure the pile as much, and it was driven in less time, and with a less umber of blows, and the same power as was applied to the smaller hammer.

The leaders of the machines were from thirty-five to fifty feet long.

The hammers were hoisted by men working with a crank, and on a treadwheel, and with horses, but chiefly by steam-power. The expense of these several methods of driving piles are in the order in which they have been stated above.

A contract was made for the use of one of Nasmyth's steam pile-drivers, and one of his best machines was imported. Unfortunately, however, the machine was constructed too light to perform the severe labor to which it was here subjected.

When in order, it produced the most astonishing results—driving the piles in less than one-third the time or expense of any other known method.

Its principle consisted in very rapid short blows, with a very heavy hammer. The steam cylinder was inverted over the hammer, to which it was connected directly by the piston-rod; and the hammer, which weighed two and a half tons, was hoisted by the stroke of the engine at every revolution. Both the cylinder and the hammer, were supported by the pile itself, to which it was loosely attached by a deep cap or band. The cylinder moved up and down, alongside a spar, and the steam was conveyed to it by a flexible tube leading from the boiler on the frame below. The hammer made about sixty blows per minute.

The concrete masonry which was used in the foundation was made as follows:

A soft mortar was made of one part of hydraulic cement, and two parts of clean sharp sand; into this was thrown five parts of stone, broken, not to exceed one and a half inches in diameter. The mass was thoroughly mixed, and immediately thrown into the place where it was required for use.

The foundation was put down in the following manner:

The bearing-piles were sawed off at a level thirty-three and a half feet below mean high tide. The earth was removed to a depth two and a half feet lower, which space was filled with concrete masonry.

The piles were capped with yellow-pine timber, twelve by fifteen inches scantling, trenailed and bolted to the piles, and laid transversely to the axis of the dock. The spaces between the timbers were filled with concrete. Yellow-pine plank three inches thick were jointed, and closely laid on and spiked to the timbers. On the top of the plank another set of timbers of the same size were laid, breaking joints with those below. The spaces were filled with concrete, and covered with plank in the same manner as the first floor.

At the foot of the dock an apron is extended for thirty feet in front, to protect the lower end of the foundation from undermining.

It is composed of timber and plank, and supported on piles, with concrete masonry between and below the timbers, in the same manner as the foundation of the dock. It is prevented from floating by trenailing and bolting to the piles, and by inserting dovetailed stone between the ranges of timbers

The tide tables which had been kept for several years at this station, showed that the level of the foundation should be placed six inches lower than had at first been supposed to be necessary It was accordingly assumed at a level which would give twenty-five feet of water on the mitre-sills at high tide, for two-thirds of the days in the year.

The Masonry.—It is believed that no modern structure in the world surpasses this, in the size of the stone, in the accuracy of their workmanship, and their durability.

The quantity of masonry which has been laid to form the walls of the dock is 23,375 cubic yards, and in the draining and discharging culverts, and the engine-house, and other masonry connected with the dock, there is 5,250 cubic yards.

All of the facing-stone has come from the Sullivan and Frankfort quarries in Maine, and New London in Connecticut.

The interior stone was chiefly obtained from the Staten Island and the Highland quarries in New York

A system of inverted arches occupies the whole extent of the lower part of the structure, and serves not only to distribute the weight of the walls over the whole surface of the foundation, but to resist the immense hydraulic pressure from beneath. The floor of the main chamber is first formed of a tapering course of cut-stone, twenty-seven inches thick at the head, and twelve inches thick at near the mitre-sill; the second course of stone is uniformly three feet thick, and the arches are extended to a height nine feet above the floor on each side. The floor of other parts of the dock is made in a similar manner.

The mitre-sills are immense blocks of granite; the key-stone is estimated to have weighed about fifty tons before it was cut; its weight is now 43,300 pounds; sixteen similar stones form the mitre-sills, and the smallest stone weighs 13,300 pounds.

The floor of the chamber is level on the bottom for thirty feet wide, and the sides are carried up in steps or altars for the convenience of shoreing the vessel and working under her bottom, as represented in Fig. 1136, where the Ohio, ship-of-the-line, is shown "in dock," sustained by the keel-blocks and shores.

The side walls are laid up with English bond, alternate courses of stretchers and headers; the stones in the alternate courses are of the same length which gives what is termed "plumb-bond," although the stones in the same course differ in length, a variety of lengths having been previously determined upon to facilitate the quarrying of the stone. These lengths have, however, been so arranged as that adjoining stone do not differ to exceed three inches, and increase and diminish gradually from the shortest to the longest stone. The difference in length is therefore imperceptible.

The courses are chiefly twenty-four inches thick, a few near the bottom being twenty-seven inches thick. The beds of the stone in the stretcher courses are from three to three and a half feet broad, and in the header courses are from four to five feet broad. The length of the headers is from three to four feet, and of the stretchers from six to eight feet. The headers are in all cases one-half of the length of the stretchers.

The smallest stone in the face exceeds three thousand pounds, and the average is about six thousand pounds. Many of the coping and other large stones exceed fifteen thousand pounds. The interior stones are also large, and will average upwards of fifteen hundred pounds.

The facing stones are all laid to a joint not exceeding three-sixteenths of an inch, and the joints are kept up full to the lines for the full depth of the stone.

The facing stones have been backed up with a course of scabbled stone cut to the same thickness, and laid to joints not exceeding half an inch.

The interior and rear of the wall has been laid up with coursed rubble, which has been so selected that either one or two courses made up the thickness of the facing course.

The following extract is taken from the contract for the granite facing:

"All of the stone must be of the most durable description of granite, entirely free from sap, stains, or seams, and obtained from quarries which may be approved of, by the Engineer in charge of the work; all of the stone which show in the chamber must be of the same color and general appearance.

"Patterns for quarrying and cutting the stone will be furnished by the government; on all the arch-stones full corners and edges will be required on the back lines of the stone; all of the stone will be delivered cut, except such stone as may be directed to be delivered unwrought, in which case they shall be quarried out without any unnecessary excess of stone, but of sufficient size to fill the patterns. The cut-stone designed for the facing of the work must be delivered with perfect edges on the show-lines, and none will be received which are in any way marred or nicked.

"The stone must be delivered in the order in which they are required for use, as far as practicable.

"In the courses of the chamber above the inverted arch, and in the other walls where an additional width of bed is permitted, the minimum size will be given in the bills, but stone of greater width will be received.

"Suitable 'lewis' holes shall be drilled in the bed, or such other surface as may be directed, to receive a lewis of sufficient size to suspend the stone with safety.

"Such cranes, machinery, and assistance as may be required for discharging the stone from the vessels at the Navy Yard, will be furnished by the government.

"The cutting which is required to be done on the face of the stone which shows, and also on the builds of the outer stone, shall be as hereinafter described as first-class work; that required on the beds, builds, and joints, shall be as hereinafter described as second-class work; that required on the rear of the front and interior stone, shall be as hereinafter described as third-class work. The beds and joints must be dressed up full to the square, and no slack joints will in any case be permitted. The cutting will be required to be done in the following manner, to wit:

"*First-class work.*—The arris must be kept clean and sharp, with fine-cut drafts run around the surfaces to be dressed. Within these lines the surfaces must be taken down fair and even with a patent hammer of eight plates. No holes or depressions of any kind that will show in the face will be per-

mitted; and the dressing with the hammer must be level and square, so as to present a smooth fair appearance.

"*Second-class work.*—A good arris must be kept; clean draft-lines must be run around the surfaces to be dressed. Within these lines the stone must be dressed down to a fair even level surface, with a common pean hammer. No depressions of any kind will be allowed within six inches of the face; none which exceed six inches in diameter, or one inch in depth, or where they shall together exceed one-fourth of the surface in which they occur.

"*Third-class work.*—Draft-lines shall be run around the surfaces to be dressed. Within these lines, they shall be pointed down to a fair even surface and finished with a pean hammer, so as to make good close work, of not exceeding half an inch joint. No cavities or depressions will be allowed which exceed eight inches in diameter, or one and one-half inches in depth, or when they shall together exceed one-fourth of the surface in which they occur."

The following extract is taken from the contract for the backing-stone.

"They shall be of a sound durable description of granite or gneiss, free from sap or seams, split out by wedges in blocks, with parallel beds and sides; at least three-fourths of the bed, and one-half of the build, must have a fair level bearing-surface; the vertical joints must be split down at right angles to the bearing surface of the stone; the stone must all be drilled on the top bed to receive a lewis of such size and form as shall be directed. The dimensions of the stone must in no case be less than the following: viz., length, two and one-half feet; width, one and one-half feet; thickness, eight inches. And no stone larger than the following will be received: viz., length, eight feet; width, four feet; thickness, two feet; and the stone must average not less than twelve cubic feet."

The whole of the masonry was laid in mortar made of one part of Hydraulic cement and two parts of clean sharp sand; the cement used was from the celebrated "Lawrence and Newark" manufactories, at Rosendale, New York.

It was required to be fresh ground, very fine and lively, and transported under cover in barrels, containing about three hundred pounds; the barrels to be made of seasoned air-tight staves, and to have twelve hickory hoops, and each barrel to be well papered. Every tenth cask was subjected to the following tests: *first*, mixed up in flat cakes of two inches diameter, the moisture carefully dried from the surface by means of blotting paper, until it was set enough to bear one-fourth of a pound weight on a wire of one-twelfth of an inch diameter, and then put in water, where, after the lapse of not exceeding five minutes, it should bear one pound on a wire of one-twenty-fourth of an inch diameter.

Second, a similar-sized cake, after the lapse of five days' insertion in water, was required to bear a wire of one-twenty-fourth of an inch, loaded with fifty pounds.

Third, two bricks united by cement and put in water five days, must resist one hundred pounds before separating.

No cement was used until after it had stood the above tests. They were made with water at a temperature of 70°. The mean of a large number of these tests is as follows:

The time to dry in air, to bear one-fourth pound on a wire one-twelfth inch diameter, was 8 minutes.

The time to set in water, to bear one pound on a wire one-twenty-fourth inch diameter, was three and one-fifth minutes.

Force required to thrust a wire one-twenty-fourth inch diameter, through cakes of cement two inches diameter, and three-fourths of an inch thick, after being immersed in water 24 hours, 65 pounds.

do.	do.	48	"	70 "

do.	do.	15	days,	155 "
do.	do.	50	"	390 "

The joints of the whole masonry have been pointed up in the following manner: Cement and sand were put in an iron mortar slightly moist and made nearly into an impalpable powder; this was driven into the joint to the depth of an inch by an iron caulking tool, and the upper surface rubbed with a steel tool until it became very hard; in a few days this pointing was nearly as hard as the adjoining stones.

The masonry of the dock was laid up in an unprecedented short time. The first stone was laid May 12, 1847, but the foundation was not entirely completed until June, 1848. The first coping-stone was laid July 4, 1849, and the whole work completed during that season. This dispatch was owing to the systematic arrangements of the various operations, and to the number and capacity of the machines used in the construction. On the completion of the work it was found that there were no stone left on hand.

The prices which have been paid for the stone used in this work are as follows:

For the granite coping, hollow quoins, and other expensive stone, sixteen dollars per cubic yard. For the plain facing-stone, ten dollars; for the second class, nine dollars; and for the rubble stone, five dollars per cubic yard. For the fine cutting on the hollow quoins, checks, etc., one dollar per superficial foot; on the facing stone, forty cents; for the second class of cutting on the beds and joints of the facing stone, twenty cents; and for the third class of dressing on the interior stone, twelve cents per superficial foot.

The weight of a cubic foot of the several kinds of granite, sienite, and gneiss, used on this work is as follows: Sullivan, Frankfort, and Seal Harbor, 168 pounds; Blue Hill, 165; Quincy, 169; Millstone Point, 170; Breakneck, 169; Staten Island, 186; and Kips' Bay, 172.

The Gates.—The folding gates are similar to those used in canal locks, though of much greater dimensions. Such gates have usually been built of wood, though a few docks in Great Britain have them made with cast-iron frames, and covered with oak or sheet-iron.

The low temperature of the atmosphere in this climate renders the use of cast-iron dangerous where it is subject to violent concussions; to avoid this objection, Mr. McAlpine was induced to arrange a gate

made of wrought-iron, on an entirely original plan; they are the first iron gates which have been built in this country. They are made as follows:

Two leaves are to be erected so as to turn on the quoin posts, and secured to the masonry of the dock by steps and straps, and arranged to be worked by capstans in the walls, from which chains are extended to open and close the gates.

The frame of each leaf is composed of a series of horizontal curved bars of wrought-iron, bolted to the quoin and mitre posts, and covered on the outer side by a sheathing of boiler-plate, riveted and secured together by angle-iron.

The outer extremity of each leaf is supported by two rollers traversing on circular tram-plates, laid on and secured to the floor of the masonry.

The quoin-post is a cylinder of cast-iron. The mitre-post is made of wrought-iron, and a buffer of oak inserted where the two leaves come in contact. A similar buffer is inserted at the bottom of each gate where it comes in contact with the mitre-sills.

There are two valves in each leaf for the passage of water to and from the chamber of the dock. Each leaf is thirty-eight feet three inches long, and thirty-one feet high, curved on a radius of seventy-six feet seven inches on the outside of the gate. The gate is twenty-six inches wide at the quoin-post, and twenty-two inches wide at the mitre-post. The quoin-post is turned and planed to fit the quoins and collar-straps.

The horizontal bars are made of plates of wrought-iron, twenty-two inches wide and three-fourths of an inch thick, curved to suit the form of the gate, and made up alternately of three and four plates to each bar, and secured at the joints by splicing-plates.

The sheathing is made of boiler-plates, from ten to fourteen feet long, and two to four feet wide. The bottom courses are five-eighths of an inch thick, and they gradually decrease in thickness, and are one-quarter of an inch thick at the top of the gate; they are secured to the horizontal plates by means of angle-iron riveted to each. The horizontal joints are lapped, and the vertical joints are butted, and riveted, and chipped, and caulked, so as to be water-tight.

The mitre-post is made up of a plate of iron (welded) thirty-one feet long, twenty-two inches wide and one inch thick, set upright, with side pieces secured by angle-iron; the whole secured to the horizontal bars by shelf pieces of angle-iron.

The valves are made of cast-iron and set in a cast-iron frame, bolted to the bars of the gate. The valves are opened by screws placed on top of the gate.

The rollers are of cast-iron, eighteen inches in diameter, and set in a frame with a long rod and screw, by means of which the extremity of the gate may be raised at pleasure. On the top of the gate is placed a foot-walk, supported by iron bars, and a hand-rail of wrought-iron.

The capstans are geered, and the chain drum is provided with an ingenious arrangement for laying the chains which are extended to open and shut the gates.

India Rubber is inserted in the buffers.

The whole surface of the gates is painted, to protect it from corrosion.

The horizontal bars were originally designed to be welded in one bar and to be made of iron one inch thick, and the bars at the bottom of the gate placed twelve inches apart.

Some doubt having been expressed whether such a bar contained the requisite strength, a model bar of the same form and length proposed was made of four plates of iron, twenty-two inches wide and three-fourths of an inch thick, with lapping plates over the joints three feet long. This bar was first tested by loading it, with the ends secured and resting against abutments.

A weight of 92,000 pounds was put on the middle of the bar, which deflected it two inches; the yielding of the frame prevented any further weight being applied, but it was subsequently tried without abutments, and deflected three inches with 50,000 pounds; six inches with 65,000 pounds; ten inches with 71,000 pounds, and broke with 75,299 pounds; the fracture being a rent near the middle, extending up from the lower edge six inches.

For drawings and descriptions of the *floating gates* or caisson, see Gates, and for the machinery for clearing the docks from water, see Pumping Engine.

The Machines and Tools used.—A steam-engine, with a cylinder of fifteen inches diameter, and four feet stroke, was erected to drive the temporary pumps used for draining the work during its progress.

Two other steam engines, one of twelve and the other of five horse power, were used at times during the construction of the work. These engines were all fitted up with winding-drums, by which power was conveyed to the several machines.

The mud was hoisted out by tubs suspended from the booms of the derricks and by cars moving on inclined planes, which were elevated by means of a rope leading to the winding-drums of the engines. In a like manner the hammers of the piling-machines were elevated, and heavy stone were hoisted and lowered on the cranes and derricks.

Grindstones, saws, planing and groving and screw-cutting machines were also driven by the surplus power of the engine. The edges of the flooring-plank, and the grooving and tongueing of the sheet-piles were all done by machines driven by steam-power.

The drawings of some of the most useful of these machines will be found under the several heads of "stone-setting machines," "lewis," "crane," "derrick," "piling-machine," "stone jack," "pumping-engine," where a full description of them will also be found.

It remains only to state how these machines were applied. The stone were chiefly transported on cars; lines of railroad encircled the pit, from which branches led to within reach of each of the laying-derricks, the piling-derricks, and the discharging cranes. The stone were hoisted out of the vessels with the cranes worked by steam-power, and loaded on cars and transported to the stone-cutters' sheds or piling-derricks, where they were assorted and stowed away. Thence they were taken as required by the laying-derricks placed around the margin of the pit. The discharging-cranes were cheap machines. The piling-derricks were chiefly the old excavation-derricks refitted.

The Cost of the Work.—The amount which has been expended to the 1st of October, 1849, is $1,418,198,78. This sum has been classified under the following heads of expenditures, viz.:—

Offices	$69,418 17	Culverts and well	32,485 74
Coffer-dam	206,378 36	Temporary drainage and steam engine	105,139 07
Earthwork	149,802 58	Workshops	104,293 23
Foundation	127,250 03	Miscellaneous	6,566 41
Masonry	600,569 84		
Gates	16,295 35		$1,418,198 78

It is estimated that the sum of $420,000 will be required to finish the work; but in these amounts are included the value of machines and tools, the cost of constructing a machine-shop, and grading and levelling the Navy Yard, which are inappropriately charged to the dock, and which, if deducted, would make the cost $1,750,000.

Description of the Drawings. Fig. 1137 shows a plan of the masonry. The entrance to the dock is at S Z; near by is shown the groove into which the caisson or floating-gate is sunk. D D D D represent the four capstans which open and close in the two folding-gates. G B is a drain sunk below the level of the floor of the chamber.

Fig. 1138 represents an elevation of the walls, and also of the timber and pile foundation. The entrance to the dock is at *f*, the groove for the floating-gate. At A is the recess to receive the wing of the folding-gate when open. B to *y* represents the chamber in which the vessel is received. At K is the gallery leading to the exhaust culverts running through the walls, a section of which is shown at J. *p p p p* represent the piles which support the structure, on the top of which are shown the timbers and plank. In Fig. 1139 is shown a section of the walls through the point marked A on the plan and elevation, being the recess to receive the folding-gates when they are open. The culvert passages which are used to fill the dock are shown at F.

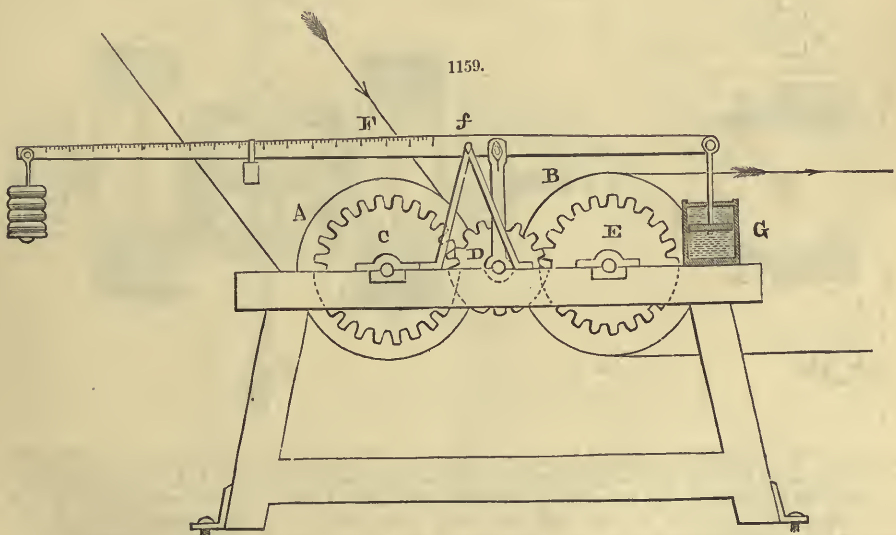
Fig. 1140 is an elevation of the entrance wall, showing the filling culverts at F, and the slides at the head of the dock for lowering timber by I.

Fig. 1136 represents a section of the dock in the receiving-chamber, with a line of battle-ship resting on the keel-blocks and shores. The exhaust culverts are shown at E. In all of these drawings the most important dimensions are marked in feet and inches, which obviates the necessity of any further description.

DYNAMOMETER. See Brake.

DYNAMOMETER, *invented by S. Brown, of Lowell:* the principle of which consists in measuring the power used by weighing the strain on an intermediate geer.

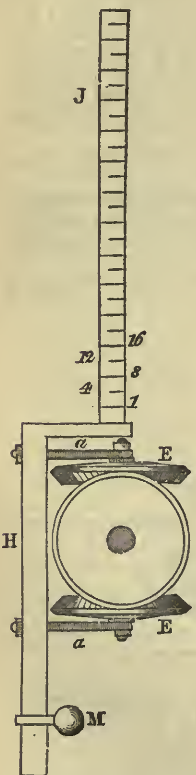
1159.



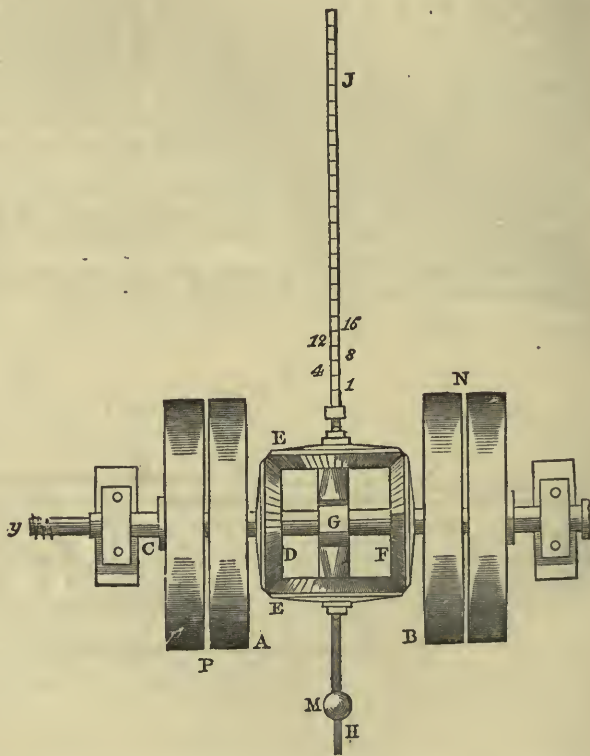
Description.—A is a pulley, Fig. 1159, which receives the power from the driving-pulley, which is transmitted through the geers C D and E to the pulley B, thence to the driving-machine. The pulleys are out side of the frame, the geers C E inside of the frame, and supported by it; the intermediate geer D hangs in a stirrup, supported by the beam F, which is a steelyard, whose fulcrum is *f*. But it must be remarked, that the strain on the centre of the intermediate geer (since the pilot line of the geer on one side is the point of application of the power and on the opposite side is the fulcrum) is double the power transmitted by the machine. G is a cylinder filled with water, in which a piston, fitting loosely, is attached to the beam F, and is used as a regulator to prevent sudden oscillations in the beam, which invariably occur in such machines.

DYNAMOMETER. Figs. 1160 and 1161 are two views of a dynamometer constructed on the principle of what is called the "differential-box," and consists of two pair of belt-pulleys A A, B B, mounted on the shaft C C: one of these pulleys on each side is loose, while the other is fast. The fast pulley on the side A A, and the bevel-wheel D, are both fastened to the shaft C C. The bevel-wheel F is fastened on a small tube connected with the pulley B. The wheels E E are connected by G, which is constructed so as to revolve round the shaft C C. To apply this simple machine, a belt from a drum on the main driving-shaft is brought to the pulleys A A, whilst another belt is carried from the pulleys B B, to the machine or machinery, the weight of which is to be ascertained. And it is plain, that if the pulleys A A, and the wheel D, are once put in motion, the wheels E E will also revolve on their axis, and at the same time the connection-shaft G will revolve round the shaft C C, thus leaving the wheel F and the pulleys B B, standing still; but, if the wheels E E are kept in their present horizontal position, and prevented from revolving round the shaft C C, it is equally obvious, that the wheel F and the pulleys B B will then be moved at the same speed as the wheel D and the pulleys A A; hence the weight required to keep the wheels E E in their present position, is equal to the weight required to move the pulleys B B. The weight thus required, is found by means of the lever H J. The arm H is attached to the centre of the wheels E E, by the straps *a a*, Fig. 1160. The arm J is divided upon the principle of the Roman steelyard. The weight M is merely intended to balance the arm J, and being

1160.



1161.



fastened with a set-screw, can easily be shifted on the arm H, as may be found requisite. Therefore, when the wheels E E are kept in their present position by means of the lever J H, it is evident that a weight of 20 lbs. acting upon the pulleys A A at P, will balance another of the same weight at N, of the pulleys B B. Now the distance from the centre of the shaft C C to the division on the lever J marked 1, is equal to the radius of the belt-pulleys; hence a weight of 20 lbs. at 1 will counterbalance the same weight at P,—that is, making no allowance for friction, the amount of which is ascertained by the additional weight required to balance the given weight at P; and having once ascertained the proper allowance for friction, the machine is put in motion by shifting both belts on to the fast pulleys, and moving the balance weight along the lever J from 1 to 4, 8, 12, or to whatever number will balance the wheels E E; and the weight thus indicated on J, is the weight required to move the machine or machines, from which deduct the allowance for friction. A worm at *y* on the end of the shaft C C, works into a wheel with an index and pointer, in order to show the speed at which the machine is driven, and also to determine the difference of the weight of any machine at different speeds. From the above description it is presumed that the principle upon which this dynamometer is constructed, as well as the mode of applying it, will be easily understood.

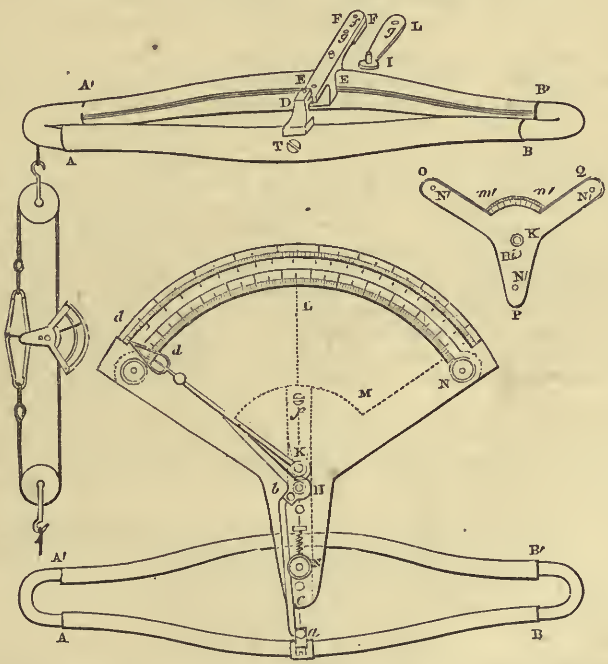
An improvement has been made on this machine by J. B. Francis, Esq., of Lowell, by which the

power is transmitted to and from the dynamometer in the same line; thus, instead of the pulleys B B a geer is employed, which works in an equal geer fixed to the end of an extra shaft parallel to C C, on the opposite end of which, and on a line with A A, is a pulley of the same size as A A, from which power is transmitted to the machine to be driven. The beam is balanced without the use of a moveable weight M, and to this end a regulating pump is attached, as in Brown's machine. A clock is driven by an endless-screw on the extra shaft, which registers the revolutions of the shaft, and a bell strikes at every 50th revolution. The beam J is so graduated, that the power used, or weight raised 1 foot high per second, is obtained directly, by dividing the weight as shown on the beam, by the number of seconds occupied by the shaft in making 50 revolutions. The friction of the machine was taken by the use of Prony's friction break, placed on the extra pulley, and was ascertained exactly by a course of experiments, on different speeds and weights.

DYNAMOMETER. *Regnier's Dynamometer* resembles a common graphometer, the principal part of which instrument is a steel spring bent in the form of an ellipsis; it should be properly tempered, and well welded, and covered with leather, to prevent injury to the hands when used. This spring is represented by A A′, B B′, formed by two equal plates united at the ends by rounded half-rings. The dimensions of this spring vary according to the tension required, or the weight to which it is applied.

The dynamometer used to ascertain human strength weighs little more than two pounds, and serves to measure a thousand times that weight; its total length is about 12 or 13 inches, and its greatest breadth, as measured in the middle of the two arcs, is 2·2 inches, and the least breadth at the extremity of these arcs is $\frac{3}{4}$ of an inch. The thickness of the arcs at their centres is nearly 2 inches, and its height, which decreases from the centre towards its ends, from $\frac{1}{10}$ to $\frac{4}{10}$ of an inch; the chords of the two arcs are 6·4 inches. This length, added to that of the two demi-rings, gives for the total length of the dynamometer 12 or 13 inches. The distance between the parallel chords is about $\frac{3}{4}$ of an inch, and the perpendicular of the arcs are each $\frac{7}{10}$ of an inch, giving about 2·2 inches for the total distance between the centres of the arcs.

1162.



There are two methods of stretching the spring, by pressing it in the direction of the perpendicular of the two arcs which form it, or by drawing it with the two rings at right angles to that perpendicular: these two limits of tension are indicated by two scales drawn on the same limb, called scales of pressure and tension: the first gives the pressure of weight from zero to 264 pounds avoirdupois. The greatest pressure brings the centres within 0·4 of an inch of each other, each perpendicular, which is 0·7 of an inch when there is no pressure, is reduced to 0·5 of an inch. The brass limb on which the scales are drawn is fixed on the centre of the arc A′ B′ of the spring, and the opposite arc A B carries a counterpoise *a b*, 3·1 inches long; the extremity *b* of this counterpoise acts on a small branch *b* H, 0·3 of an inch of a bent-lever, *b* H *c*, whose other branch H *c* is a needle, 2·4 inches long, from the centre H of rotation to the index *c*. Below this index is a small cylindrical thread, 0·1 of an inch, which is fixed to the needle H *c*, and serves as a foot when it turns on the centre H, parallel to the limb. This first needle by turning communicates a rotatory movement round the centre K to another needle K *d d′* which rolls on

the smooth portion of the screw K, and leans on the limb by a foot G furnished with a washer to reduce friction. This second needle has two indices d and d', to mark the pressure and traction; it is moved by the first needle H c; the divisions of the arcs described by the two indices are numbered in pounds, which indicate the weight brought by the needle to these divisions: as long as the spring is not stretched, the needle H c preserves its primitive position, and the needle K $d\,d'$ of the scales remains on the divisions to which it is drawn by the tension of the spring; whence it is seen that the system of two needles gives us the power of preserving the measure of a tension, when the force which produced this tension no longer acts. The greatest arc which the needle H c can describe is determined by the course of the counterpoise $a\,b$, which is 0·39 of an inch. The points b and c of the bent-lever G H c describe arcs of the same number of degrees: with regard to the positions of the two needles H c, K $d\,d'$ to the right line H K L of their centres, the angle c K L, which the second needle makes with this right line, is equal to the angle c H L of the first with the same right line, increased by the vertical angle H c K of the two needles, for in the triangle H c K, whose sides H c and H K are constant, the angle c K H is the supplement of the angle c K L, and of the sum of the two angles c K H and H c K. The distance H K of the centres H and K is about 0·46 of an inch, and it results that the total arc described by the needle K $d\,d'$ is nearly one-third of the circumference.

To preserve from injury the system of these three pieces, viz., the counterpiece $a\,b$, the bent-lever b H c, and the needle with two indices K $d\,d'$, the limb is covered by a plate N N N, which rests on the three pillars, 0·39 of an inch high. If the axis of rotation of the bent-lever were prolonged, it would meet this plate in the point H′, the centre of the arc of a circle $m'\,m''$ which terminates it, and whose radius is equal to the length of the needle H c. The divisions of the arc $m'\,m''$ are figured, and the figures indicate the same tensions as those on the scale of traction.

The dynamometer just described indicates on the scale of traction a tension of a ton weight, which is greater than the most powerful effort of a horse, but nevertheless too small to measure the ordinary effort of a power applied to a screw.

M. Regnier constructed a dynamometer on the same principles, which measures a traction of 6,600 lbs.: the spring was of the same power and length as the old one, but the two arcs or plates of which it was composed were longer, thicker, and further apart in their centres; their distance from each other was 4·5 inches; by the greatest traction it was only diminished 0·4 of an inch; these arcs had in the middle a breadth of 1·8 inches, and a thickness of 0·2 of an inch; the total weight of the instrument was 5½ lbs.

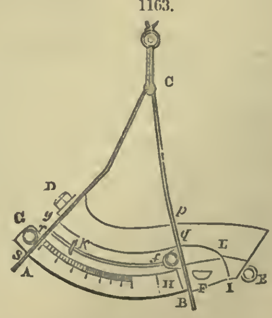
By placing the machine between the two ends of a cord passing over two or more pulleys, the ratio of the force which separates the extreme pulleys to the tension of the cord will be known, and by this disposition we can measure a traction much more considerable than that which is indicated by the scale of the dynamometer. Fig. 1162 shows the arrangement with two pulleys.

Details of the Construction of the Dynamometer.—Two supports D D′ of steel, are adjusted solidly on the two opposite branches of the spring in the direction of the perpendicular of the axis. The first support D, cut in a fork, carries a screw on which the extremity a of the counterpoise $a\,b$ rolls; it is about 1·4 inches high, and 0·59 wide; it is retained on the centre of the arc A B by a strong screw, whose head is marked T on the convex part of the arc. The second support D is also retained by a screw, the extremity of which, t, is seen on the concave part of the arc A′ B′; the upper face E E of this support is about 4 inches long: on the opposite face E F, which is of the same length, is a brass plate I L, fixed by a single screw g, which is level with E F in g: the plate, hardened to make a spring, carries at its extremity a pivot I, which passes through the support and the limb; this pivot, like that of a compass-needle, serves as a centre to the bent-lever b H c: the limb is applied to the face E F of the support D′, and is fixed there by two screws $e\,f$. The plate I L being a spring, the pivot I yields to a pressure of the counterpoise, and prevents any rupture of the mechanism which turns the needles or the scales.

The covering plate O P Q is voided at K′ in a small circle of a diameter nearly equal to that of the head of the screw K, round which the needle K $d\,d$ works, with a slight friction on the limb: if this friction be too slight, a turn-screw which passes through the circular opening K′ will tighten the pressure. The lower pivot of the bent-lever b H c rolls on the pin I′; its upper pivot rolls on the side H′, which is riveted to the covering plate O P Q.

Spring-Balance and Eprouvette. The spring-balance most used in commerce is formed of two steel branches A C, C B, bent at an angle of 45°; each of the arcs D $p\,q$ E, I H G, is fixed to one of the branches and traverses the other. By drawing the rings E G, which terminate the arcs in opposite directions, we bring the branch A C near B C; a circular scale figured from 5 to 40 indicates the respective positions of these two branches. The branch A C pushes before it a small cursor k of card or leather, which slides easily on the metalic wire $f\,g$, attached to the branch C B of the balance. To graduate the scale, suspend the balance by a ring E fixed to the branch A C, and attach weights to the ring G, which is at the extremity of the scale. The numbers on the scale indicate the tension of the spring.

1163.



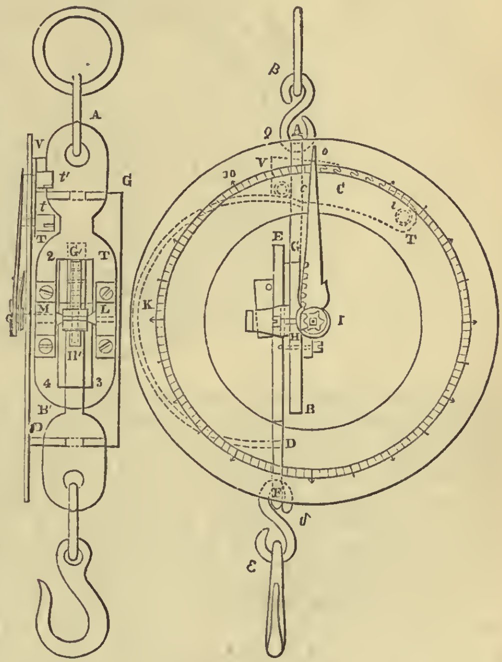
Regnier has made an excellent instrument of this spring-balance for trying the strength of powder. The length of the branches A C and C B is about 4·8 inches, and their breadth about an inch; a small brass cannon, whose breech H is on the branch C B of the balance, and whose mouth I is closed by the fuse I L of the obturation D I L E fixed on the other branch A C of the balance, contains a given weight of the powder to be tried; it is primed by a little powder put in the pan F: the powder within the cannon is fired and drives it away; after the ignition the two branches

of the balance approach, and the cursor k indicates on the scale the tension of the spring at the moment of the explosion. The iron D E, and the brass arc G H on which the scale is drawn, pass through openings $p\ q$, $r\ s$ made in the middle of the plates C B and C A.

A dynamometer for measuring animal force was invented by Mr. Graham, and afterwards improved by Desaguliers, but it was found to be inconvenient for the purpose, as it was made of wood. Leroy afterwards formed one in a metal tube 10 or 12 inches in length, with a spring within it placed vertically on a stand. This, however, was not found so useful as Regnier's, where the sides of the spring are made to approach each other, and move an index, which marks the degree of approximation on a semicircular scale: a man can ascertain by it the mean force he exerts with either hand, or with both together; it was with this kind of dynamometer that M. Quetelet, of Brussels, made his experiments upon the strength of men of different statures and ages.

Another kind of Spring-Balance.—The spring of this balance is bent in a curve C K D, terminated by two braces, C B, D E, one of which supports the pinion I, and the other a rack D E G H, of which the toothed portion G H catches the pinion I. This pinion and the needle which marks the tension of the spring turn on the same axis.

1164.



The face is a circle whose centre is on the axis of the pinion I, and is fixed by two screws t and t', on the plane T V, which is soldered to the upper brace A B, which carries the pinion. To graduate the scale, suspend the balance by the ring A, and attach known weights to F by the hook $d\ c$. The rack G H will work the pinion I, and the needle fixed on the axis of this pinion takes up successively the positions figured from 0 to 100; these numbers express the force of tension on the spring in pounds. The index of the needle describes about $\frac{5}{8}$ of the inch as the maximum tension of the spring, or for the greatest distance between the extremities C and D of the spring, which is about 1·1 inch.

The plane of the balance being supposed vertical, as in the projection, on another vertical plane passing through the axis of the pinion; the face of the brace A B, perpendicular to the plane of the limb, is drawn parallel to itself in A′ B′; we see on this face in the parallelogram 1 2 3 4, the projection of an opening made in the thickness of the brace A B, to make way for the toothed part G H of the rack; the breadth, 1 2 or 3 4, of this opening is 4 inches; L M is the projection of the axis of the pinion I; the spring C K D is projected in C D; the plane on which the face is screwed has for its projection T V. The spring is 0·11 of an inch thick, and 1·2 inches broad. To render this balance more convenient, a needle is added, which turns freely on the face round the axis of the pinion I, and may be employed as the dynamometer; it is even preferable for measuring the ordinary strength of men.

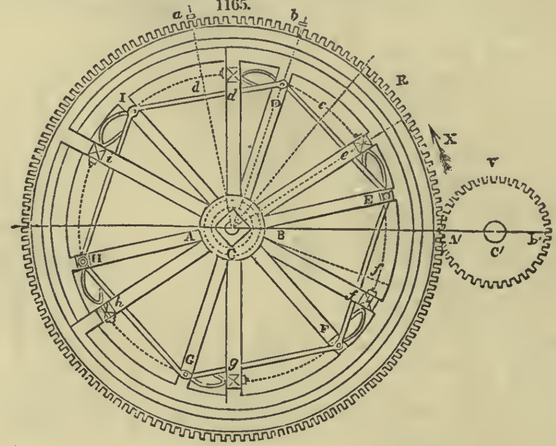
Of the Dynamometric Machine, and the Measurement of the Tangential Force of an Axletree.—Let A B, Fig. 1165, be the section of an axle moved by water or any other power; an unknown but constant resistance acts tangentially to this axle, and we require to measure it. To resolve this question, suppose we fix on the axle A B of a wheel D E F G H, of any number of rays C D, C E, C F, &c.; this wheel turns with the axle. Another wheel having the same number of spokes, C d, C e, C f, turns freely on the same axle; springs D d, E e are attached to the couples of the spokes, C D, C d, C E, C e of the two wheels, so that the points of attachment D and d of the extremities of the springs are in a plane perpendicular to the axis of rotation C of the axle A B, and at an equal distance from this axle.

Having disposed the power or mover so that it shall turn the wheel freely in the direction of the arrow X, it is evident that the extremities $d\,e$, $f\,g$ of the springs fixed to this wheel, would swerve from the points of attachment D E F, &c.; that the equal angles D c d, F c e, E c f, &c., whose sides pass through the extremity of the springs, considered in their primitive position, would become other equal angles D c d, E c e, E c f, &c., and all the other springs would be stretched, if not equally, at least at the same angle: when the total tension of the springs is equivalent to the resistance applied tangentially to the axle, the system of the two wheels will turn on the axis A B as one and the same wheel. Now suppose that the axis turns, and that we can measure one of the angles D c d', at which all the springs are stretched, we shall have in the triangle D C d' the angle C, the equal sides C D, C d, and consequently the perpendicular let fall from the centre C on the side D d, or the radius of the circle to which the force which stretches the spring is tangential. We may, besides, observe the number of turns of an axis in a given time, whence we may deduce the velocity of the point at which the force

that stretches each spring is applied. Multiply this velocity by the sum of the tension of the springs the product will be the dynamic effect of an axis in a unity of time, for example 1″.

To measure the angle D c d, which moves in a plane perpendicular to the axis of rotation C of the axis A B, we fix on the lines C d, C D, the middle of the radii, two small hammers a b, coupled by a spring D d', which each moves in a plane perpendicular to the axis of rotation C, and at equal or unequal distances from this axis, but greater than the radii of the wheels. These hammers strike two bells placed beyond on circles described through a and b. This being arranged, we can with a seconds watch measure the time which elapses between the two consecutive sounds resulting from the blow of each of the hammers on the bells, and knowing besides the time of the entire revolution of the hammers, these two portions of time will be in the ratio of the arc which measures the angle of the right lines passing through the extremity of each spring to the entire circumference. This angle being known, we can easily measure the weight which stretches each spring at a known angle, and the sum of these weights will be the total tension of the dynamometric machine.

1165.



By this description it will be seen that simple springs without needles or scales, whose force of tension for the same lengthening may be sensibly unequal, give exactly the measurement of a tangential force applied to axes: by taking springs capable only of a tension of a ton, we may place eight on a circle of 39·37 inches radius, and eight others on a concentric circle of 8 decimetres, supposing the axle makes four turns per minute; the dynamometric machine will show, on this hypothesis, that the dynamic effect produced by a force applied to an axle is nearly equivalent to that obtained from 80 horses.

Another dynamometer deserves to be mentioned: a vessel containing water should have a cylinder, made of some heavier substance than the water, suspended in it by a rope passing over a pulley: when the upper surface of the cylinder is on a level with the surface of the water, the weight of the cylinder, or the force which it exerts upon the rope, will be equal to the absolute weight of the cylinder in air diminished by the weight of a quantity of water of the same magnitude as the cylinder: a horse or a man pulling at the rope to raise the cylinder above the fluid surface, the weight of the cylinder will gradually increase; and if the magnitude and specific gravity of the cylinder are duly adjusted to the force, there will be a particular position of the cylinder at which its weight will exactly balance that applied. The forces in equilibrio, or those required to be measured, will be equal to the absolute weight of the cylinder, diminished by the weight of a quantity of water equal to the magnitude of the immersed part of the cylinder: a scale attached may be so set out, that it will accurately measure the force applied, and the cylinder can be increased to any length by diminishing its diameter, so that a very lengthened division may be adopted.

ECCENTRICS. The term *eccentric* is applied in general to all such curves as are composed of points situated at unequal distances from a central point or axis. The ellipse, the curve called the *heart*, and even the circle itself, when supposed to be fixed upon an axis which does not pass through its centre, are examples of eccentric curves.

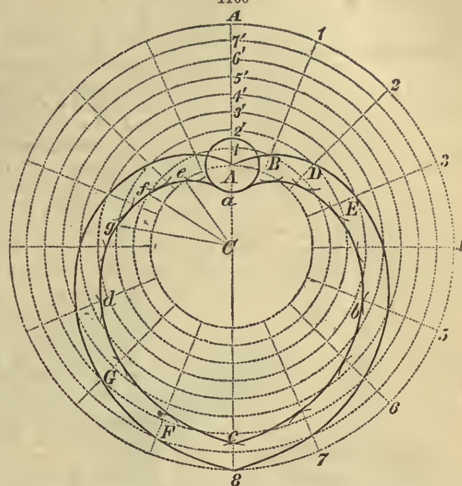
The object of such curves, which are of frequent occurrence in machinery, is to convert a rotary into an alternating rectilinear motion; and their forms admit of an infinite variety, according to the nature of the motion desired to be imparted. Examples of their application occur in many arrangements of pumps, presses, valves of steam-engines, spinning and weaving-machines, &c.

Fig. 1166 illustrates the distribution of the eccentrical symmetrical curve called the heart, which is such as, when revolving with a uniform motion on its axis, to communicate to a moveable point A, an uniform rectilinear motion of ascent and descent.

Let C be the axis or centre of rotation upon which the eccentric is fixed, and which is supposed to revolve uniformly; and let A A′ be the distance which the point A is required to traverse during a half revolution of the eccentric. From the centre C, with radii respectively equal to C A and C A′, describe two circles; divide the greatest into any number of equal parts (say 16), and draw through these points of division the radii C 1, C 2, C 3, &c. Then divide the line A A′ into the same num-

ber of equal parts as are contained in the semicircle (that is, into 8 in the example now before us), and through all the points 1′, 2′, 3′, &c., draw circles concentric with the former; the points of their intersection B, C, E, &c., with the respective radii, C 1, C 2, C 3, &c., are points in the curve required, its vertex being at the point 8.

1166



It will now be obvious that when the axis, in its angular motion, shall have passed through one division, in other words, when the radius C 1 coincides with C A′, the point A, being urged upwards by the curvature of the revolving body on which it rests, will have taken the position indicated by 1′; and further, when the succeeding radius C 2 shall have assumed the same position, the point A will have been raised to 2′, and so on till it arrives at A′, after a half revolution of the eccentric. The remaining half A G F 8 of the eccentric, being exactly symmetrical with the other, will enable the point A to descend precisely in the same manner as it is elevated. It is thus manifest that this curve is fitted to impress a uniform motion upon the point A itself, but in practice a small friction roller is usually interposed between the surface of the eccentric and the piece which is to be actuated by it. Accordingly, the point A is to be taken as the centre of this roller, and the curve whose construction we have just explained is replaced by another similar to, and equidistant from it, which is drawn tangentially to arcs of circles described from the various points in the primary curve with the radius of the roller. This second curve is manifestly endowed with the same properties as the other; for, supposing the point *e*, for example, to coincide with A, if we cause the axis to revolve through a distance equal to one of the divisions, the point *f*, which is the intersection of the curve with the circle whose radius is C 1′, will then obviously have assumed the position 1′; at the next portion of the revolution, the point *g* (which is such that the angle *f* C *g* is equal to *e* C *f*) will have arrived at 2′, and so on. Thus it is plain that the point *a* will be elevated and depressed uniformly by means of the second curve, in the same manner as that denoted by A is actuated by the first.

It is obvious that the movable point A must, in actual working, be held in contact with the surface of the eccentric; this is generally accomplished by the action of a weight or of a spring; but in forms similar to fig. 1166, in which all the diameters, as A 8, B F, D G, &c., are equal, two friction-rollers A 8 connected and placed diametrically opposite each other may be used, which will be thus alternately and similarly impelled; in many cases an eccentric groove is cut, and the friction-roller or point A, is made to slide in this groove.

ELECTRICITY. All substances are susceptible in a greater or less degree of electrical excitation, but according to their readiness to evince electric properties by friction, they are classed as electric or non-electric. Electric substances have not only the property of electrical excitation, but also the power of confining, or imprisoning, as it were, the communicated electricity upon other bodies, in which it could not under the same circumstances be so excited; while on the other hand, the non-electric substances allow the electricity to pass off. Non-electric substances, therefore, have been called *conductors*, and *electric* substances, *non-conductors* or *insulators*. These expressions are merely relative, yet the difference in conducting powers in certain bodies is enormous; that of iron, for instance, being estimated at 400 000,000 times greater than that of water.

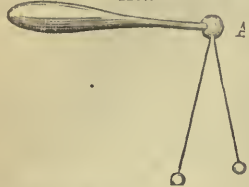
Excitation of Electricity by the Mechanical Movements of Bodies.

* Various names have been applied to denote the different modes of producing electrical excitation. When one body is rubbed by another, as in the case of the common frictional electrical machine, this peculiar mode of excitation has been termed "Frictional," and "Mechanical," and hence the term "frictional electricity" and "mechanical electricity" has originated. The excitation developed by means of heat, has been denoted "Thermo-electricity;" that developed by means of magnets, "Magneto-electricity;" that by means of the chemical decomposition of zinc by acids in the battery cell, "Galvanic" and "Chemical" electricity. The excitation developed by the organs of certain fishes, has been termed "Animal" electricity. These several distinctive names appear to have been introduced into popular use for the convenience of arranging classes of facts of different modes of exciting electrical action, rather than for establishing any discrimination in the essential nature of the electricity excited. Indeed, Professor Faraday instituted a course of experiments for the express purpose of proving that there is no actual difference in the nature of electricity, however excited, and that all these kinds of "electricities" are identical. Considering all electric excitation to be simply the propagation of mechanical action through the medium of electric matter, and that impulses of mechanical force are all identical in their nature, however excited, and however propagated, the preceding result, verified by Faraday, might be theoretically anticipated. The presence of electric matter in motion, or in an excited state, is tested by its propagation of motion to some kind of freely movable and palpable portions of matter. In the

* Allen's Philosophy of the Mechanics of Nature.

construction of all kinds of electroscopes, the principal study has been to arrange the lightest, or most flexible portions of matter, in the most freely movable positions near each other. Although feathers, pieces of threads, and of straws, may serve to detect by their movements the propagation of electric action, yet convenience has been consulted in using other substances systematically arranged in the form of instruments. One of the simplest kind of electroscopic instruments is constructed of a couple of

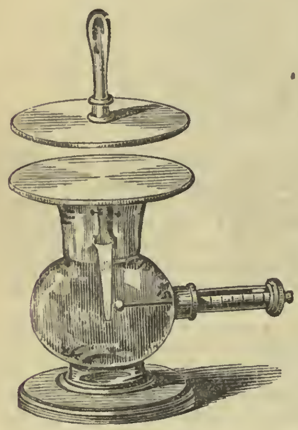
1167.



balls of the size of a pea, made of the pith of alder or of a cornstalk, suspended by very fine silver wires, or threads coated with black lead, and suspended from a metallic knob A, attached to a glass handle to insulate it, as shown in the figure. On bringing the knob A into contact with an excited body, the balls will become divergent as seen in the figure; and if a body be not electrically excited, the balls will continue drooping in contact with each other. The different degrees or extent of their divergency will of course indicate the degree of intensity of the electro-dynamic action. This fact of a reciprocal separation or repulsion of two bodies, is assumed to be a test of electrical excitation.

Hare's Electroscope.—Fig. 1168. By inserting a wire M, with a brass knob affixed to the end of it, which may be approximated by means of a screw cut upon its circumference to within a very minute distance of a single strip of gold leaf. The intensity of the propagation of the electro-dynamic action

1168

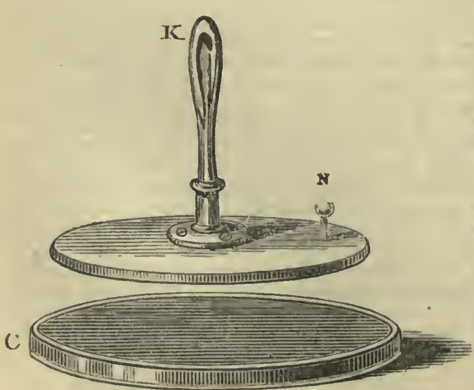


through a space of air being found to decrease in the inverse ratio of the squares of the increased distances, this instrument becomes thus exceedingly sensitive to the slightest disturbances of electrical matter in the gold leaves propagated from the metallic cap, which is made of zinc. By means of this simple instrument, one of the most important facts in the whole science of electro-dynamics may be experimentally demonstrated by bringing into contact with the plate various kinds of metals, as the plate insulated by a glass handle. A disturbance of the natural electrostatic condition of the plate and of the gold leaves suspended therefrom, is producible by the simple approximation and contact of various bodies with the plate; the sifting of various pulverized substances thereon being sufficient to produce the movement of the gold leaf. Both of these metallic plates may be separately examined by the test of the contact with other electroscopes composed of pith balls or flexible gold leaves, and no signs of electricity will be discoverable. Now place the plate of copper on the plate of zinc, which is called the *cap of the electroscope*, and hold one hand in contact with M, which is to be screwed up until the ball at the end of it is brought close to the tip end of the pendent strip of gold leaf; and with the other hand, touch the copper plate, and then lift it by the glass handle from the zinc. At the instant the separation is effected, the gold leaf will be seen to strike the ball, if the latter be previously brought to within the distance of $\frac{1}{20}$th of an inch from the former. This instrument serves the purpose of a delicate *electrometer* to measure very minute degrees of intensities of electrical action.

To demonstrate that an *artificially excited* body will develop electrical excitation in another unexcited body with which it may be brought into contact, Volta invented a very simple kind of electrical machine, which he denominated *The Electrophorus.*—The name of this electrical apparatus is derived from the Greek words signifying "*Producer of Electricity.*"

The *electrophorus* consists simply of a cake of sealing-wax, which material is selected as being a readily-excitable substance. A more tough and useful compound is commonly used, made by melting

1169



together equal parts of pitch and resin, combined with a little linseed oil. This composition, whilst in a melted state, is poured into a flat circular tin dish, having a rim of about half an inch in height, as shown at C. A round metallic plate D, adapted to the size of this cake of resinous matter, is affixed to the insulating glass handle K, by which the plate of metal may be alternately lifted from the cake of resin, and again brought into contact therewith.

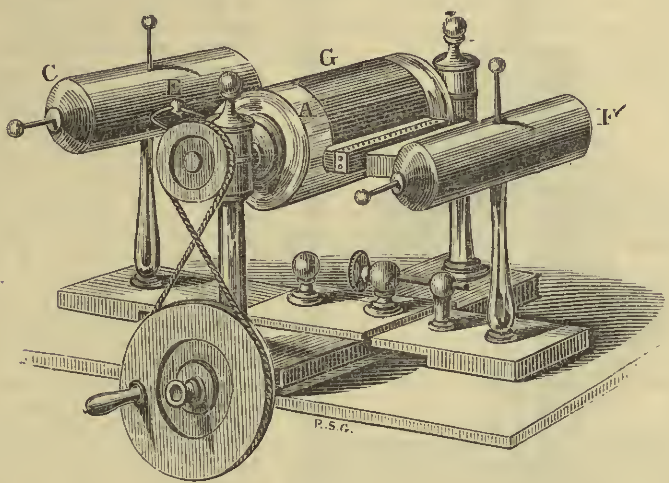
Whenever it is desirable artificially to propagate electro-dynamic action from the cake of resin to some adjacent body, the circular plate of metal is taken by the tip of the glass handle, and brought into contact with the cake of resin, and at the same time the finger is brought to touch the plate. Then the finger is to be withdrawn, and the plate removed by holding the tip of the glass handle.

The electrophorus is used practically for producing instantaneous light, by causing an electric spark, always excitable in an instant from

the plate on being lifted from the cake of resin, to kindle a jet of hydrogen gas artificially arranged to issue from a small apparatus, containing a lump of zinc in acidulated water.

The mechanical *pressure* of bodies, as well as friction and contact, propagates electro-dynamic action. Elastic India-rubber or caoutchouc, develops extraordinary electric excitation by sudden compression Sparks issue in vivid coruscations to a distance of several inches from between the rollers used for compressing sheets of this material in the process of incorporating it into manufactures of cloth. In certain processes of calico printing, the India-rubber, dissolved in spirits of turpentine and alcohol, and mixed with ultra-marine blue, or other colored substances, is passed with great pressure between the engraved copper rollers and the cloth to be imprinted therewith. A torrent of sparks I have noticed to issue from the compressed India-rubber, too intense to be sustained by the knuckles, held near them, without absolute pain. Indeed, the process of printing with this material was finally suspended from the danger of burning up the building and machinery employed, the sparks having actually set fire to the composition of turpentine, alcohol and India-rubber, and caused the cloth in the machine to be burnt up.

1170



Frictional electrical machines were first constructed to be operated by the *successive approximations* or *contacts* of the parts of the revolving glass cylinder A, against the parts of a rubber attached to a hollow metallic cylinder F, mounted on a pillar of glass. This pillar is sustained on a sliding base-board at the bottom, capable of being moved by a screw towards the glass cylinder, to regulate the intensity of the pressure, and consequently of the friction of the rubber. The rubber is made of leather stuffed with horse hair to constitute an elastic cushion.

Another hollow metallic cylinder, termed a "prime conductor," is represented at E, furnished with a row of pointed wires facing the glass cylinder, designed to serve for collecting the electricity excited therefrom. To prevent the escape or propagation of the electro-dynamic action from the prime conductor, it is *insulated* by the intervention of a non-conducting glass pillar. A flap of silk G, is attached to the cushion, and is spread out over the top of the revolving cylinder, to suppress the dissipation of the electrical action by the reaction of the air, before it reaches the row of points at E.

A revolving movement may be imparted to the glass cylinder by the animal motive power of the human hand applied to turn the crank-handle attached to the pulley W. Into this pulley a grooved score is turned, adapted to receive the cord that extends from it to a similar groove in a pulley attached to the axis of the glass cylinder.

The conductor E has also been denominated the *positive* conductor, in contradistinction to the conducter attached to the rubber, which is denominated the *negative* conductor, the former being supposed to contain an accumulation, or "positive" excess of the fluid; and the latter supposed to have yielded up a portion of its natural share of electricity, and to be reduced to a "negative" state.

To augment the excitation, it is usual to apply to the rubbing surface of the cushion a compound of metals triturated with lard. One part, by weight, of tin, and two parts of zinc, are melted together, and mixed with six parts of mercury, which are to be well stirred together until solidified. The brittle compound is then pulverized in a mortar, and mixed with a sufficient quantity of lard to reduce it to the consistency of a paste.

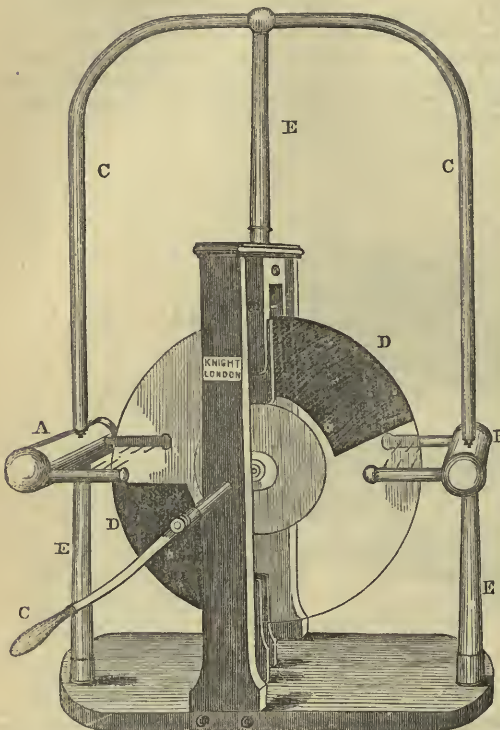
A superior improved *Plate Electrical Machine* has been introduced, which has superseded the use of the cylindrical machines, one of which is represented in fig. 1171.

The glass plate is caused to revolve by means of the crank handle C, attached to an axis passing through the plate, which is supported between two pillars. Attached to the inner sides of these pillars are four cushions, compressing the plate between them at the upper and lower portions of the disc, each having flaps of silk, D D, appended thereto. The intensity of the pressure of the cushions is reg-

ulated by screws. The two opposite conductors A B, are supported by two stout glass pillars E, E fixed at each end of the mahogany base-board, on which the other parts of the machine are mounted. The brass arch C C, is sustained at the centre and lower ends by the glass pillars E, E, E, and connects the two conductors A B.

The large electrical machine at the Polytechnic Institute, in London, has a plate of the diameter of 7½ feet, the sparks from the huge conductor of which, it is stated, "are nearly sufficient to fell a man to the floor."

1171



By scanning the details of the arrangement of the parts of the preceding machines, it is to be particularly noticed here, that the system kept in view throughout all the plans of their construction is simply confined to two distinct principles.

1st. To move one portion of matter near another, in order to disturb the natural state of rest of the electric matter existing in connection with both bodies.

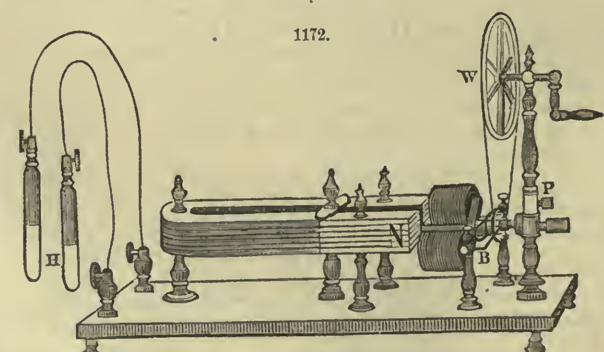
2d. To direct the consequent propagation of the electro-dynamic impulses in some one specific line of action, by means of interposed non-conducting substances, and of a continuous line of conducting substances, to concentrate them on a determinate point.

"*Magneto-Electricity*." The earliest account published of the first successful experiment in exciting electricity by the influence of magnets, appeared in April, 1832, in the "Annals of Philosophy," as communicated by Professor Faraday.

"If a wire, connected at both extremities with a galvanometer, be coiled in the form of a helix around a magnet, no current of electricity takes place in it. This is an experiment which has been made by various persons hundreds of times, in the hope of evolving electricity from magnetism; and, as in other cases in which the wishes of the experimenter and the facts are opposed to each other has given rise to very conflicting conclusions. But if the magnet be withdrawn, or introduced into such a helix, a current of electricity is produced *whilst the magnet is in motion*, and is rendered evident by the deflection of the galvanometer. If a single wire be passed along a magnetic pole, a current of electricity is induced through it, which can be rendered sensible. Whenever, also, a piece of metal is moved near a magnet, so as to intersect the magnetic curves, electricity is evolved, according to very simple laws."

Fig. 1172 represents a powerful magneto-electrical machine. The driving wheel W, may be turned either by the hand, or by a band moved by steam power or water power.

1172.



From the wheel W, a band is extended around a smaller wheel, or pulley to be turned thereby. The upper part of the pillar P, slides into the lower part, and admits of being fixed higher or lower by the binding screw P, so as to tighten the band as desired. An U magnet N, is fixed horizontally with its two poles as near to the ends of the armature B, as will allow the latter to revolve without touching

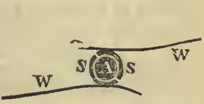
them. The armature is made of a piece of soft iron, bended twice at right angles to resemble also the shape of the letter U. Around each of its legs is wound a helix of fine wire coated with thread. This piece of iron with its environing coils of insulated wire, is fixed upon an axis extended from the pillar P to another pillar erected between the poles of the magnet. This axis is caused to revolve rapidly by the band from the multiplying wheel W.

Both of the arms of the revolving bar of iron are rendered magnetic for an instant, as they successively pass the two approximated poles of the permanent steel magnet N; and they cease for an instant to be magnetic on passing away from the influence of these two magnetic poles. The leg of the iron bar which approaches the N pole acquires the opposite south polarity, and the other, the opposite north polarity. The intensity of the excitation increases until the ends of the armature are exactly opposite to the ends of the poles of the steel magnet, and then diminishes to a minimum, when they stand crosswise to each other. By the continuance of the motion, each leg of the iron armature becomes oppositely excited on approaching the opposite pole.

These rapid transitions of magnetic excitations in the revolving bar of iron induces equally rapid transitions of excitation of the electric matter existing in connection with the coils of wire, wound around them both continuously. But it is manifest on inspecting the arrangement of these two coils of wire revolving about the axis, that their ends cannot remain connected with any stationary portion of the apparatus, as they would become broken off by the revolving movement. To overcome this difficulty, Dr. Page has invented a "*Self-acting Current Changer*."

In the figure, A represents a sectional view of the axis of the spindle carrying around the iron prongs with the environing wire coils. S, S, represent two semi-cylindrical plates of silver fitted to the axis A, but insulated therefrom by varnished silk or otherwise, and turning with the spindle. To each one of these semi-cylindrical pieces is soldered one of the two ends of the wire coiled about the iron prongs. In contact with these semi-cylindrical pieces, and gently pressing against them whilst they revolve beneath them, are the two elastic silver springs W, W, which remain at rest, being soldered permanently to the ends of the conducting wires that are designed for propagating the electric action to the bodies to be affected thereby. By this arrangement a continuous metallic contact is preserved between the ends of the wire coils revolving on the spindle, and the ends of the conducting wires leading to the two screw cups, shown at the opposite end of the base-board of the machine.

1173



By means of the mechanism of the revolving armature and coils, several thousand changes in the directions of propagation of the ebbing and refluent electric surges may be produced in a minute, when the wheel W is very rapidly turned by the crank handle, or preferably by steam or water power. The intensity of the ebbing and returning surges of electric action is correspondingly augmented with the rapidity of their movements toward and from the poles of the permanent magnet.

Although the directions of these ebbing and returning surges are reversed twice during each revolution, yet the connections of the two semi-cylindrical pieces are such as to turn all the ebbing surges in one direction, by one of the connecting pieces S, and all the refluent surges uniformly in an opposite direction through the opposite connecting piece.

It is necessary to adjust the contact of the springs with the semi-cylindrical pieces revolving with the spindle, so that the direction of the current in the coil may be reversed at the moment when the ends of the iron prong and coils have passed the poles of the permanent horseshoe magnet. By means of this arrangement, the effluent current of electric discharges are made always to escape in the direction through the binding-cup B, and the refluent current of shocks to return by the opposite binding-cup A; and thus by this regular changing of the connection with the ends of the wire environing the electro-magnetic iron prong, the *initial currents* of electricity are always directed to move separately in one direction, and the *terminal* currents in the opposite direction, in the same manner as occurs between the exciting rubber and main conductor of the electrical machine, and between the zinc and copper of a galvanic battery.

The uniform propagation of electro-dynamic action, in an uniform current produces less violent effects on the nerves and muscles of animal bodies than oppositely directed alternate surges of electric action. By adding to the magneto-electric machine the apparatus of a "contact breaker," designed to interrupt very rapidly a continuous action, it is capable of producing such a "torrent of shocks," when the machine is of large size, and the revolutions of it are rapidly accelerated, and such violent spasmodic contractions of the muscles of the hands, which grasp the handles, shown at H, in the preceding figure, as to prevent the tortured experimenter from dropping them, to relieve himself of the agony which he thus involuntarily endures. By means of this machine, impulses of mechanical force may be propagated through the medium of electric matter to put in motion light machinery, as that for striking a bell, with as much systematic regularity as the same impulses are commonly propagated through leather bands and iron shafts, for putting in motion mill machinery.

These magneto-electric machines excite electric currents which resemble those of galvanic batteries, being sufficient to operate electric telegraphs, to decompose water, to deflagrate metals, to heat fine wires red hot, to fire gunpowder, and to precipitate gold and silver from their solutions.

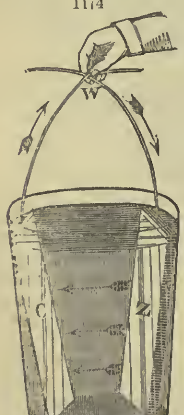
Mr. Shaw gives the following account of a powerful magneto-electric machine constructed by Mr. Woolrich, and used in the workshops of Birmingham for the practical operations of electro-plating and gilding. The magnets are made to revolve by the motive power of the steam engines which impel the other machinery operated in these workshops. He states, "that although the first cost of the magneto-electric machine is certainly greater than that of the galvanic apparatus necessary to produce the same amount of power, yet the expenses of working it are incomparably less, being limited to the cost of a trifling motive power of a steam engine or water-wheel. The economy of the magnetic machine for constant use must eventually gain for it a preference to the voltaic battery, where metal is to be depos-

ited on a business scale. All the wear and tear of these machines is, of course, limited to the friction between the axis and its bearings, and to that between the contact breaker and springs."

The expense of the consumption of the materials of acids and metals is very considerable in ordinary galvanic batteries. Thus, as illustrated by Mr. Shaw, "in depositing zinc, as in zincing or galvanizing the surface of iron, supposing two cells, arranged as an intensity battery, to be employed, the quantity of zinc deposited would be just one half of that decomposed and consumed in the battery, and very nearly the same proportion would obtain in the case of copper. Hence, the expense of this mode of plating or depositing metals, as compared with the value of metals deposited, is very great." By the use of the magnetic machine, on the contrary, the expense of depositing is limited to the trifling cost of the motive power required to produce the rotation of the armatures of the apparatus. So uniform is the current of electricity excited by this apparatus, and so regular is the process of the deposition carried on by means of it, that the mill governor, or regulator of the steam engine, serves actually to adjust it with such precision. that in a large establishment in Birmingham, where this process of electro-plating is extensively carried on, the quantity of metal deposited as a coating is estimated by the time during which the machine is worked. "Repeated weighings having demonstrated that the relation between the time of working and the quantity of deposited metal is sufficiently accurate." From 300 to 400 ounces of silver per week have been deposited from sulphite solutions of this precious metal, by a magneto-electric machine, described by Mr. Shaw, when the armatures were caused to make 650 revolutions per minute. In this magneto-electric machine, there are 8 armatures and coils, each of which become magnetic and cease to be magnetic four times in passing between the poles of 4 fixed permanent horseshoe magnets; and as the drum that carries them makes 650 revolutions per minute, there are, consequently, 20,800 changes per minute, from an unmagnetic to a magnetic state, induced in the 8 soft iron armatures; and an equal number of times per minute is a portion of the electricity naturally existing in connection with the wire coils expelled and returned. Thus 20,800 electric discharges per minute are turned by the *pole changer* to flow off in one uniform direction along the conducting wire, to exert their electro-mechanical action, like the regular current of a galvanic battery. During the most prolonged periods of the constant use of these magneto-electric machines, it is stated by Mr. Shaw that no appreciable diminution of their power has taken place, and no expense or delay is necessary to maintain them in good working order, such as is necessary whenever galvanic batteries are employed. The use of this magneto-electric machine in the art of Electro-Plating has been patented in England by J. P. Woolrich.

Galvanic Battery. When a piece of zinc is dropped into a vessel containing acidulated water, bubbles of gas are seen to issue from the metal, and the electro-dynamic impulses are propagated therefrom in every direction. By these counterbalanced opposite directions, the impulses neutralize each other's actions and reactions. Consequently, no decided electro-dynamic action is perceptible. This experiment has been repeated thousands of times before the discovery of the galvanic battery arrangement, without developing electric excitation. But if a plate of copper or platinum, as at C, in the figure annexed, be placed oppo site to the zinc Z, the impulses are determined through the water to the atoms of the copper plate, in one common specific direction.

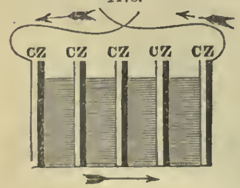
1174



One of the earliest modes of arrangement of the plates of galvanic batteries in a series was invented by Cruikshanks, and which, from its compactness, is still in use. The copper and zinc plates are soldered together in pairs, as it were back to back, each zinc plate being made to face an opposite copper plate as shown in fig. 1175.

Each plate is inserted in a groove, in a trough, and serves to form a water-tight partition, dividing the trough into an equal number of cells with the pairs of plates intervening between them. This kind of battery has been in very general use in lecture rooms.

1175.



Where a great number of pairs of plates are required to employ their combined powers of action, they are compactly arranged in battery form as shown in fig. 1176. The plates are suspended stationarily, and the troughs below, filled with acids, are raised up to submerge the plates therein by means of the two racks shown at each end of the apparatus. Small pinion wheels affixed to a shaft turned by the crank handle H, work into the teeth of these racks, and elevate or depress the troughs at the pleasure of the operator.

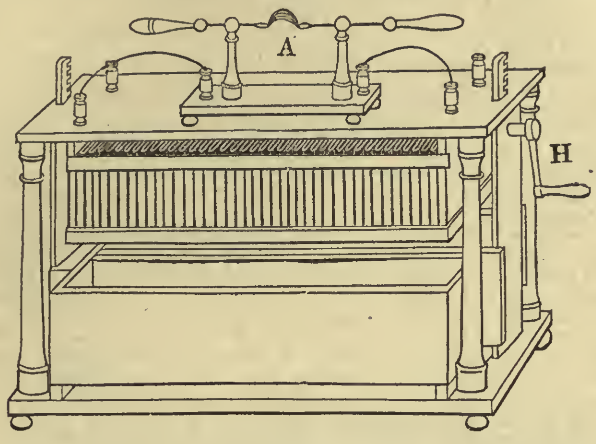
In the battery represented at fig. 1176, there are two distinct series of 50 pairs, each connected with two of the four cups on the table above the battery. By this arrangement the whole may be used as a single series of one hundred pairs, or as a battery of fifty pairs of double size, accordingly as the respective connections are formed with the binding cups. There being two separate troughs, only half of the battery may be used by removing one trough. These numerous pairs more particularly exhibit the phenomenon of electric flame between two separated points of the battery circuit as shown in the wood cut.

The usual mode of arrangement of batteries designed for the purpose of developing the phenomenon of heat, is in several pairs of very large sheets of zinc and copper, all the sheets of the former being connected by conducting wires, and all the sheets of the latter being similarly connected to represent the action of two single pairs.

Hare's Calorimotor—Fig. 1177. Dr. Hare devised a peculiar arrangement of the plates of a galvanic

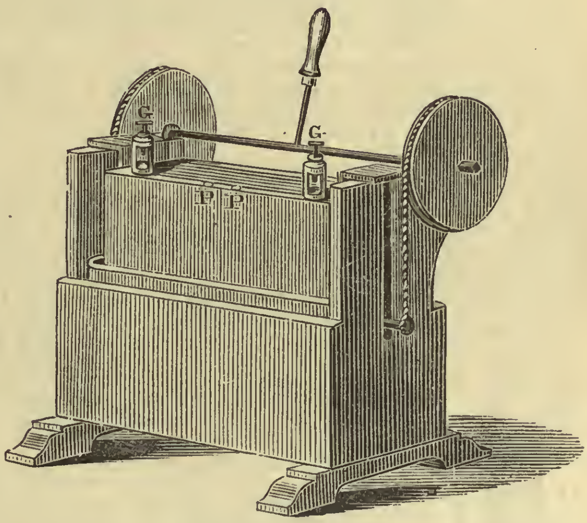
apparatus, in the year 1818, consisting of twenty-one plates of copper, communicating by a slip of metal, and twenty plates of zinc similarly connected, the plates of the one set being alternated between

1176.



those of the other, thus constituting only an equivalent to one pair, with one associated zinc surface and one associated copper surface, with the liquid interposed every where between them. Dr Hare remarks, "I ought to mention, that by means of a silver thimble, within which a minute piece of zinc was supported and insulated, Wollaston made an elementary battery capable of igniting a minute platinum wire. In enlarging the size of the galvanic apparatus, my course was diametrically opposite."

1177.



The figure represents the plan of Dr. Hare's instrument of four zinc and six copper plates. On pressing down the handle G, the pulleys are caused to revolve, lifting by the cord wound thereon the trough with the acid, whereby the plates are immersed therein.

For the purpose of producing an intense action in burning or deflagrating metals, &c., Dr. Hare constructed a convenient apparatus upon an enlarged plan, with 200 pairs of plates, each 14 inches by $7\frac{1}{2}$ inches, with the copper and zinc plates soldered together in a wooden trough on the "Cruikshank" plan, joined lengthwise, edge to edge to another trough, so that when the sides of one are vertical, those of the other must be horizontal. These troughs being united by a bar, serving as a pivot, when the bar is turned by a lever, the plates being placed in one of the troughs, and the acid in the other, by turning the trough containing the acid, it is caused to discharge its contents into the one containing the plates.

He made a very powerful battery by means of several sheets of zinc soldered together to form one continuous sheet, nearly fifty feet in length, with a similarly formed copper sheet of equal dimensions, wound together like a scroll, the two metals being kept separated by a rope of hair, wound intermediately between the sheets.

The calorific action of these galvanic batteries produced very surprising results in heating wires red hot and in deflagrating metals, &c.

Mr. Bain made the experiment of burying a large sheet of zinc in the moist earth of Hyde Park, London; and at another spot, more than a mile distant, he buried a sheet of copper of similar size. These two sheets he connected by a conducting wire, trained along the railings of the inclosure. With this simple apparatus he succeeded in producing the various phenomena usually attainable from a regular galvanic battery. "Without troubling himself with the preparation of acids and voltaic troughs,

he produced the excitation of regular electric currents, of sufficient intensity to be transmitted to distant places along connecting wires."

It is stated by Mr. Tylee, a chemist of Bath, England, that a battery composed of thirty pairs of zinc and copper plates, which he buried in the moist earth of a garden, formed a *terrestrial battery* admirably adapted for electro-plating processes; but the time required for completing the process was longer than with the acid battery.

In the practical operation of the original galvanic batteries, composed of plates of zinc immersed in acids, it was found that three distinct obstructing causes impeded the uniformity of the electrical excitation, viz: 1st, the accumulation of a coating of bubbles of hydrogen at the surface of the copper plate forming a non-conducting screen; 2d, the accumulation of the earthy matter of the oxide in the form of a crust or scale on the surface of the plates of zinc, serving as a coating to intercept the further access and grouping of the atoms of oxygen of the acids with those of the zinc; and 3d, the gradual exhaustion of the excess of atoms of oxygen, constituting the strength of the acids in their grouping with those of the zinc. The accumulation of bubbles on the surface of the plate, sometimes forms such a non-conducting coating as to prevent the plate from performing the designed functions.

Availing himself of the plan of arranging rows of pointed wires in electrical machines for determining more freely the propagation of electro-dynamic action, Mr. Smee contrived to impart to the surface of the plate a similar system of the sharp points of crystals of metals artificially formed thereon. He used plates of silver on which platinum on angular points of crystals are deposited. A wooden cross was used to sustain the pairs of metal plates, to each one of which screw-cups were soldered thereto, to insure contact. As the natural polarized condition of the atoms of copper plates is subject to be disturbed by the contact of acid solutions, and reduced to an oxide, like the metal zinc itself, in which cases counteracting neutralization of the electro-dynamic action of the battery is produced, Mr. Smee introduced the use of platinum as a substitute for copper.

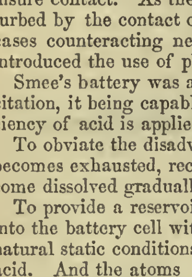
Smee's battery was a great improvement in the constancy of the development of effective electric excitation, it being capable of sustaining "active operation for six, eight, ten, or more days, when a sufficiency of acid is applied to it."

To obviate the disadvantage of a necessity of supplying fresh acid occasionally, as that in the cell becomes exhausted, recourse was had to the use of a quantity of acid crystals placed in the cells to become dissolved gradually, to furnish an uniform supply, for sustaining "constant batteries."

To provide a reservoir of acid, a quantity of the sulphate of copper or blue vitrol of commerce is put into the battery cell with the acid, in charging the battery. The atoms of zinc, in recoiling to their natural static conditions, become grouped with the atoms of the sulphur and oxygen of the sulphuric acid. And the atoms of oxygen previously united with those of the copper, become united with the atoms of the hydrogen set free by the decomposition of water, so as to reproduce water. No appearance of hydrogen, therefore, is perceptible in the cell of this kind of battery. The accumulation of bubbles of hydrogen is thus obviated.

The sulphate of copper battery, originally employed by De La Rue, is thus more effective than Smee's battery; but it is found that although the coating of bubbles of hydrogen is avoided, and a constant supply of acid is attained, yet the zinc becomes speedily coated with a scale of oxide, and with a coating of revived bright particles of copper. The only remedy for this difficulty is to withdraw the zinc plates and to scrape off the brown oxide and particles of copper adhering thereto. The crust of copper as well as that of oxide, accumulated on the plate of zinc, conspire to diminish the rapidity of the recoil of the zinc, and the consequent propagation of electro-dynamic reaction therefrom.

1178



The preceding defects have been, in a great measure, obviated by the ingenuity of Becquerel and Daniell, by protecting the zinc from the immediate access of the particles of copper and oxide. The zinc is inclosed within some porous substance, capable of intercepting the deposit of the obnoxious particles, as shown in the figure. In the sectional view given, C represents the outer copper vessel, serving both for containing the acid solution of sulphate of copper, and also to perform the function of a conductor. Within the copper cell is placed another smaller cell, made of porous earthenware, thus forming two distinct cells. The outer cell is used for containing the sulphate of copper, and the inner cell some other saline solution. The intervention of the porous vessel serves to keep the amalgamated zinc clean and bright for a longer time, and to impart to this battery a superior character as a "constant battery." The supply of sulphate of copper is furnished from a quantity contained in a muslin bag immersed therein, or from a deposit of it in the projecting nose of the outer copper vessel, as shown in the figure. Daniell recommends a mixture of eight parts of water and one of sulphuric acid, which is to be saturated with sulphate of copper, for the supply of the outer copper cell, the internal porous earthenware tube being filled with the same acid mixture without copper. The porous tubes should be well soaked in dilute sulphuric acid for an hour or two before being used; and after their removal from the battery, they should be repeatedly rinsed or soaked for some time in warm water to dissolve all the metallic salts from the pores; otherwise they will soon become broken, by the crystallizations of salts in the pores, like that of water crystallizing or freezing in bottles.

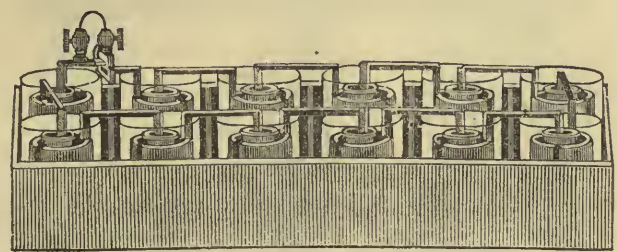
The zinc of commerce always contains more or less iron and other foreign substances, which develope minor circuits of counteracting currents, and essentially diminish the intensity of the excitation. To obviate this disadvantage, and also to keep the zinc plates clean and bright, Mr. Sturgeon originally applied a coating of mercury to the surface of the zinc. This coating serves also to prevent the wasteful recoil of the atoms of zinc to their natural polarized conditions whilst the battery is not in action by the connection of the battery circuit. This coating of mercury produces a result very different from

what might be theoretically anticipated; for, instead of protecting the zinc by preventing the immediate contact of the acid, it is found that the oxidated particles of zinc are withdrawn from beneath it, leaving the surface of the mercury clean and bright. The zinc is more rapidly decomposed by this arrangement, instead of becoming protected from further action of the acid, as occurs when a crust of oxide becomes deposited thereon. With this improvement the battery becomes far more "constant" than before, being capable of propagating a nearly unvarying electro-dynamic action during several days in succession, care being taken to provide an adequate supply of the crystals of blue vitriol, and to stir the solution in order to diffuse it equally throughout the external cell. For purposes requiring an uniform electro-dynamic action to be continuously sustained, as in the process of electro-plating metals, this form of battery is advantageous.

A still further improvement in the use of acids employed in battery cells, was made by Bunsen and Groves, by using nitric acid in contact with the platinum plate, contained in the porous earthenware vessel, shown in the preceding figure. Sulphuric acid, diluted with four or five parts of water, is poured into the outer glass vessel containing the zinc cylinder, which has a division in it to admit the acid freely both to the internal and external sides.

In the figure is represented a series of a dozen pairs of Grove's battery, in the order in which they are commonly arranged.

1179



Bunsen's battery is very generally used on the continent of Europe. Cylinders of carbon, in contact with the nitric acid, are substituted for platinum, the carbon being moulded to an iron tube, by coking pounded bituminous coal therein. By soaking the coke in sugar, and calcining it a second time, great compactness is given to the cylinder.

The Dry Galvanic Pile of De Luc is constructed of sheets of paper, coated on one side with gold or silver leaf, and alternated with thin leaves of zinc. By means of a circular steel punch, about an inch in diameter, discs may be cut out of sheets of this paper foil, all of one exact size, adapted to be packed neatly together in a long glass tube. The atoms of the leaves of zinc very slowly become united with the atoms of oxygen of the air recoiling to their natural polarized conditions of groupings of an oxide, whereby a feeble propagation of electro-dynamic action is sustained during surprisingly long periods of time. Mr. Singer constructed a dry pile of 20,000 series of discs of silver, zinc, and writing paper, which propagated an intense electro-dynamic action, like that produced by frictional electrical machines, causing a pair of pith balls of an electroscope to become divergent. A pith ball suspended by a silk thread between two metallic knobs, one connected by a wire with the top cap of the pile, and the other with the lower cap of the pile, continued to vibrate unceasingly between the two knobs during several years. A thin glass jar containing fifty square inches of coated surface, charged by ten minutes contact with the column, was found by Mr. Singer to propagate sufficient electro-dynamic action to fuse one inch in length of platinum wire of the diameter of $\frac{1}{5000}$th part of an inch. He states that an efficient Pile may be made of one kind of metal only, as of zinc foil, if one side be made bright, and thus rendered more readily oxidizable than the opposite surface.

The black oxide of manganese contains an extraordinary excess of oxygen, capable of freely uniting with zinc and other metals. Zamboni improved De Luc's Pile by coating one side of the paper discs with this substance, mixed with sulphate of zinc, and the other side with tin foil. These piles are capable of developing sparks across a space of air of $\frac{1}{16}$th of an inch, and also of producing chemical decompositions.

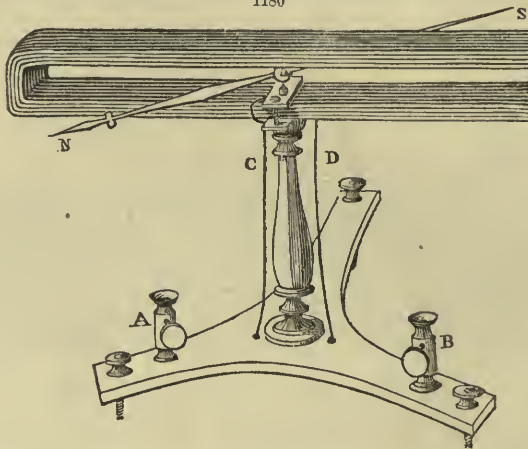
Taking advantage of the long sustained electro-motive power of the pile, an ingenious experimenter, Buzengeiger, attempted to render it available for operating the pendulum of a clock. By means of this arrangement of a Dry Pile, the pendulum was alternately attracted and repelled. It was thus made to move the clock-work, instead of receiving its motion therefrom, as in ordinary clocks. In the year 1815, he thus succeeded in constructing the first *Electrical Clock* ever propelled by electro motive power.

A great variety of other arrangements of galvanic batteries have been constructed with different kinds of metals, some of them with iron plates instead of zinc, and others to be operated upon by alkaline solutions, instead of acids. To describe them all would far transcend our limits.

Tests of Galvanic Action. The fact of the propagation of electro-dynamic action in the modified form denoted by the term "electric currents," is judged of by the test of the simple movement of the magnetic needle in swinging around on its pivot. The *degree of intensity* of the electro-dynamic action propagated, is judged of by the test of the extreme extent of the angle of its divergency from its natural north and south position; whilst the *direction* of the propagation of the electro-dynamic impulses near the needle is judged of by the particular crosswise direction in which a particular pole of the needle is urned or deflected to one side or the other.

Schweiger, in Germany, reasoning that if a single current passing directly along on one side of a magnetic needle exerted sufficient force to turn it on its pivot, it might be expected that by multiplying the circuits of the same current about the needle, the intensity of the electric forces would become multiplied to the same extent as the number of circuits, he accordingly wound numerous turns of copper wire (coated with silk to insulate from each other the overlapping coils) about a small piece of board. On withdrawing this piece of board, and inserting a magnetic needle within the cavity of the flattened coils of wire adapted to admit the needle to work freely therein, he constructed the *Galvanometer*—one of the most useful and important instruments now employed for testing the presence of the slightest propagations as well as intensity of electricity in motion; for in passing several hundred times about the needle, both above it and beneath it in the returning convolutions of the wire, its influence becomes correspondingly multiplied. Hence this instrument was originally called a "*Galvanic Multiplier*," as exhibited in the figure. N S, represents the needle inserted between the multiplied coils of wire, the ends

1180



of which, C and D, are extended downwards to the binding screws, A B, which are used for receiving and confining the ends of the conducting wires connected with the galvanic battery, or other bodies subjected to electrical excitation.

In using the galvanometer to measure the intensity of the electric force by the divergency of the magnetic needle, it is also to be noticed, that the scale of degrees marked on the circle does not denote the absolute force excited. A feeble electric current may cause the end of the needle to swing around over 10°; but by doubling the power of the current, it does not become urged to swing around 20°. The reason for this is obvious, the action of the deflecting force being reduced nearly in the ratio of the square of the distances of the separated conducting bodies and poles of the magnetic needles, and the action of the magnetism of the earth to bring back the needle to its north and south position being increased in proportion as the needle becomes turned more nearly at right angles to the north and south meridional lines.

For very delicately testing slight electric disturbances in experiments with the galvanometer, it is usual to employ an Astatic Needle, composed of two needles with their north and south poles reversed and confined together, to neutralize each other's terrestrial magnetism. This needle will remain stationary in whatever position it may be turned. The action to be tested is applied to the upper or lower needle, both being environed by spiral coils of the conducting wire.

In using a magnetic needle as a *galvanometer* to measure the intensity of electro-mechanical impulses, it is preferable to suspend it by silk cord or fine wire, requiring some exertion of motive power to produce a twisting, caused by the movement of the needle. The *torsional* resistance in this case becomes a test of the extent of the electro-dynamic action; whilst the deflections of the needle may be limited to a range of only about 20°.

Thermo-Electricity. Dr. Turner reduces the sources of heat to six in number;—1, The Sun; 2, Combustion; 3, Electricity; 4, The bodies of animals during life; 5, Chemical Action; 6, Mechanical Action. All these sources of heat are also sources of electrical excitation.

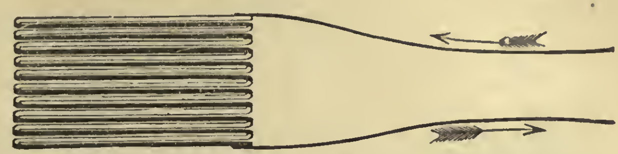
Thermo-Electric Batteries. The metals selected experimentally for producing the most intense excitation of electricity by means of heat, are German silver and silver, bismuth and antimony.

In experimenting with thermo-electric batteries formed of plates of bismuth and antimony, the bismuth being fusible at a low temperature, a very moderate heat must be applied. For this reason German silver and brass are preferred, as they admit of being safely excited by the contact of the red-hot iron, which will melt the bismuth.

To render the arrangement of the series of plates or wires of a thermo-electric battery more compact, they are laid side by side, as shown in the figure. They are insulated from each other by pasteboard, except at the ends, where the respective plates of bismuth and antimony, or of German silver and brass, are alternately soldered together, as in the arrangement of the series of plates of a voltaic pile.

The figure represents a series of ten pairs. The heat of the palm of the hand held in contact with the soldered ends of this battery induces sufficient excitation to affect a galvanometer needle.

1181



A more perfect thermo-electric battery is commonly constructed as exhibited in fig. 1182, consisting of 60 pairs of plates of bismuth and antimony, each ¾ of an inch broad, and ¼ of an inch thick. They are packed together in a case, B; but are insulated from one another, except at the soldered junctions of their ends, as above stated. The soldered ends of one series are arranged together on the under side of the case, where they may be heated by the radiation of the hot iron plate E, the edge of which only is

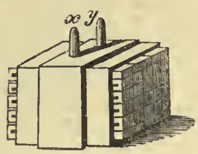
1182

exhibited in the cut. The opposite series of the soldered ends are arranged together on the upper side of the case, as seen at A, which forms a reservoir for receiving a refrigerating mixture of snow or ice and table salt. The plates are insulated from each other, and from the case, by pouring fluid plaster therein; which also serves to render the consolidated mass impervious to the water resulting from the melting ice.

By thus combining two extremes of temperature at the opposite ends of the plates, there is produced a correspondingly extreme disturbance of the temperature of the plates, and development of electric forces, as tested by the two conjoined iron semi-circles D, environed by a coil of the conducting wire C; whereby "a weight of forty or fifty pounds is required to separate them." Indeed, this thermo-electric battery is adequate to exhibiting various electro-magnetic phenomena which a galvanic battery is commonly used to exhibit; and also to give shocks and sparks.

The mechanical forces brought into action upon the needle of a galvanometer by slight disturbances of temperature, have been recently illustrated in an interesting manner by the experiments of Nobili and Melloni in France. The thermo-electric battery employed by them consisted of fifty small bars of bismuth and antimony, forming a bundle about one and a half inches long, and about one inch in diameter, inclosed in a band, as shown in the annexed figure. To facilitate the radiating and imbibing properties of the two extremities of the bundle of bars, the conjoined ends are all blackened. The extremities of the circuit are terminated at the two poles x, y.

1183



The bars of antimony and bismuth are insulated from each other by coatings of dry paper or silk throughout their lengths, and are soldered together alternately at their ends. The terminating bar of each series is separately connected with the ends of a wire forming the coil beneath the galvanometer n, m, fig. 1184, in the same manner as the copper and zinc plates of a galvanic battery are connected by the wires g and h, with the battery poles x, y of the preceding figure.

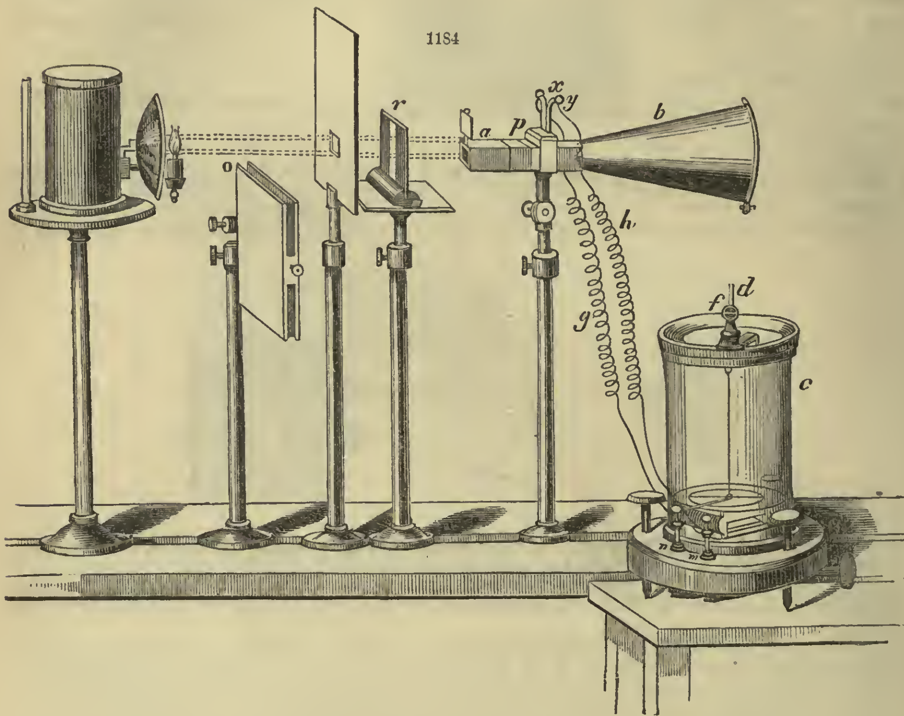
In the position of the instrument indicated in the figure, it is intended to denote at p, the blackened ends of the bars of the thermo-electric series, heated by a lamp, with a reflector. The dotted lines, representing the radiation of the heat through the aperture of the screen r; whilst the temperature of the other ends of the bars P, remains the same as that of the surrounding air.

The heat of the lamp induces a disturbance in the electrical equilibrium of the bars of antimony and bismuth. The electricity is determined to move in one uniform direction in a closed circuit through the conducting wires soldered thereto, and through the coil in proximity to the galvanometer needle; which is thereby swung around on its pivot. To prevent local disturbances of the needle by currents of air, the galvanometer is inclosed under a bell-glass, and is suspended from d by a very flexible fibre of silk. At o is a movable screen, designed to intercept the propagation of heat from the lamp, when an experiment is suspended.

The least radiation of heat from a lamp, or from the bodies of living animals, presented before the aperture of this instrument, causes the needle of the galvanometer to move around on its pivot. This thermo-electric battery, taken in connection with the appended galvanometer, constitutes a far more sensitive test of the approach of a warm body than the most delicate thermometer. The approach of a person within thirty feet of it, caused the needle to move, as stated by Nobili and Melloni. The slight heat of the bodies of insects, of phosphorescent wood, putrefying fish, &c., was thus detected. The ap-

paratus, therefore, constitutes a most sensitive THERMOSCOPE, far transcending the powers of any thermometer. A change of temperature of only $\frac{1}{1500}$th part of one degree of Fahrenheit's scale produces a perceptible movement of the needle!

1184



In the excitation of electricity by electrical machines, the movement of one portion of matter near another at sensible distances, each carrying with it its respective electrical atmosphere, reciprocally disturbs the state of rest of these atmospheres, and produces the phenomena of electrical excitation. This mode of exciting electricity by means of electricity, has received the name of *Inductive Excitation*, and constitutes a general law of the propagation of impulses through the medium of electric matter.

The propagation of action of electric currents across a space intervening between two conducting bodies, through the medium of the electric matter diffused throughout the atmosphere, appears to have been first noticed by Professor Faraday in the year 1832, and described in the "Annals of Philosophy," among the "proceedings of the Royal Institution."

"If two wires, A and B, be placed side by side, but not in contact, and a voltaic current be passed through A, there is instantly a current produced by induction in B, in the opposite direction. Although the principal current in it be continued, still the secondary current in B is not found to accompany it, for it ceases after the first moment; but when the principal current is stopped, then there is a secondary current produced in B, in the opposite direction to that first produced by the inductive action, or in the same direction as that of the principal current."

The nearer the circuits are approximated, the more intense is the resultant disturbance of the state of rest of the electric matter in the form of powerful sparks and shocks. For this reason thin plates of metal are wound into coils like ribbons, and substituted in place of wires, approximated only at arcs of their circumferences. The sides of the ribbons of metal are of course to be insulated from actual contact with each other by an intervening coating of silk or varnish.

1185

By using a coil of this copper fillet of the width of an inch, and of the length of two hundred and thirty-four feet, Mr. Noad states that a pair of zinc and copper battery plates of only $\frac{1}{8}$th of an inch in length and $\frac{1}{20}$th of an inch in width, were adequate to propagating sufficient electro-dynamic action to become manifest in sparks, on rapidly breaking and renewing the contact with the battery circuit; and with a large battery very brilliant sparks were visible.

The phenomena of the mechanical action of these *initial* and *terminal secondary currents* have been elaborately developed by the experiments of Professor Henry. He states that when the length of the wire in the coil of a helix is increased, the power of the battery continuing uniformly the same, the intensity of the shock is correspondingly increased, until finally, the greater resistance opposed by very long wires, to the passage of the primary exciting current, serves to counteract,

and even to reduce the intensity of the shocks. Whilst the shock from a small battery is increased by the intervention even of a short ribbon coil, that from a large one did not appear to be much increased thereby. But when the length of the coiled wire is increased in proportion to the increase of the size of the battery, then the intensity of the shocks becomes surprisingly increased.

He found that the current from a battery of 16 pairs of Cruikshank's arrangement, which produced only very feeble effects when transmitted through a short ribbon coil, gave shocks *too strong to be taken through the body*, when transmitted through a spiral coil of copper wire $\frac{1}{16}$th of an inch in diameter, and five miles long.

Whilst the intensity of the shocks of the secondary currents is thus increased by the extension of the length of the wire, the power of the primary current becomes correspondingly decreased as tested by its power of heating fine wires red-hot, and of deflagrating thin sheets of gold leaf, and of other metals. It was found also by Professor Henry, that these *secondary* currents produce the effect of inducing *tertiary* currents, and in like manner, subordinate currents of *fourth and fifth orders*, even up to the seventh, have been discovered to be induced in a series of coils!

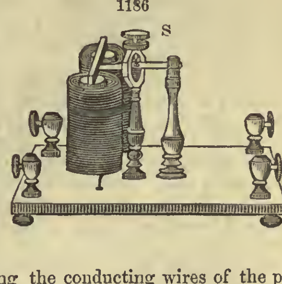
The remarkable facility of propagation of mechanical action through the medium of electric matter, by inducing the electro-polarization of series of atoms constituting conducting bodies, has been illustrated by many interesting experiments. The following demonstrate that the electro-polarization of a conducting wire is propagated not only through floors of rooms and other intervening bodies, to induce their electro-polarization, but even through great distances of intervening atmosphere. "A copper wire was suspended by silk strings around the ceiling of an upper room, so as to form a parallelogram of about sixty feet by thirty on the sides; and in the cellar of the same building, immediately below, another parallelogram of the same dimensions was placed. When a spark from an electrical machine was transmitted through the upper parallelogram, an induced current was developed in the lower one, sufficiently powerful to magnetize needles, although two floors intervened, and the conductors were separated to the distance of thirty feet. Two wires, about four hundred feet long, were stretched parallel to each other between two buildings; a spark of electricity sent through one produced a current in the other, though the two were separated to the distance of three hundred feet; and from all the experiments it was concluded that the distance might be indefinitely increased, provided the wires were lengthened in a corresponding ratio."

To prove that the same effect is produced by the action of the electrical discharges in the form of lightning in the heavens, Professor Henry made the following modification of the foregoing arrangement: "One of the wires was removed, and the other so lengthened at one end, as to pass into my study, and thence through a cellar window into an adjoining well. With every flash of lightning which took place in the heavens, *within at least a circle of twenty miles* around Princeton, sewing needles were magnetized in the study by the induced current developed by the wire. Being led from these results to infer, that induced currents must traverse the line of a railroad, I found that sparks were seen at the breaks in the continuity of the rails, at every flash of a distant thunder-cloud."

Professor Page gives the result of one of his experiments, made with a galvanoscope, connected with the metallic roofing of the Patent Office building, containing an area of twenty-two thousand feet of surface exposed to the atmosphere, and a plate of copper buried in the earth adjacent thereto. "I may safely say that the needle is affected by a flash of lightning one hundred miles distant."

In order to exhibit the experiments of secondary currents, and the consequent shocks and sparks, various kinds of machines or electrotomes have been invented for the express purpose of breaking and renewing the contact of the ends of the conducting wires with extreme rapidity. A self-acting electrotome, contrived with movable parts, to be operated by the motive power of the battery current itself, is now manufactured, for applying very conveniently a series of intense shocks for medical purposes.

1186



The primary current from a galvanic battery or magneto-electrical machine, is propagated through coils of insulated or coated wire wound about the two vertical ends of a bar of iron, bended to the form of the letter U, as shown in the figure; whereby this piece of iron is converted into a temporary electro-magnet, whilst the current circulates about it. Directly above the tops of the prongs of this temporary magnet is a piece of iron, serving as a *keeper* or *armature*, sustained by a spring, which allows freedom of motion to the cross-bar to descend in obedience to the attractive impulses, and causes it to rise from the ends or poles of the U shaped bar, at the moment the current ceases to circulate about the coils. The distance to which the cross-bar is lifted by the spring above the tops of the ends or poles of the electro-magnet, is adjusted by the screw S, which depresses the spring by the contact of its lower end therewith. The screw cups at one end of the machine are designed for receiving the conducting wires of the primary current from the battery, and are connected by wires beneath the base-board with the ends of the spiral coils wound about the bended iron bar. Leaving the extremity of the wire of the coils, the current flows beneath the base-board into the brass pillar, and through the screw S and flexible spring to the adjacent brass pillar, to which one end of this spring is attached. Descending this pillar the current is transmitted by wires beneath the base-board to one of the screw-cups at the end farthest from the electro-magnet, and thence through the circuit of the arms of the experimenter or through a connecting wire uniting the two screw-cups to the fourth cup adjacent to the electro-magnet, from whence it completes its circuit to the exciting battery. By this arrangement the electric shocks are propagated from the same wire which transmits the primary current.

When the connection with an excited battery is formed, the current transmitted about the coils environing the U shaped bar of iron converts this bar into an electro-magnet. The armature is instantane-

ously drawn down in contact with the poles adjacent thereto, depressing the flexible steel spring from its pressure and contact with the point of the screw S. Its contact therewith is thus broken; and consequently, the further circulation of the electric current about the wire coils wound around the poles of the U magnet is cut off. The immediate effect of thus cutting off the current is the cessation of further electro-magnetic action on the armature; which, on being released from its constrained position is urged upwards by the action of the flexible spring, until it comes in contact with the end of the screw S. This contact restores again the circulation of the current, which, in turn, again restores the electro-magnetic action, and brings down the armature. The separation of the spring from contact with the end of the screw is again produced, and this operation is repeated with such rapidity as to produce a humming sound, like that made by the rapidly-vibrating wings of a bee.

In his "Experimental Researches," Professor Faraday has classified the propagation of electro-dynamic action under three heads viz: by *Disruption*, *Conduction* and *Convection*.

Considering that all bodies which serve to propagate impulses of mechanical force through the medium of electric matter, represent simply pathways of electric currents, he has applied the term ELECTRODE to denote conducting bodies. To that particular end of the electrode at which the current is supposed to enter, he has given the name of ANODE, and the term CATHODE has been similarly adopted by him as a suitable term to denote the point of departure of the current from a conducting body. But instead of the idea of regularly flowing currents from atom to atom, and mass to mass, throughout the whole length of conducting wires and other bodies, it would be preferable to adopt the idea of the simple propagation and reception of mechanical impulses constituting the phenomenon of polarization, through the medium of the electric matter existing in connection with groupings of atoms, corresponding with the propagation of mechanical action by the undulatory waves of fluid water and air. On the surface of quiet waters the waves may be seen propagating the impulses simultaneously imparted to them from numerous disturbing causes, in equally numerous relative directions, the undulations crossing and recrossing each other, and even running in opposite directions, without interference. A similar result occurs in the propagation of impulses through the air in the modified form of sounds. The electric waves of polarization appear to be similarly propagated through the medium of the perfectly mobile electric matter by the waves of polarization of the atoms of the telegraphic wires.

Living vegetables and animals,		

CONVECTION. It has been noticed that the molecules of air, turpentine, &c., on becoming polarized are urged from the battery pole, thus propagating the electro-dynamic action in the modified form of mechanical movements of the atoms. These movements are considered as wafting the electric matter across a space occupied by air; and hence the term "Convective," has been applied to designate this mode of ferriage of electric matter, instead of its propagation by mechanical action through the medium of electric matter.

The term "disruptive" implies a breaking through, and is figuratively employed to denote the noisy discharges of lightning or electric sparks through the air. This mode of propagation is manifestly effected by *breaking through* the fluid atmospheres of all gaseous or aeriform particles, as the term *disruptive* implies. The propagation of mechanical action through the atmosphere appears therefore to be effected directly by displacing the particles in its progress, and by opening a void space therein. That this result is really produced by disruptive discharges of electricity is proved by the fact that sounds are caused by the collapsing of the displaced air into the void space left as an open pathway through a portion of transferred fluid. Sounds are similarly produced by the collapsing of the air into the void space produced by the action of a whip-lash in *snapping* it. The prolongation of the continuous sound of thunder-peals, or of "rolling thunder," is ascribable to a difference in the velocity of the propagation of sound and of electro-dynamic action. The undulations of the air advance with the velocity of only 1130 feet per second, or a little more than a mile in five seconds; whilst the undulations of the electric medium are propagated about a million of miles in the same period.

The various expedients devised for the protection of buildings, and of the occupants of them, from injury by disruptive discharges of lightning, are all founded on the principle of providing some more readily polarizable body than the materials employed by masons and carpenters in the construction of edifices.

* *Lightning Conductors.*—The first lightning conductors consisted merely of metallic rods or chains proceeding from the highest point of the building or the ship, in a direct line to the earth or sea; but this was not found in all cases sufficient. Instances have occurred in which the conductors have been fused or

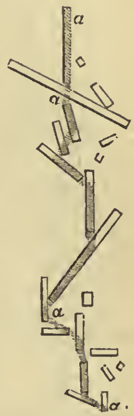
* Aide Memoire to the Military Sciences.

shattered, and hence arose a prejudice against their use, under the idea that they did more harm than good, by inviting the destruction they were intended to prevent. An attentive examination, however, of numerous cases of damage from lightning has shown that the path of discharge from the cloud to the earth is always in the line of least resistance. This line may not be the shortest lineal distance, but it is in all cases the shortest electrical distance; that is, the lightning picks out the best conductors in its transit to the earth, selecting with the nicest discrimination metal cramps and fastenings, and by its expansive power shattering and destroying inferior conducting substances, such as wood, brick-work, and stone.

The following diagrams from experiment, illustrate this principle fully:

1183.

1182.



Figs. 1182 and 1183. The shaded part shows the direct track *a a* taken by the electric fluid along a line of metallic conduction, disregarding every thing but its own course. Fig. 1182 may represent the conducting masses in a building. Fig. 1183, the passage of the fluid across the bight of a wire-rope, or of a chain.

Hence the principal danger in using chain or wire conductors in the upper masts of shipping, as when these last are lowered they are apt to leave the chain or wire-rope hanging loosely; and when handling this as a bight, the seaman's body becomes the shortest course (*a' a'*, Fig. 1183) for the electric action, on the very same principle that a metallic rod-conductor of proper dimensions may be passed through a barrel of gunpowder with perfect safety, though a chain would ignite it at once.

To guard effectually a structure from the stroke of lightning.—First: The conductor should be of metal, and one of the best conducting metals should be selected. Second: The conductor should be capacious. Third: The conductor should consist of several branches with pointed rods projecting freely into the air from distant summits of the building, and connected by horizontal branches passing along the ridges, and from these sending off other branches to the ground.

Copper is the best conductor: the rods should not be less than half an inch diameter, if solid; three-fourths of an inch is preferable, and generally ample. If hollow, they may be from 1 to 2 inches in diameter, and about one-fifth of an inch thick.

If iron rods be used, they should not be less than three-fourths of an inch diameter when solid: if hollow, not less than 2 inches diameter and three-tenths of an inch thick, and jointed.

The hollow conductor (if sufficiently thick for stability) is better than the solid rod of equal length and weight, because the metal should display as much surface (in lateral dimensions) as possible consistently with strength, to reduce the intensity of action on surface, and heating effect in transverse sectional area; but unnecessary length should be avoided.

The conductor should involve in its course the principal detached masses of metal in or on the actual walls and framing of the building or ship: if not allowed this course freely, it will be apt to take it in a summary and violent manner. Figs. 1188 to 1192.

It should be placed as close as possible to the walls, &c., which are to be defended,—not at a distance from them; and should be carried down at once directly into the ground; and when below the surface, it should then divide into two or more pointed branches *a a a*, Fig. 1187, slanting away from the building. If circumstances permit, the lower end should pass into a well, or a stream, or a drain, or at all events into earth that can generally be kept moist from any neighboring gutter. It is a useless precaution to pass condctors through glass linings and holdfasts, as has been recommended, since the lightning will always take the direct course down the rod until interrupted; on which last account chain conductors are very inferior to those of rod, being a series of interrupted conductions from which the lightning is ready to turn aside at any point of contact of the links,—provided that at such point a freer and easier line of conduction be offered by some neighboring body than what the chain itself affords.

The conductor should be attached to the most prominent points of the building, Fig. 1190: if its length be very considerable, its transverse dimensions must be increased; and in doing this, the provision for a sufficient conducting surface insures that for the heating effect.

In ornamental buildings, such as honorary columns, &c., for the sake of appearance, the conductor may pass down withinside; it must, however, be firmly fixed, and the line of conduction made and kept complete and undisturbed.

In extensive ranges of buildings, all the most prominent points should have long pointed rods projecting freely into the air, at least 4 or 5 feet above the building; and the larger the range the higher they should be. Fig. 1190.

It does not appear that any single conductor hitherto made can insure beyond a horizontal radius of 40 feet; hence, in practice, less should be taken; though a wider range may be allowed if the roofs be of zinc, lead, copper, or any other metal in *well-connected* sheets; or if the ridges and hips only be thus guarded, and the whole well joined to the conductor, and to iron gutters and pipes, now commonly used, and a free passage be provided to the ground at different places. The points of contact must be numerous, to reduce the heating effect (or chance of fire) at such points, as the whole electric action will condense there, having still to pass through them on its way down. There is no reason why lightning conductors should not be painted or lacquered.

In addition to the diagrams given in Figs. 1184, 1185, and 1186, showing the construction of hollow conductors for buildings,—those for the protection of shipping, Figs. 1189 to 1192, are likewise noticed, as probably providing for the most complicated cases that are likely to occur in the most extreme cases on land.

Fig. 1186, the head of the conductor.

Fig. 1187, conductor complete, showing the lower termination *a a a* as buried in the ground, or received in water.

Fig. 1188, application of conductors; the points *a b c d e*, &c., connected by bands of metal *c n d t e h*, &c., into one general whole.

Fig. 1189, ships' conductors, consisting of two strips of sheet-copper, from 1·5 to 5 inches wide, and from 1-8th to 1-16th inch thick, in lengths of 4 feet. They are let double into a groove in the mast, so as to insure continuity of conduction by breaking joint, as shown in the figure: these strips are kept in thorough contact, and are secured to the mast by copper nails, 6 inches apart, in the drilled and countersunk holes *d a*. The upper surface of the upper piece A A is slightly rounded, so as to conform to the surface of the mast in transverse section.

Fig. 1190, the cap *a b* and the hole *b* through which the moveable mast *e x* slides, are furnished with similar plates; these are led from the square hole at *a*, by which the cap *a b* is fixed to the head of the mast D, into the round hole at *b;* and there is a lining of copper in this part of the hole next to the conductor at *b*, by which the metallic line is continued to the next mast D.

Figs. 1191, 1192, the bolts *a b c d e f*, passing through the ship, and in which the general line of conduction terminates, are clenched upon metallic rings and plates, in connection with the copper sheathing; and there are additional bands *m n*, Fig. 1191, leading from the fore-mast and mizen-mast directly to the stem or stern under the decks; other bands *g h*, Fig. 1192, traverse the beams, and they all terminate in the sea by bolts clenched on the copper sheathing. Fig. 1192 is a section suited to the beams abaft each mast.

Electricity applied as a moving power.—The operation of voltaic electricity in magnetizing iron, and the disappearance of the excited magnetism directly its action is suspended, or nearly so, has furnished a means of obtaining to a certain extent a considerable moving force applicable to the purposes of machinery.

Mr. Cook, of Saratoga, made an interesting exhibition of an electro-magnetic machine, in the year 1838, in Barclay street, New York. The whole apparatus was of the most simple construction, consisting of two sets of magnets, one revolving within the other. The external magnets being excited by the fluid generated by the action of an ordinary galvanic battery, while the polarity of each magnet was constantly and regularly changing, a perfectly uniform motion was communicated to the cylinder, which might be increased indefinitely as additional force is applied. The machine was thirty inches in diameter, and contained seventy-eight magnets, each weighing four pounds. The machine, in full operation, made eighty revolutions per minute—considerably more than can be obtained by the force of one man.

Professor Jacobi, of St. Petersburg, by means of an engine on this principle, succeeded, in the years 1838 and 1839, in propelling a boat upon the Neva at the rate of 4 miles an hour. This boat was 28 feet in length, about 7 feet wide, and drew nearly 3 feet water. It contained 10 persons; the engine was worked by a voltaic battery of 64 pairs of platinum plates, excited with nitric and sulphuric acid, and propelled the vessel through the medium of paddle-wheels.

A large *Electro-magnetic Locomotive Engine* was constructed by Mr. Davidson, and tried on the Edinburgh and Glasgow railway, the account of which, with drawings, was published in the Practical Mechanics' and Engineers' Magazine, for November, 1842. The carriage was 16 feet long and 6 feet broad, and weighed above 5 tons, including the apparatus of batteries, magnets, &c. This Electro-magnetic Locomotive was propelled by means of electricity with a velocity of only about 4 miles per hour.

Professor Page, in his lectures before the Smithsonian Institution, exhibited a bar of iron weighing one hundred and sixty pounds, which was made to spring up by magnetic action, and to move rapidly up and down. The force operating on this bar, he stated, averaged *three hundred pounds*, through ten inches of its motion. He then exhibited his engine of between four and five horse-power, (operated by a battery contained within a space of three cubic feet,) with two feet stroke, the whole weighing about one ton. It made 80 strokes per minute, whilst driving a circular saw ten inches in diameter, sawing up boards into laths. He has since experimented with a locomotive engine on the Washington railroad. The engine was propelled at the average rate of ten or twelve miles in an hour. Many other experiments have been made, but as yet no machine has been produced practically useful.

Amongst other applications of electricity to useful purposes, the application of magneto-electrical action in arresting the oscillations of the compass-card on board ship is not the least important. Electrical currents are excited in non-magnetic metals, such as copper, zinc, &c., when placed near a magnet in motion, or when themselves set in motion near a magnet; and these currents so tend to arrest the motion, that if an ordinary magnetic needle be caused to oscillate within a ring of copper, the amplitude of the oscillations rapidly diminishes, and the needle is speedily reduced to rest. On this principle, the common compass-card employed at sea is placed within a dense ring of copper,—the poles or extremities of the magnet being near the interior of the ring; this, with some valuable and judicious improvements in the construction and mounting of the needle, so fetters the vibrations, that even although the instrument be extremely sensible of the least motion, and of the action of the magnetic force of the earth, yet the compass-card is found steady in the heaviest sea, and under the violent motion of steamboats when struggling with a gale.

For further and still more important applications of electricity to the improvement of the arts, and the conveniences of life, see the following articles: also, BLASTING and TELEGRAPH.

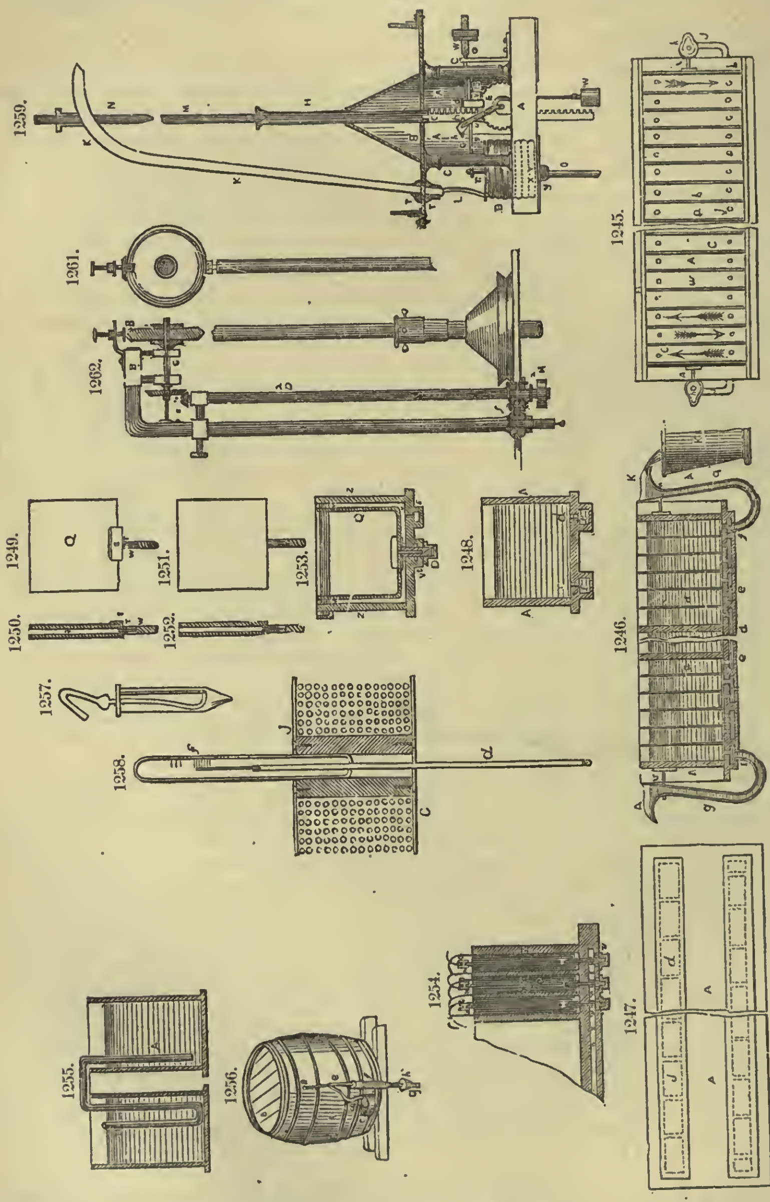
ELECTRIC LIGHT. The improvements in the construction of galvanic batteries consist in making them on what is termed the "perfluent" system of supply and discharge, to contradistinguish it from the "percolating" system, which has recently come into extensive use. According to the percolating system, the liquid employed (usually sulphuric acid) is supplied to and discharged from each of the cells of the battery, in separate and distinct streams or series of drops; the liquid, as it becomes exhausted, though not entirely so, dropping out through an orifice in the bottom of the cell, and being then allowed to run to waste, and the place of the discharged liquid being supplied by fresh drops descending from above into each cell. But, according to the new system, the liquid is supplied in one stream only, which passes continuously through the entire series of cells, entering by the first cell of the series, and passing off through the last. No diminution of electric intensity is observed to take place in the perfluent battery, from bringing the cells into communication with one another, owing to the circuitous course which the fluid is made to take between cell and cell. In proportion, of course, as the duration of the transit through each cell is shortened, the chance must be proportionally lessened of each portion of the liquid coming into contact with the acting metal or element in that cell; yet, as no drop of the fresh liquid supplied to the battery can make its way to the final discharge outlet without going through the whole of the cells, what it misses in the first cell, it is sure to encounter in one or other of the remaining cells. The cells last in order of a perfluent battery necessarily act less powerfully than the earlier cells of the series; as, for example, the last six cells of a series as compared with the first six. The diminution of power, that is to say, the quantity of electricity which the cells are capable of circulating, does not appear, however, to follow exactly in the ratio of the strength of the exciting liquids; for the difference in power between the middle and initial cells of a series is proportionally not so great as the difference between the middle and the terminal cells. When it is desirable to obtain intensity in the electric current rather than great quantity, the terminal cells should be made about equal to the quantitative power of the others, by uniting the similar conducting wires of several cells together, and using them as if proceeding from one cell. Thus, as it would be technically expressed, the last three cells in a fifteen-cell battery (say the 15th, 14th, and 13th) might be connected for quantity, and the two next preceding pairs (say the 12th and 11th, and 10th and 9th) be connected also for quantity, and the first eight cells might be worked singly, in the usual manner of a series. But, however great may be the differences in power between the initial, middle, and terminal cells of a series in each cell, regarded by itself apart from the others, the degree of exhaustion, and consequently of electric action, is always very nearly uniform throughout every part of the cell.

The details of a battery constructed on this perfluent principle are represented in Figs. 1245, 1246, 1247, and 1248 of the drawings annexed. Fig. 1245 is a view of the battery, as seen from above; Fig. 1246 is a vertical longitudinal section; Fig. 1247 is a view of the trough from beneath; and Fig. 1248 is a vertical cross-section. A is a wooden trough, the parts of which are firmly bolted together; *a a* are slate partitions, the edges of which fit closely into the sides and bottom of the trough, and are about two and a half inches apart; *b b* are thicker partitions of wood, which are inserted at short intervals, say every six cells, and made fast to the sides by screws and nuts; $c\,c^1$ are two parallel rows of holes made in the bottoms of the cells, two in each; $d\,d^1$ are two corresponding rows of wooden covers, which are made fast to the bottom of the trough, Fig. 1247, one underneath each adjoining pair of holes, as $c\,c$ or $c^1\,c^1$, with the exception of the two end ones, which cover one cell only; *e* is a groove cut out in the upper surface of each cover, and made just of width enough to embrace two of the cell holes, as $c\,c$ or $c^1\,c^1$, and so establish a channel of communication between them; *f* is an aperture made in the bottom of the end cover of the series of holes; *d* and f^1, similar apertures in the bottom of the opposite end of the same series of holes, into each of which apertures there is inserted a piece of copper tubing, to which there is attached one end of a flexible hose, *g* or g^1, (made of vulcanized caoutchouc, gutta percha, or any other suitable substance or combination of substances,) which terminates at the other end in a funnel *h* or h^1; and $i\,i^1$ are eye-bolts affixed to the ends of the trough on the outside, which respectively sustain in an upright position the funnels *h* and h^1, there being a slit or opening in the eye of such bolt, to admit the neck of the funnel. The whole of the inside of the trough is well coated with marine glue.

The mode of operation with this apparatus is as follows: The liquid is poured in at the funnel *h*, and passes into the first cell through the hole *o* of that cell; from the first cell it goes out through the hole *e* into the first of the grooved covers of the series *d*, whence it flows into the second cell through the hole *c'* of that cell; from the second cell it next passes through the hole *c* of that cell into the second of the grooved covers of the series *d*; and so on to the end of the series, (as indicated by the arrows in Fig. 1245,) when it discharges itself through the flexible hose *g'* and *h'* into a receiving vessel K.

The arrangement just described is, however, chiefly suitable for those batteries which use but one sort of exciting liquid, but in batteries where two fluids are used it may be expedient to adopt the modifi-

cation of the perfluent system represented in Figs. 1249 to 1254. The internal cells in this case are supposed to be made of earthenware or some other porous material. Fig. 1249 is a side view of one of these cells, and Fig. 1250 a vertical section across the middle. A hole Q is made in the bottom of this cell, and into this hole a varnished copper tube *r*, with a collar and washer of vulcanized caoutchouc at top, is dropped. The tube is pulled tightly down upon the washer, in order to prevent any of the liquid escaping between the washer and the bottom of the cell. Or, instead of this arrangement, one of the escription represented in Figs. 1251 and 1252 may be substituted. S is a cradle which is cemented on



to the under end of the cell by marine glue, and encloses it completely. The tube *r* is screwed on to the bottom of this cradle, and through it up to the hole in the cell. In both cases the tube has an oval aperture *w* cut transversely through it, and terminates at its under end in a solid screw-point. The trough for the reception of porous cells of this description is made in the manner represented in Figs. 1253 and 1254; the former being a transverse vertical section of the trough through the centre of one of the cells, and the latter a longitudinal vertical section. Q is the internal porous cell and Y the zinc plate suspended therein. X X are the plates of negative surface, say copper, placed outside of the porous

cell. Z Z Z are the sides and bottom of the trough, the spaces *m m* between which and the porous cell form the external cell, which contains the second fluid, (say sulphate of copper.) A^a is an open channel for the discharge of the second fluid, which runs along the outside of one wall of the trough, near to the top, and communicates by lateral apertures *p p* in the wall, with the spaces inside *m m*, appropriated to that fluid. V is a grooved or channelled under-cover, which extends along the bottom of the trough from end to end, and comes immediately under the line of holes in the porous cells Q. The lower end of the tube *r*, which is attached as aforesaid to the bottom of each porous cell, and enclosed by the cradle, is passed downwards through an orifice in the bottom of the trough, and also through another orifice in the bottom of the under-cover V, till the oval aperture *w* in the tube coincides with the groove *t* in the bottom of V; so that when the whole of the cells are fixed in their places, the channel *t* forms through the medium of the apertures *w w* a common channel of communication between all the cells. U is a nut which takes on to the end of the solid screw-point of the tube *r*, and by turning which the parts S, *r*, V, and Z are all screwed tightly together. For the sake of greater security against leakage, and against the intermixture of one of the fluids with the other, washers of vulcanized caoutchouc are inserted between the crade S and the bottom of the trough, and between the bottom of the grooved channel V and the shoulder of the nut U. E is a second under-cover which runs parallel to V, (on one or either side of it;) the groove *e*, in which the second cover communicates by a series of holes *n n* with the external cells above, containing the second fluid, serves as a common channel through which these cells may be supplied from a flexible hose. The second fluid is, after passing through the external cells, discharged from the end of the channel A^a.

The perfluent system may be also carried into effect by employing siphons instead of the grooved under-covers *d d'*, V, and E, before described, to transmit the liquid from cell to cell successively, as shown in Fig. 1255, which represents two adjacent cells of a battery. The long end A of the siphon descends to near the bottom of one cell, in order that it may carry over the densest portion of the liquid therein, and deliver it through the short end B into the next cell. Or, if the liquid employed is of such a nature that it becomes lighter as it becomes exhausted, (sulphate of copper, for instance,) then the legs of the siphon are reversed, the liquid entering it by the short end, and being carried over by the long end.

Part of the invention consists in attaching to all galvanic batteries in which a gradual change of liquid is required, an equilibrated hydraulic cistern and graduated meter, such as represented in Figs. 1256 and 1257. A is a cask, closed at top, so as to prevent the action of the atmospheric pressure on the surface of the liquid contained in it; and *b* is an orifice near to the bottom, which opens into a small outer cistern *c*. This arrangement ensures that the liquid flowing through any channel from the little cistern *c* will always flow at the same rate, whether the cistern be full or nearly empty. From this little cistern a loose piece of vulcanized caoutchouc tubing *d* proceeds, and is connected with the glass tube *e*, from which is suspended the meter *f*, having a small hole at the bottom, so that the rate of flow out of this hole is indicated by the height at which the surface of the liquid stands. The meter is graduated to units, which shows the amount of flow requisite to supply the chemical action which is going on in the battery when the electric current is circulating at a rate indicated by corresponding units on the galvanometer described in Fig. 1258, which is included in the circuit. The meter, with its tube *d*, is suspended so as to enable the rate of flow to be adjusted by hanging it at an altered level in relation to the cistern, according as the galvanometer may indicate to be necessary. The parts *d e* form in fact a siphon, which only requires to be filled with liquid when the apparatus is first set in action, after the cistern is charged. The liquid issuing from the meter is received by a funnel *h*, or otherwise led to the battery.

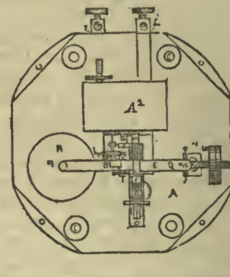
Also the employment in galvanic batteries, having copper or mercury for the negative element, of a liquid amalgam of zinc and mercury, enclosed in a bag or case of lawn or horse-hair cloth, or any other finely reticulated fabric, but not made of metal, which allows of the acid passing freely through its meshes to act on the bottom and sides of the zinc amalgam, while the bag or case retains the amalgam itself.

Again, the employment of lead as the positive element in galvanic batteries, (instead of the zinc which is now commonly used,) combined with a solution of nitric acid or of acetic acid, in some one or other of the forms best calculated to act on the lead.

The new galvanometer is such that it can be made a permanent adjunct to, or part of the battery, so as to be always indicating what amount of electricity is circulating when any sort of duty is being performed by it, and the weights of materials combining or used per minute at any particular time. This improved galvanometer consists of a thick piece of insulated copper wire A wound round a wooden or brass cylindrical centre, fitted with ends C C. One end of this coil is in metallic connection with the positive or negative pole of the battery, and the other extremity is placed in connection with the part of the lamp, (or other piece of mechanism for actuating which the battery is used,) which would receive the conductor from the said pole of the battery. In the hollow cylindrical centre of the coil there is placed a rod of soft iron *d*, as shown in the figure, which moves loosely up and down in it, and is prolonged by a short brass stem or index *e*. A graduated scale *f* is fixed to, and rises from, the upper end of the coil, so as to show the height at which the electric influence causes the index to stand. The graduations are represented in the figure as marked on a glass tube, within which the index and rod *d* slide. These graduations are so made as to indicate the number of grains of pure zinc consumed per minute in each cell of the galvanic series, the current produced by which causes the index to stand at each such division of the scale. Any galvanometer of this kind can be graduated from a standard one. The standard can be graduated by ascertaining experimentally the weight of zinc consumed per minute, but a less tedious process is to graduate it from a Petrie's Galvanometer, which indicates all the required units of electricity and their fractions, by means of weights; the accuracy of that instrument being first tested by one such direct experiment on the zinc consumed. This improved galvanometer may be made of a shorter and thicker wire, making fewer coils, if the iron rod is partially counterpoised by a spring or weights, or hydrostatically with mercury.

Figs. 1259 and 1260 are representations of a lamp embodying this improvement. The skeleton of this lamp is composed of a foundation-plate of wood A, a sole-plate B of brass, firmly connected by pillars C and a three-legged stand K rising vertically from the sole-plate B, the feet of which are fastened to B by nuts beneath, but insulated by circular washers of dry hard wood (of the form shown in section *i j*.) A hole is bored vertically down through the centre of the top of the stand K, into which hole the upper electrode N is fixed by three metal wedges jambed into key-ways or channels, sloping upwards and outwards, so as to keep the inner faces of the wedges parallel to the central axis. A glass shade is fixed to the sole-plate B so as to cover K. H G is a shaft which slides vertically into the central axis of the lamp, through holes in A and B, and has a socket at top which carries the lower electrode M. The lower part G is cut with teeth which work into a pinion F, which turns on a spindle in fixed supports. A barrel F′ is attached to the pinion F, and a weight W is suspended by a string which passes round F′ and is fixed to it, so as to counterpoise the weight of H G. On the spindle of the pinion F is fixed a wheel E, having square teeth. A lever T turns loosely on the same spindle as a fulcrum, and carries a double pawl U V, which turns on a pin which projects from the side of T, so that this pawl U V can lock into the teeth of the wheel E in either direction. A long horizontal lever Q passes over this pawl from a joint or fulcrum *a*, and this lever carries a light spring or tongue *l* close beneath it, the end of which is kept from springing away from the lever by resting in a step in a little stirrup or fork *d*, which is attached to the lever Q, and embraces the wheel E and the end V of the pawl. The pawl and its lever T are kept in a state of slow vibration from side to side by means of a crank S, which works in a fork at the end of T, the crank S being made to revolve by an ordinary train of wheel-work, furnished with an escapement or fly-wheel A², and driven by spring power or weights. When the lever Q is turned a little downwards its tongue *l* presses V into the teeth of the wheel E, and the vibratory motion of T causes V to drive the wheel round, notch by notch. The wheel does not follow the pawl in its back motion at every stroke, for this is better ensured by having a spring *n* (Fig. 1260) fixed to A, and pressing against the side of G. This motion of the wheel causes the pinion to elevate the rack G slowly, so as to raise its electrode M towards N. But when the lever Q is raised or turned upwards, the notch in the stirrup lifts the tongue *l* off V, and allows U, the heaviest end of the pawl, to drop into the teeth of the wheel E. This drives it round in a contrary direction, so as to lower the rack G and draw its electrode M further from N. Whenever the lever Q is raised, the lower step in the stirrup *d* catches the sides of V and draws it (V) up out of the teeth of the wheel, in case V should have become jambed or hitched in the teeth, so that the counter-weight of U might be unable to release it. The means by which the end of the lever Q is raised or lowered are these: R is a regulator coil, one end of its wire is connected with the binding-screw *e*, and the other end, L, is brought up and fixed in contact with K. An iron rod O moves freely up and down in the central hole of the coil, and is prolonged upwards by a stem of wood *p*, by which it hangs to the end of the lever Q in the manner shown in Figs. 1259 and 1260. The rod O passes through a hole in the centre of a cup *y*, which screws into the bottom of the coil-case. Around O there is a circular weight X which rests on a small step in O when O is raised. When O sinks below its medium position it is left behind, resting on the edge or rim of *y*. The object of this arrangement is, that when O is actuated by a force equal to its own weight, added to half the weight of X, then it will have a tendency to return to its medium position, with a force of half the weight of X, whether it be raised higher or sunk lower than that position. The mode of action is as follows: The end of the negative wire from the battery is set in the binding-screw *f*, and is conducted thence by a metal connection to the supports of the spindle of the pinion, and to the spring *n*. The current passes through these into the rack; thence to the lower electrode M, from which it passes to the upper one, N, producing the light between them. From N it proceeds through the stand K to the wire L, of the regulator; thence to the clamp *e*, which is in connection with the other end of the regulator wire, and into which the positive wire from the battery is clamped to complete the electric circuit. The current, in passing through the regulator, tends to raise the iron centre O, which being connected to the lever Q, is counterpoised by the weight W¹, which screws along an extension of the lever beyond the fulcrum *a*. To put the lamp into adjustment, the driving geer being wound up, and the battery being in a state of activity fit for the permanent action intended to produce the light, and its wires connected with *e* and *f*, as described, the lever Q is raised by hand until the electrodes have separated to the greatest extent compatible with obtaining a permanent light from them. The screwed weight W¹ is turned backwards or forwards until it keeps O balanced, just so as not to sink below its medium position, when the electrodes are separated as aforesaid. When in this position, the shoulder of O touches the weight X, which is resting on the rim of *y*. The lever Q carries a little projecting piece or catch *g*, which meets the bent arms attached to the crank-spindle S, and thus arrests the motion of the crank, when the lever lies so that O is in its medium position; but whenever it rises above or sinks below that point, the catch *g* allows *h h* to pass beneath or over it accordingly, so that the crank can revolve freely and work the ratchet U V.

1260.



A front view of a lamp on this plan is given in Fig. 1261, and a side or edge view in Fig. 1262. A¹ is the disk, which, as shown in section, Fig. 1262, resembles in its form two cones, placed base to base, so that there is always one sharp or feather-edge in sight of the negative electrode, which is of the ordinary single-cone form. B¹ is the scraper; B² is a frame which carries the shaft C², to which the disk electrode A¹ is attached. D² and E² are a bevelled wheel and pinion, which geer into one another, the latter being fixed to the shaft G². At the bottom of this shaft there is another wheel H², to which the clock-work or other apparatus for giving motion is attached. The shaft G² may be insulated in various ways, either by the interposition of plates of ivory or wood, J K, screwed together, or by gutta-percha or india-rubber rings.

To increase the temperature of the metallic electrode A^1, the operator sometimes passes the metallic holders B B through a block of glass D D D, or some other similar bad conductor of heat, as represented in Fig. 1263, so that the heat and radiant light may be developed with as little loss of the former as possible by radiation.

An elevation of a small iridium bracket lamp is given in Figs. 1264 and 1265. A^1 is the electrode of iridium, which is fused on or otherwise fixed to two pieces of platinum B B, which are fixed into two copper or other metallic holders C C. These holders are insulated by means of ivory, wood, or vulcanized india-rubber washers D D, or some other suitable non-conducting substances, so as to prevent contact with the bottom metal plate of the lamp E. To one of the metallic holders a copper wire a^1, passing through the hollow tube B^1, is connected with one pole of the battery, and the electric circuit is completed, and the current made to pass through the brass-work of the lamp to the electrode, by turning the ivory knob X, which is attached to a screw-shank Z, making a metallic communication with the other holder. W Y is a ring of brass, which is screwed into the bottom of the lamp. A glass shade, of any shape or form, may be placed on the plate E.

Fig. 1266 represents a triple electrode suspending-lamp. A A A are three ivory knobs, with metallic shanks, for making the necessary communication, as before described.

An apparatus embodying the chief of these arrangements is represented in Fig. 1267. The parts in this apparatus which are similar to those in the permanent light apparatus, Figs. 1259 and 1260, before described, are indicated by similar letters. A helix coil of insulated copper wire A, is employed for the purpose of producing the prime-moving force which actuates the sliding shaft which holds the electrode. This helix is fixed to the bottom of the framework C C′ C″. A cylinder of soft iron, B, moves freely up and down in it; to the top of B is fixed the rack E, which slides through the hole at c'', and carries the electrode M, fixed in a socket, so that this shaft can move the electrode M to or from the lower end of the electrode N, which is fixed in the top of the tripod K by wedges or screws. K is fixed and fur-

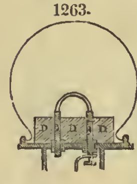
1263.



nished in the same manner as that shown in Fig. 1259, and before described. The weight of the shaft B E is rather overbalanced by the weight Q, which is attached by a string passing over a pulley R to B. A pinion F works into the rack E, and fits it loosely with a back lash of about a tenth of an inch. The pinion F is connected with an ordinary train of multiplying wheel-work (concealed behind the brass plate c''') and terminating by any well-known sort of fly or escapement motion of such kind, that F Y will be prevented from revolving quickly, but will at the same time yield with a slow motion to any slight force from the rack E, so as to prevent the rack E from moving up or down too quickly. The negative wire from the galvanic battery is connected with one end of the helix coil A, and the other end of it is soldered to the brass case, so that the current passes through the helix wire to its case, and thence by means of the springs D which are fixed to the case, and are in contact with the iron cylinder B, up the shaft D E, to the electrode M, whence it flows through N, down K, and returns to the positive pole of the battery, by means of the wire y. But when the current thus passes the helix, A causes the shaft B to be drawn downwards, which motion separates the two electrodes M N, and light is evolved until the electrodes become too far separated, when the current suddenly ceases, the light becomes extinguished, and the helix ceases to draw B downwards, when the weight Q begins to draw it upwards again, until the electrodes touch one another, whereby the electric current is re-established, and the light is repeated as before.

The apparatus which has been described, Fig. 1267, may be modified in manner following: Fix a regulating coil with a properly weighted iron centre, &c., just like that described in Fig. 1259, (at R, o,

p, x, y.) This coil is fixed to *c*, Fig. 1267, and its wire is permanently included in the electric current and O, instead of P, moving a ratchet V V; when it drops, it presses a spring or lever in connection with the negative wire from the battery in contact with the shaft B, so that most of the electric current passes from the negative wire through the lever to B direct, and B is no longer drawn down by the action of A, but begins to rise by the force of the weight Q, which in this modification of the apparatus is made to overbalance the shaft as it does in Fig. 1267.

The apparatus employed, Fig. 1267, in any of the preceding modifications may be made to act by substituting the arrangement shown in Fig. 1268, for the parts A and B, which gives a greater moving power, and allows the electrode shaft to move through a long space not limited by the length of the coil A. A′, Fig. 1268, is a helix coil, similar in construction to A, but differing in form, as is indicated in the sectional view, Fig. 1268. A short hollow cylinder B′ is substituted for B; a brass rod B″ (or a bar "feather edged," for the sake of lightness) passes freely through B′, and ratchet teeth are cut in it as shown, by which a spring ratchet *g* suspends B′, in the position shown in the engraving. An end H, which screws on to the top of the central tube of the coil A, carries the conducting springs D D, and guides the shaft B″; when the shaft B″ rises (carrying B′ with it) it brings the projecting end of the ratchet *g* against the slanting side of H, the pressure of which pushes the ratchet out of the teeth and lets B′ descend for the space of one notch or tooth, so that B′ is always ready when the current in A′ acts to draw the shaft B″ a fraction of an inch lower, and yet does not prevent the shaft from gradually moving upwards to any extent to supply the waste of the electrode, while B′ never follows the shaft higher than H.

The helix coil last described, Fig. 1268, may have its action on B′ augmented by making certain parts of the case in which the coil is wound, to be of soft iron in place of brass, as shown by the section of the case in Fig. 1269, the parts marked *a* being iron, and those *b* brass.

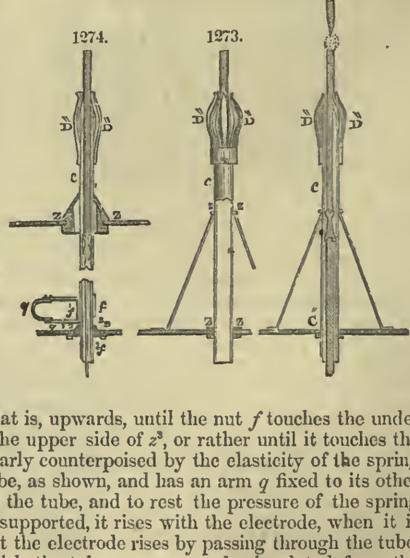
An electro-magnet may be used in place of the helix coil surrounding the moving piece of iron B^1; the poles of the electro-magnet being presented obliquely or directly beneath B^1, the form being altered so as to be the better suited to be attracted by both poles of the electro-magnet.

Reflectors may be adapted to electric lighthouse lamps as well as to electric lamps of all sorts.

The intensity of the electric current (whatever may be the nature of the lamp or apparatus used for producing the light) is effected by including in the electric circuit a long coil of insulated copper ribbon wound in an iron case, as shown in section, Fig. 1270, and part side view with cover removed at Fig. 1271. The coil may be made in pieces separately wound on, and their ends joined in succession, the two extreme ends A *e* of the first and last coils being made to pass through the holes *p q* in the case. A hollow cylinder of iron, or a number of bits of flat iron bar *g h*, are placed around the coil like the staves of a cask, and are held together by elastic bands of vulcanized caoutchouc. A good proportion for the substance of the coil is one-hundredth of a square inch of copper in section to every 40 yards of length. The ends of each coil are held from slipping back or unwinding, while the next coil is being wound, by being bent round and backwards over a pin K K′, screwed into the side of the iron case. The numbers annexed to the arrows indicate the succession of the different portions of the coil on which they are placed. The letters A B C D E indicate the commencement of each of the coils, and *a b c d e* their several terminations.

The solid electrodes employed in electric lamps in supporting tubes, are represented in Figs. 1272, 1273, and 1274. A tube *e*, serves to guard the electrodes, to hold them steady, and to conduct the electricity freely up to the top part of the electrode, the current being passed into the tube through the sole-plate *c*″, which is put in metallic connection with the negative wire. D″ D″ (Figs. 1272, 1273, and 1274) are spring conductors (they may be of iron) fixed on the tube *e*, the tips of which embrace the electrode near the point where the light is developed. The electricity has by this means a free passage from the tube into the electrode. The tube may be fixed mechanically to the framework *c c*″, and yet insulated electrically from it, as shown in Fig. 1273, by means of collars of dry hard wood *z z*, on the same principle as the legs of the upper electrode-stand K, are insulated from the sole-plate *c*″.

1274. 1273. 1272

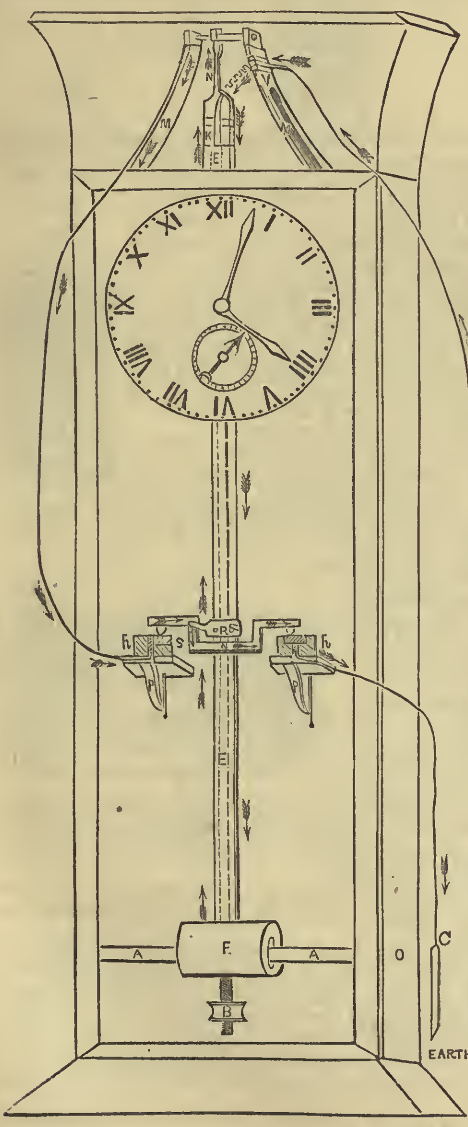


The electrode may be composed of many pieces slightly joined together, end to end, and placed in a tube, Fig. 1274, of any required length. To obviate the necessity of joining the parts firmly, the following arrangement, Fig. 1274, has been contrived, wherein the electrodes need never be drawn backwards in the tube: *c*″ is a piece of the supporting framework of the lamp, made for the purpose of holding the tube steady. The tube has a free sliding motion for a short space, that is, upwards, until the nut *f* touches the under side of z^3, and downwards, until the collar f^1 touches the upper side of z^3, or rather until it touches the part *q* which rests on z^3. The weight of the tube is nearly counterpoised by the elasticity of the spring *q*′, which is attached to an arm projecting from the tube, as shown, and has an arm *q* fixed to its other end, the further end *q* being forked so as to embrace the tube, and to rest the pressure of the spring upon the top of z^3. The weight of the tube being thus supported, it rises with the electrode, when it is pushed upwards by E^1, until *f* touches z^3, and after that the electrode rises by passing through the tube.

The parts of the fixed supports *c* and *c*″, through which the tube passes, may be insulated from the rest of the framework by collars of wood, as represented by z^2 and z^3.

The following are improved modes of preparing the materials for electrodes: take the powder of various carbonaceous matters, which make electrodes of different qualities as to illuminating power and resistance to abrasion by the electric current. The materials preferred are; first, plumbago powder, having its iron, &c., extracted by washing and warming in acids; second, lamp-black; third, charcoal powder of sundry kinds of wood; fourth, the powder of the carbonaceous concrete which becomes deposited in gas retorts; or, fifth, grains of this latter substance sifted so as to obtain a somewhat uniform size of grain: any one of these materials mixed with a quantity of brown sugar, in such proportions as are requisite to form a free paste with the powder when the mixture is melted by heat, a much larger proportion being sometimes employed for making the product cohere better. This mixture is melted and boiled (without water) until it becomes stiff; it is then pressed (while hot) into iron moulds of suitable shapes, the inside being lined with paper, or chalk, or plaster of Paris, to prevent the mixture from adhering to the mould, and to form a porous envelope through which the gases, &c., can slowly escape. The moulds have numerous small crevices or holes for the purpose of letting the gases and steam escape from the material when baked. The moulds when charged and closed tightly are heated very gradually, so as to allow sufficient time for drying and dispelling the gases without their destroying the compactness of the material. When a red heat is thus obtained, it is after a time allowed to subside, when the contents of the moulds are carefully taken out and placed upright in a crucible, which is filled with sand luted down and gradually raised to a white heat. At this high temperature they may be kept for some time, to give them greater mechanical hardness and strength; they are then covered up and allowed to cool gently, and being cleaned if they retain a coating of any other substance, they are put into close-fitting tin cases for use.

1275.



ELECTRIC CLOCK. Fig. 1275 is a view of the electric clock in the telegraph office of the Eastern Counties Railway, Eng. C Z are plates of copper and zinc buried in the earth (with a quantity of coke) a depth of nine feet; this is termed an earth battery It is computed that the electricity derived from the earth with the two plates is sufficient to work thirty clocks, and will last a number of years without being disturbed; E E the pendulum, made of wood, to the lower end of which is fastened a coil of wire enclosed in a brass case F; A A are two permanent magnets; B the balance weight for regulating the pendulum; M M a stand supporting N a steel spring by which the pendulum is suspended; K a spring to which the wire coming from *z* is attached; V a piece of wood for insulating the wire from the stand; *h h* two small pieces of wood; *t t* two metal pins passing through the wood *h h*, one of the pins *t* is joined to a brass plate, the other pin has a small gold head, brought level with a piece of agate S; *n* the break for making and breaking the contact; R two arms projecting from the pendulum; *p p* brackets supporting *h h;* suppose the pendulum is set in motion by moving it to the left, one of the arms R would be brought in contact with the break, pushing the point which did rest on the agate S on to the metal *t*, the other end of the break would still rest on the brass plate; the current of electricity would then pass from *z* up the wire (as indicated by the arrows) to the spring K, (down one of the wires at the back of the pendulum shown dotted,) through the coil in box F up the other wire to spring N, then down the wire to pin *t* along the break to the other pin, and terminating at C, the circuit would then be complete; when in the position described, the coil F would become a magnet, and be attracted back by the magnet A, the other arm would then push the break on the agate, the pendulum would then

fall back again, making the contact, thus a constant motion of the pendulum is kept up. To complete the clock, a few wheels are necessary for the proper working of the hour, minute, and second hands.

ELECTRO-METALLURGY. Electro-metallurgy, depending essentially on galvanic agency, is subject to the operation of the same principles, and governed by the same laws laid down in the books which treat of galvanism and galvanic batteries; the successful reduction, therefore, of the metals, must depend entirely upon a thorough knowledge of galvanism, and galvanic apparatus.

Independently, however, of these general galvanic properties, there are certain particular ones appertaining either to the different metals, or to the different qualites of the same metals, which have to be considered in detail, as well as the apparatus to be employed for precipitations.

The substance best adapted for the complete separation of the solutions, in a single-cell apparatus, is animal membrane. Of this there are various kinds; bladders of different textures, the lining membrane of the intestine of the ox, fine gold-beaters' skin, or bladders of various animals may be used. Animal membrane separates solutions better than any other diaphragm, but, for most purposes, it affords too much resistance to the passage of the current. Brown paper, and cartridge-paper, are frequently of value for the electro-metallurgist, and they last for a considerable period without renewal. Of late, earthenware tubes have been very extensively employed.

The following is the order in which different substances stand with regard to their capabilities of admitting the passage of electricity:

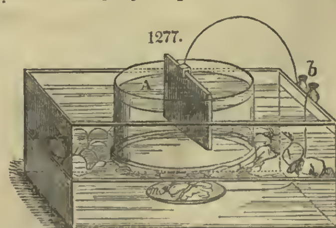
Brown paper,	Bladders of various thickness,
Thin plaster of Paris,	Thick plaster of Paris,
Porous earthenware,	Capillary tube.
Gold-beaters' skin,	

Of the various forms of apparatus, which may be used for the precipitation of the metals, the most simple is that having a porous earthenware tube, to contain the acid and zinc, whilst the negative metal, which is usually a mould, is placed externally to this, and connected by a piece of wire to the zinc. Thus, for instance, take a pound pot, Fig. 1276, and half fill it with a solution of sulphate of copper, S; in this, place the earthen vessel P, with the dilute acid A and zinc Z, and this constitutes the whole of the present form of apparatus; for, when we desire to make an electro-medallion, it is only necessary to place one or more casts in the outer vessel *m m* connected by a wire with the zinc, and then action will immediately commence. Any number of moulds may be placed in the outer vessel, provided they can radiate to the zinc. Saturation of the liquid may be preserved by suspending some of the salt in a linen bag over the mould. This form is objectionable, because the salt of zinc speedily passes through to the outer vessel; but it has the advantage of allowing the mould to be placed vertically, in which position it is much less liable to have particles of dust settling upon it. There is no limit to the size of this outer vessel; for a water-butt, a tank, or even a lake naturally impregnated with sulphate of copper, would answer.

1276.

There is another form, where bladder takes the place of the earthen vessel, and where the position of the cast is horizontal. Here, the outer vessel, Fig. 1277, which is square, is made of wood, coated internally with cement; on one part of the edge of which, a piece of brass *b* is fixed in which are two holes, one for connection with the wire of the cast *m*, the other with that of the zinc. In the interior of the trough, a moveable shelf of mahogany is placed, on which is supported a glass containing a zinc plate Z and crystals of sulphate of copper to be dissolved. The glass has a piece of bladder tied over the rim, and this forms an outer vessel similar to the porous tube in the former apparatus. It, in like manner, contains the acid and zinc; the latter being connected by a screw to a wire, in such a way that it can be readily removed.

1277.



In every single-cell apparatus, the solution of metallic salt should be maintained in the required degree of concentration, by keeping some crystals of the salt undissolved in the solution. If these crystals are allowed to sink to the bottom of the vessel, they will not answer the intended purpose of maintaining a saturated solution; for the portions of the fluid which have been deprived of their metallic salt rise to the surface, whilst the saturated parts remain in contact with the crystals at the bottom, thus preventing their solution. This difficulty may, however, be readily overcome, by placing the crystals to be dissolved in a little bag, on a shelf at the top of the liquid, by which means the saturation of the fluid will be ensured.

The only circumstance to be observed is, that the zinc be equidistant at every place from the metal on which the reduction of the new metal is to be effected, so that the deposite may be everywhere equally thick.

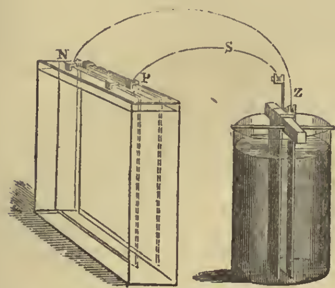
There are other metals besides zinc and iron that might be used to generate electricity: thus, lead will reduce copper, silver, gold, and various other metals. When it is employed for electro-metallurgical experiments we must form a soluble salt, of which the acetate and nitrate are most conspicuous. If we use nitrate of potash in the outer side with the lead, and a solution of metallic salt, say of copper, in the inner side, with the negative plate, the reduction will take place. It is vain to attempt to reduce a sulphate by this salt, for the sulphate of lead is absolutely insoluble. Its equivalent number is very high, one hundred and four of lead being equal to thirty-two of zinc, which is one serious objection to its use.

Tin may be used to generate electricity, it being soluble in muriatic, sulphuric, acetic, oxalic acids &c. It has a feeble force, requires a large plate, and thin porous tube. It is best used with dilute sulphuric acid on one side, and the metallic salt, which should be a sulphate, on the other. It reduces

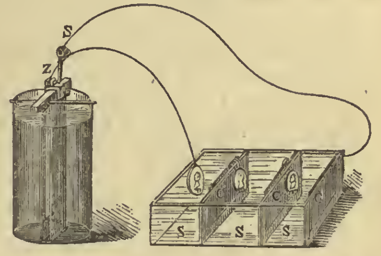
several metals, but, unfortunately, has a high combining number, requiring fifty-eight grains to generate as much power as thirty-two grains of zinc.

A solution of a salt of copper is to be placed in a convenient vessel, Fig. 1278, and the object N, on which the precipitation is to take place, is to be connected with the zinc of the battery Z, whilst a piece of sheet copper is connected with the silver S. As soon as action commences, water is decomposed, oxygen passes to the copper pole and oxydizes it, and the hydrogen passes to the negative plate. Whilst the decomposition is taking place, oxide of copper is passing to the negative pole, and the acid to the positive pole; the hydrogen reduces the oxide of copper at the negative plate, whilst the acid combines with oxide of copper at the positive end, and thus the saturation is continued.

1278.



1279.



A series of precipitating troughs, arranged like a compound battery, may be employed occasionally with only one battery. In this case, we should have one generating cell in the battery, and six, eight, or ten decomposition cells; therefore, by the fundamental laws to which the action of the galvanic fluid is obedient, we should have six, eight, or ten equivalents of metal reduced for one equivalent of zinc. Theoretically, this apparatus, Fig. 1279, exceeds every other in economy—practically, it has not been so much employed as it ought to be, particularly in the reduction of plain copper plates. The galvanic series is made by alternating the metal C to be dissolved with the object *m* to receive the precipitate, the last mould being joined to the zinc Z of the battery, and the last copper with the silver S; the positive plates should be large, and the liquid rendered as conducting as possible to lessen resistance. It is important in this apparatus that every positive and negative plate should possess nearly the same surface, and the solution the same strength, in order that the metal of the same quality should be reduced in each cell.

Description of Fig. 1280.—A, the battery cell, extending downwards 2 feet under the floor, and terminating in a point, in which a stop-cock is fixed, to draw off the saturated solution of sulphate of zinc, which is formed there. The bottom is reached by a trap-door and steps.

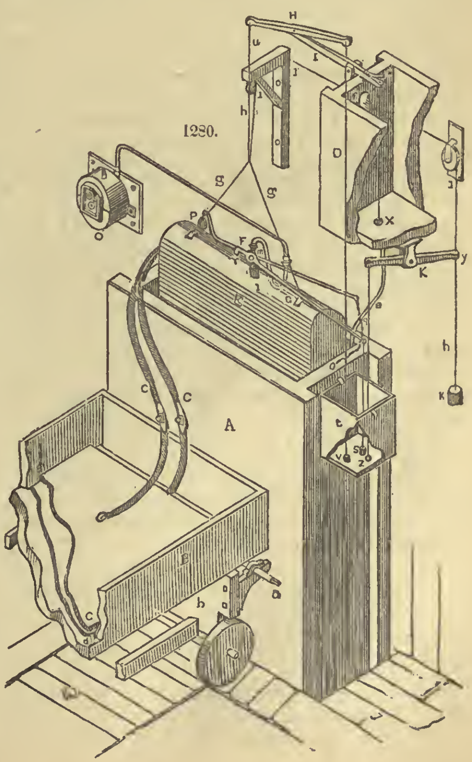
B, the decomposing trough, resting on a keel, which, for the purpose of agitating the solution, enables a rocking motion to be given to the trough, by means of a coupling shaft *a* connected with the truck *b* on which the trough is moved to any part of the room, for cleaning or changing the plate.

C C, conductors from the battery plates, each formed of five lengths of copper wire 1-10th of an inch in diameter, twisted together, and covered with water-proof tape, the one leading to the positive or dissolving plate *c*, the other to the negative or receiving plate *d*, the latter being placed on a board, with small feet or wedges, to keep it at the proper distance from, and parallel to, the positive plate.

D, a water-tight box containing a solution of sulphuric acid in the proportion of 1 to 4 water, by which the battery cell (having been originally charged with solution of the requisite strength, 1 to 30) is constantly supplied with renewed acid, through a lead pipe *e* which extends downwards into the cell about 2 feet, and is turned horizontally so as to cause a circulating movement in the solution. The box is provided with a float *f* to indicate the height of the acid solution in it, and the quantity which has passed into the battery.

In Fig. 1280 the acid box is placed near the battery cell for the sake of bringing it within the margin lines. It is nearly close to the ceiling, in

1280.



reality, so as to afford by its height a considerable force to the solution issuing from the pipe, that i may circulate freely around the battery plates.

For want of height in this Figure, it has also been necessary to omit a beam which passes along the side of the room nearly close to the ceiling, on which a small carriage and pulley travel, for the purpose of raising the plates and moving them to any part of the battery range.

E, a gasometer, or gas collector, formed of thin copper, suspended by the wires *g* and the cord *h*, which passes over the pulleys *i i i*, and terminates in a counterpoise *k*, intended to balance in part the collector. which is placed immediately over the plates in the battery, and dips into the solution. It is furnished with a stop-cock *l*, through which the gas passes by the flexible tube *m* and copper pipe *n* to a gas meter *o*.

F G, levers—the former, F, being attached to the plug of the stop-cock, having at one end a weight *p* and at the other a chain *q* fastened to the battery cell; the latter, G, turning in the same centre, and brought by a screw *r* at one end into contact with the under part of the former, F, and kept in contact with it by the pressing of the weight *p*. To its other end a small block of wood *s* is attached, dipping into a waste-box *t*, and acting as a weight when the box *t* is empty, and as a float when the box is filled by overflow from the battery cell.

H I, levers, drawn downwards by the weight of the collector, with which they are connected by the cord *u*. The former, H, turns on a pivot at the end of the latter, having at its other end a cord carrying a weight *v* which acts in the same manner as *s;* the latter, I, carrying, as before mentioned, the lever H at one end, and having at the other end a spring *w* screwed to it, from which a wire, passing through the lever, descends to the valve *x* for the purpose of raising the valve suddenly, being first closed upon the lever, until the adhesion of the valve to its seat is overcome, when the spring returns to its former position with a jerk, carrying up the valve, and opening the aperture at once to its greatest extent.

K, a lever fixed to the bottom of the box D, having at one end a small hole through which the cord *l* passes, until checked by a knob *y*, when the other end rises and lifts a valve *z* in the bottom of the box *t*.

Working of the apparatus.—The operation proceeds in the following manner. The aperture of the stop-cock *l* must be so adjusted by the screw *r* as to allow the gas evolved from the plates of the battery to escape at the same rate as that at which it is generated, allowing a slight excess to resist the uncounterpoised portion of the weight of the collector, or its tendency to sink down. Then, when the quantity evolved is greater than can pass through the aperture, the collector will ascend till the lever F is restrained by the chain *q*, when the aperture will be enlarged till equivalent to the quantity evolved. On the contrary, when the quantity evolved is less than that for which the adjustment has been made, the collector will descend and pull down the levers H and I; the weight *v* will resist the end of the lever H, and the end of the lever I carrying the spring *w* will rise, and with it the valve *x* of the acid cistern, with a jerk; a quantity of the strong acid solution will then rush into the battery cell by the pipe *e*, with sufficient force to circulate round the plates, displacing a portion of the lighter or less acid solution, which will run off by the overflow pipe *o* into the box *t*, which thus becomes a measure of the quantity of acid thrown into the cell. When the lever H then becomes released from the weight of the float *v*, the acid valve *x* preponderates, falls into its seat, and stops the supply. At the same time, the lever G of the collector is also released by the floating of the weight *z*, and the aperture of the stop-cock completely closed by the weight *p*. The gas collector in this condition rises rapidly, till the knob *y* comes into contact with the lever K, when the valve *z* opens, and the solution in the waste-box *t* runs into a vessel placed for its reception, where its deficiency of acid is supplied, and it again returned to the cistern D. The waste-box *t* being emptied, the floats *s* and *v* again descend to the bottom of the box *s*, carrying down the lever G, by which the aperture of the stop-cock is opened, and the apparatus is again in a position to throw in a greater supply of acid, if the energy of the battery is not sufficient to evolve the quantity of hydrogen for which the aperture has been adjusted. Thus the *power* of the battery depends on the stop-cock, whose normal position is adjusted in the first instance to the required openness by the screw *r;* and the state *of its working* is ascertained by the quantities of gas which pass through the meter in equal times.

The voltaic deposite of metal may take place upon any conducting substance, which is capable of acting the part of the negative metal, in the arrangement. The laws which relate to this, are the same which regulate, in a similar manner, the plates of the battery. The deposite may be effected upon most metals, except the earthy and alkaline, and upon any alloy or compound of them. It may, likewise, take place upon charcoal and plumbago.

The following is a short list of substances which may be used to receive the deposite of metal:

Carbon	In all metallic solutions, acid, neutral, or alkaline.			Lead	In all alkaline, in all but the preceding, saline and acid.		
Platinum.........	do.	do.	do.	Bismuth..........	do.	do.	do.
Gold...............	do.	do.	do	Antimony	do.	do.	do.
Palladium	do.	do.	do.	Tin................	do.	do.	do.
Silver.............	In all alkaline, in all but the preceding, saline and acid.			Iron	do.	do.	do.
				Zinc	In some alkaline		do
Copper	do.	do.	do.				

Non-metallic substances.

Sealing-wax	In all saline or acid solutions; not in alkaline.		
White wax	do.	do.	do.
Beeswax and rosin	do.	do.	do.
Stearine	do.	do.	do.
Spermaceti	do.	do.	do.
Plaster of Paris, prepared	do.	do.	do.
Some animal substances	do.	do.	do.
Most vegetable substances	do.	do.	do

Now by the preceding table we perceive that some substances may be immersed in one solution with impunity, while others would be destroyed by its action on them. It is, therefore, important to know, when we have a substance which is acted upon by any metallic solution, how to make a reverse from it that shall not be injured. For convenience a table is appended, showing at one view the modes of preparing moulds of different substances. The perpendicular row is a list of the objects to be copied, the horizontal the means of multiplying them. Suppose the operator had a valuable silver medal, of which he was desirous of making a fac-simile, he would look in the table against silver, and would there find that he could make a mould, or reverse, in copper, by electro-metallurgy; but to this he would doubtless object. He would then see by what other methods he could also make a mould, and he would find that he could succeed with each of the processes given, and perhaps he would prefer plaster of Paris, as least likely to be injurious to his medal. Having made the mould in plaster, he would see from the former table, that when prepared it might be placed in any saline or acid solution of copper, to form the fac-simile.

LIST OF THE PRINCIPAL MODES OF MAKING MOULDS OR REVERSES OF VARIOUS OBJECTS.

Carbon, from its cheapness, from its indestructible nature, and from its being unaltered in all metallic solutions, is invaluable for electro-metallurgy. One variety of it, graphite, or plumbago, usually called black-lead, has a most extensive application, which we shall hereafter have occasion more especially to describe.

Platinum, from its being unaltered by any solution, holds an important place for the reception of every metal; its great price, however, must always be an impediment to its general use.

Gold is equally valuable with platinum, but is still more expensive; yet when extended to that state in which it exists as gold-leaf, it may be applied over the surface of any soft substance, and thus a metallic surface is presented. This plan may be employed with other metals, such as silver or tin; but we have other methods which render all these modes unnecessary.

Silver only reduces gold, platinum, palladium, and two or three more metals from these acid solutions, and therefore may be employed as a negative one for the reduction of metals. Silver-leaf of a thickness of about one square foot to the ounce, and made of pure metal, is much used by the forgers. The process they adopt is, to place the coin to be copied on a piece of wood, and upon the coin they place a piece of this thin silver. They beat it gently with a wooden mallet, till a perfect impression is taken on the metal, a result soon obtained. They then copy the opposite side of the coin in the same way. The two impressions are then soldered together, and the manufacturer sallies forth and risks his neck for the illicit shilling which has cost him this labor. The reader will doubtless have no inclination to practice this fraud, and, therefore, it is unnecessary to enter further into the process; but it should be borne in mind, that the same means may be employed with a better intention by the electro-metallurgist, to obtain a mould.

We have now to treat of the alloys of lead, tin, bismuth, antimony, and zinc, which demand especial attention, because there are means of casting these alloys, and of making reverses, moulds, and medals, by more ready methods than we possess for any other metals. It has been remarked that these alloys have melting properties, not only below the mean of the melting points of the respective metals which compose them, but even some of them considerably below the fusing point of the most fusible metal that enters into their composition. To some of these alloys we owe the manufacture of type, to others the process of stereotyping, to others that of polytyping or clichée. The composition of the type-metal is stated to be 1 part of lead to 16 of antimony, and sometimes a portion of copper is added; this

portion probably varies at each foundry; as they generally consider that part of the business a secret Other compositions are given, as 6 to 2, 4 to 5, or 4 to 1 of antimony to lead. In the foundry there are a number of crucibles, each heated by a charcoal fire, one being allowed to each workman. To make a type, the operator takes a little of the melted alloy in a small ladle each time, and pours it into the mould which has the counterpart of the letter he wishes to make. The moment it is in the mould, he carries it suddenly upwards with a jerk, above his head, by which means the metal is forced into all the fine parts of the work, and a good impression is insured. Now we might expect that those who day by day work at this occupation, would attain to certainty in their proceedings; but this is by no means found to be the case, for they form a very large number of imperfect types which are obliged to be remelted. I give this process to show that with those about to be detailed a strong analogy to coining is presented. In the first case, it is with a fluid, or semi-fluid, metal; in the last with a solid mass. The alloys which may be used for these purposes are very various, according to the object from which we desire to obtain a reverse, for as a great latitude is allowed in the fusing point, so at one time we prefer the more fusible, at another that which melts at a higher temperature.

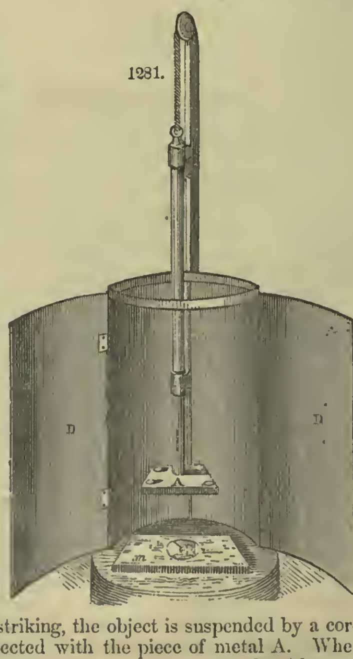
The following is a list of alloys which are employed by various authors, to which should be added all the compositions of type-metal last described, and as antimony possesses the property of expanding in the act of cooling, its alloys are well adapted for casting.

	Tin.	Lead.	Bismuth.	Zinc.		Tin.	Lead.	Bismuth.	Zinc.	
1	4	1	0	0	5	3	5	8	0	fuses about 212° Fah.
2	5	10	1	0	6	1	1	2	0	said to fuse at Fah. 200.
3	0	1	1	0	7	1	2	3	0	do. 200.
4	1	1	0	0	8	1	0	1	1	do. 200.

All these compounds are used at a point between the fluid and the solid state, for at that heat they assume a pasty appearance, which is probably caused by the alloy consisting of two parts, one more fusible than the other. In fact, if we examine the mass very attentively, it appears to be composed of a quantity of perfectly solid metal in a fine state of division suspended in another portion of alloy perfectly fluid. Having obtained our alloy in this state, it is ready for the process of making our reverse, and this process is termed the clichée. The alloy marked 1, 2, 3, 4, as well as the compositions for type-metal, will answer for iron, brass, copper, or other hard substances; perhaps No. 2 and No. 3 will be found, after type-metal, entitled to the preference. When we desire to clichée from wood, sulphur, or from another clichée, we must employ those alloys which fuse more readily, and Nos. 5, 6, 7, and 8 come into use. If hard metals are used from which to clichée, we should take care to clean them thoroughly before using, and always employ them in a cool state. In using one clichée for making a second, we must take care to employ a less fusible alloy for the first than for the second; thus the type-metal and Nos. 1, 2, 3, 4, answer as a primary mould to make casts in 5, 6, 7, 8. To clichée from plaster of Paris, the material must be prepared either by linseed oil, gum, or gelatine, which processes will be described when treating of those substances, and sulphur moulds must be employed within a few hours of their manufacture.

The simplest mode of making a clichée is to pour a little of the fused alloy on any flat surface, then to skim it clear with the edge of a card that the surface may be most perfectly bright, after which we should wait till it is nearly at the point of cooling, when with a considerable jerk the matrix is to be brought down upon the alloy, by which operation the fluid part will be forced out in all directions, and a reverse, equal in polish, sharpness, and beauty to the original, will be instantly obtained. If the alloy is used too hot, the surface is apt to present a crystalline appearance; it is therefore very important that the object should be cool enough to make the alloy perfectly hard, as soon as the blow has driven the metal into all the finest lines. When taking a clichée from an intaglio the air has not always time to get away, in which case little holes or bubbles are very apt to be caused. The surplus metal round the edges of the mould so formed is then trimmed off in a lathe; but this operation is generally unnecessary for electro-metallurgy.

1281.



The Italians have a method of taking very perfect moulds with these alloys. They take a portion of the melted mass, and place it on a piece of paper; upon this they lay the medal, and under both a piece of carpet; upon the medal they place a log of wood, and then a sharp blow on the wood will ensure the sharpness of the cast. The worth of a cast thus made, is from sixpence to half-a-crown. I have before mentioned that clichée is nothing but a process of coining, and sometimes a sort of coining-press is used for these purposes; the medal or other object is fixed either by mastic or by screws on a piece of metal A, Fig. 1281, which descends with force on the semi-fluid alloy. Previously to the operation of striking, the object is suspended by a cord passing through a ring, and attached to the rod of iron connected with the piece of metal A. When every thing is ready, the doors are shut and the cord let loose, which allows the object to fall with great force on the metal.

An impression may be given to a perfectly clean bright surface of sheet-lead, by placing upon it the object to be copied, and then with a steady hand dealing a heavy blow. By this mode even a sealing-wax impression may be copied, although this, at first sight, would appear hardly credible. By pressure alone, it would be difficult to obtain the result which can be given by the blow. Rolled lead, first scraped, in order to remove any oxide from the surface, and then flattened by running it through a press upon a polished iron plate, will readily take the impression of the most delicate work or engraving. The object to be copied is simply to be placed upon the lead, and then the two are to be sent once, and once only, through the printing-press, as in the ordinary operation for taking a print. The pressure in rolling is far greater than can be given by direct pressure, though there are instruments used by embossers capable of exerting great power. The disadvantage of forming moulds by rolling is a liability of distortion of the image from imperfect stretching of the metal.
